CONTENTS OF VOLUME 4

VOLUME EDITORS

Volume 1 – Basic Concepts and Polymer Properties

AR Khokhlov, Moscow State University, Moscow, Russia
F Kremer, University of Leipzig, Leipzig, Germany

Volume 2 – Polymer Characterization

T Hashimoto, Japan Atomic Energy Agency, Ibaraki, Japan
HW Spiess, Max Planck Institute for Polymer Research, Mainz, Germany
M Takenaka, Kyoto University, Kyoto, Japan

Volume 3 – Chain Polymerization of Vinyl Monomers

GW Coates, Cornell University, Ithaca, NY, USA
M Sawamoto, Kyoto University, Kyoto, Japan

Volume 4 – Ring-Opening Polymerization and Special Polymerization Processes

S Penczek, Polish Academy of Sciences, Lodz, Poland
R Grubbs, California Institute of Technology, Pasadena, CA, USA

Volume 5 – Polycondensation

H-W Schmidt, University of Bayreuth, Bayreuth, Germany
M Ueda, Engineering Tokyo Institute of Technology, Tokyo, Japan

Volume 6 – Macromolecular Architectures and Soft Nano-Objects

AHE Müller, University of Bayreuth, Bayreuth, Germany
KL Wooley, Texas A&M University, College Station, TX, USA

Volume 7 – Nanostructured Polymer Materials and Thin Films

E Kumacheva, University of Toronto, Toronto, ON, Canada
TP Russell, University of Massachusetts, Amherst, MA, USA

Volume 8 – Polymers for Advanced Functional Materials

K Müllen, Max Planck Institute for Polymer Research, Mainz, Germany
CK Ober, Cornell University, Ithaca, NY, USA

Volume 9 – Polymers in Biology and Medicine

DA Tirrell, California Institute of Technology, Pasadena, CA, USA
R Langer, Massachusetts Institute of Technology, Cambridge, MA, USA

Volume 10 – Polymers for a Sustainable Environment and Green Energy

JE McGrath, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA
MA Hickner, The Pennsylvania State University, University Park, PA, USA
R Höfer, Editorial Ecosiris, Düsseldorf, Germany

EDITORS-IN-CHIEF: BIOGRAPHIES

Krzysztof Matyjaszewski received his PhD degree in 1976 from the Polish Academy of Sciences under Prof. S. Penczek. Since 1985 he has been at Carnegie Mellon University where he is currently J. C. Warner University Professor of Natural Sciences and director of Center for Macromolecular Engineering. He is also Adjunct Professor at the University of Pittsburgh and at the Polish Academy of Sciences. He is the editor of *Progress in Polymer Science and Central European Journal of Chemistry*. He has coedited 14 books and coauthored more than 70 book chapters and 700 peer-reviewed publications; he holds 41 US and more than 120 international patents. His papers have been cited more than 50 000 times. His research interests include controlled/living radical polymerization, catalysis, environmental chemistry, and advanced materials for optoelectronic and biomedical applications.

Dr. Matyjaszewski has received 2011 Wolf Prize, 2011 Prize of Société Chimique de France, 2009 Presidential Green Chemistry Challenge Award, 2004 Prize from the Foundation of Polish Science, and several awards from the American Chemical Society (including 2011 Hermann Mark Award, 2011 Applied Polymer Science Award, 2007 Mark Senior Scholar Award, 2002 Polymer Chemistry Award, and 1995 Marvel Creative Polymer Chemistry Award). He is a member of US National Academy of Engineering, Polish Academy of Sciences, Russian Academy of Sciences, and received honorary degrees from l'Institut Polytechnique, Toulouse, France; University of Athens, Greece; Russian Academy of Sciences; Lodz Polytechnic, Poland; and University of Ghent, Belgium.

Martin Möller studied chemistry at Hamburg and Freiburg. He received his PhD degree in 1981 from the University of Freiburg.

He was a Feodor-Lynen Research Fellow of the Alexander von Humboldt Foundation at the Polymer Science and Engineering Department, University of Massachusetts, Amherst, USA. After his habilitation in 1989 at Freiburg University he was professor at the universities of Twente, Enschede, The Netherlands and Ulm, Germany. Since 2002 he is professor of Textile and Macromolecular Chemistry at RWTH Aachen University, and since 2003 also the director of DWI-Interactive Materials Research Institute at RWTH Aachen University. He has served on the editorial board of several polymer journals. His fields of interest include polymers self-organization of macromolecules, surface modification and activation, formation of functional nanostructures, and organic–inorganic hybrid structures. Martin Möller has received the the Körber-Prize 2002. He is a member of the Deutsche Akademie der Technikwissenschaften (acatech) and of the Academy of Sciences of the state of North-Rhine Westphalia.

EDITORS: BIOGRAPHIES

Alexei R. Khokhlov was born in 1954 in Moscow, Russia. He graduated from Moscow State University in 1977, received his PhD in 1979 and Doctor of Science in 1983. He is Full Professor and Head of the Chair of Physics of Polymers and Crystals. He is a Member of Russian Academy of Sciences (2000), Chairman of Polymer Council of Russian Academy of Sciences (2002) and Laureate of the Russian National Award (2007).

Friedrich Kremer is Professor of Molecular Physics, Materials Research Spectroscopy, Institute of Experimental Physics I, University of Leipzig, Germany. His research interests include broadband dielectric spectroscopy, time-resolved Fourier transform infrared (FTIR) spectroscopy, and experiments with optical tweezers. In 2005 he was awarded with the Karl Heinz Beckurts – Prize; in 2011 he received the Wolfgang-Ostwald-Prize from the German Colloid Society.

Takeji Hashimoto received his MS degree in 1969 and PhD in 1971 (with Prof. R. S. Stein) from the University of Massachusetts. He was appointed as an assistant professor at Kyoto University, Japan, in 1971, and was promoted as a full professor in 1994. He was director of the Hashimoto Polymer Phasing Project, ERATO (Exploratory Research for Advanced Technology), supported by JST (Japan Science and Technology Agency), from 1993 to 1998. He served as a group leader and invited researcher for the project 'Neutron Scattering and Structure-Functionality of Soft Matters' at the Advanced Science Research Center (ASRC), Japan Atomic Energy Research Institute (JAEA), Tokai, from 2003 to 2005. Since his retirement from Kyoto University in March 2005, he has been a professor emeritus of Kyoto University, and served as a full-time visiting researcher at ASRC, JAEA, Tokai, from 2005 to 2008 and as a group leader for the physical science and life science group. He has been a visiting scientist at JAEA, Tokai, since 2008 and a visiting professor at the School of Science and Technology, Kwansei-Gakuin University, Sanda, Japan, since 2009. He has received several awards including the Society of Polymer Science Japan Award (1986), the High Polymer Physics Award (Ford Prize) from the American Physical Society (1987), the award for Young Rheologist from the Society of Rheology, Japan (1989), the Society of Fiber Science Japan Award (1990), the Osaka Science Award (1992), the Turner Alfrey Award from

Midland Molecular Institute, Midland Section of ACS (1997), the Fraser Price Memorial Award from the University of Massachusetts (1997), the Chemical Society of Japan Award (2003), the Japanese Society for Neutron Science Award (2004), and Society of Polymer Science Japan Award for Outstanding Achievement in Polymer Science and Technology (2006).

Hans Wolfgang Spiess, born in 1942, received his doctoral degree in physical chemistry in 1968 from the University of Frankfurt with H. Hartmann. After a postdoctoral stay at Florida State University (with R. K. Sheline), he returned to Germany in 1970 and joined the Max Planck Institute for Medical Research (with K. H. Hausser), taking part in the rapid development of novel NMR techniques for studying molecular motion in liquids and solids. In 1978, he finished his habilitation in physical chemistry at the University of Mainz in the group of H. Sillescu. Subsequently, he held professorships of physical chemistry at the University of Münster (1981–82) and macromolecular chemistry at the University of Bayreuth (1983–84). In 1984, he was appointed a director of the newly founded Max Planck Institute for Polymer Research in Mainz. His research interests include the development of magnetic resonance techniques for elucidating the structure, dynamics, phase behavior, and order of synthetic macromolecules and supramolecular systems. He applies these methods to the study of new polymer materials to relate their microscopic and macroscopic behavior. Spiess has served as chairman of the European Polymer Federation (1991–92) and as chairman of the Capital Investment Committee of the German Science Foundation (1994–96). From 1999 till 2005, he has been a member of the Scientific Council of the Federal Republic of Germany. His achievements have been honored by several distinctions, including the Leibniz Prize of the German Research Foundation in 1987, the European Ampere Prize, the Liebig Medal of the German Chemical Society, the Award of the Society of Polymer Science (Japan) in 2002, the Walther Nernst Medal of the German Bunsen Society for Physical Chemistry in 2007, and the Paul J. Flory Research Prize in 2010. He is doctor *honoris causa* of the Technical University of Cluj-Napoca, Romania (1997), and of Adam Mickiewicz University, Poznan, Poland (1998).

Mikihito Takenaka received both the master's degree in engineering in 1988 and the doctor's degree in engineering in 1993 with Prof. Takeji Hashimoto from Kyoto University. In 1997, he was appointed as an assistant professor of the Department of Polymer Chemistry in Kyoto University. He was promoted to associate professor in 2011. His research scope includes the dynamics of phase transitions of polymer alloys and the directed self-assembling of block copolymer thin films.

Geoffrey W. Coates was born in 1966 in Evansville, Indiana. He received a BA degree in chemistry from Wabash College in 1989 and a PhD in organic chemistry from Stanford University in 1994. His thesis work, under the direction of Robert M. Waymouth, investigated the stereoselectivity of metallocene-based Ziegler–Natta catalysts. Following his doctoral studies, he was an NSF Postdoctoral Fellow with Robert H. Grubbs at the California Institute of Technology. During the summer of 1997, he joined the faculty of Cornell University as an assistant professor of chemistry. He was promoted to associate professor in 2001 and to professor in 2002. He was appointed to the first Tisch University Professorship in 2008.

The research focus of the Coates Group is the development of new catalysts for the synthesis of macromolecules as well as small molecules. Professor Coates' research concentrates on developing new methods for reacting commodity feedstocks in unprecedented ways. His current research centers on the development of homogeneous catalysts for olefin polymerization, heterocycle carbonylation, epoxide homo- and copolymerization, and utilization of carbon dioxide in polymer synthesis.

Professor Coates is an Alfred P. Sloan Research Fellow and has received awards from the ACS (A. C. Cope Scholar Award, Affordable Green Chemistry Award, A. K. Doolittle Award, Carl S. Marvel – Creative Polymer Chemistry Award, and Akron Section Award), NSF (CAREER), MIT Technology Review Magazine (TR 100 Award), Research Corporation (Innovation Award), Arnold and Mabel Beckman Foundation (Young Investigator Award), David and Lucile Packard Foundation (Fellowship in Science and Engineering), and Dreyfus Foundation (Camille and Henry Dreyfus New Faculty and Camille Dreyfus Teacher-Scholar Awards). In 2006, he received the Stephen and Margery Russell Distinguished Teaching Award at Cornell University and became a member of the American Association for the Advancement of Science. In 2011, he was identified by Thomson Reuters as one of the world's top 100 chemists on the basis of the impact of his scientific research. He is a member of the editorial advisory boards of the *Journal of Polymer Science*, *Chemical Reviews*, and *ChemCatChem*. He is a member of the editorial board of *Dalton Transactions* and is an associate editor for *Macromolecules*.

Mitsuo Sawamoto was born in 1951 in Kyoto, Japan. He received a BS (1974), an MS (1976), and PhD degrees (1979) in polymer chemistry from Kyoto University, Japan. After a postdoctoral research at the Institute of Polymer Science, The University of Akron, Akron, OH, USA (1980–81), he joined the faculty of Department of Polymer Chemistry, Kyoto University, Japan in 1981 as a research instructor and is currently Professor of Department of Polymer Chemistry, Graduate School of Engineering, Kyoto University, Japan since 1994.

He served as President of the Society of Polymer Science, Japan from 2008–10, and is currently an executive member of the Science Council of Japan, a titular member of IUPAC Polymer Division, and one of the Editors of the *Journal of Polymer Science, Part A, Polymer Chemistry*. He is also the principal investigator of a research project "Sequence-Regulated Macromolecules" (2006–10; Grant-in-Aid for Scientific Research: Creation of Novel Academic Disciplines) and the project leader of the Kyoto University Global Center of Excellence (GCOE) Project "Integrated Materials Science" (2007–11), both granted by the Ministry of Education, Science, Culture, and Sports, Japan via the Japan Society for Promotion of Science.

With over 350 original papers and over 30 reviews, he has received, among others, Award of the Society of Polymer Science, Japan (1992), Divisional Research Award of the Chemical Society of Japan (1999), and Arthur K. Doolittle Award of PMSE Division, the American Chemical Society (2002). His research interest includes development of novel precision polymerizations and catalysis (living cationic polymerization with Lewis-acid catalysts (1984) and living radical polymerization with transition metal complex catalysts (since 1995)), the synthesis of designed functional polymers, the nature of polymerization intermediates, and most recently the sequence regulation in chain growth polymerization for single-chain functional macromolecules of carbon-based backbones.

The first paper on his living radical polymerization has been cited thus far over 1600 times and is ranked number two in the most cited papers published in *Macromolecules*; a comprehensive review on this discovery published in *Chemical Reviews* has now been cited over 1200 times and has been selected as one of the ACS 2007 Highly Cited Papers (within top 1%) in the latest ten years (1998–2007); and he was ranked number one in Japan and number three in the world among the most cited scientists in organic and polymer chemistry for the period of 1997–2001.

Stanislaw Penczek is Professor of Polymer Chemistry at the Polish Academy of Sciences (Centre of Molecular and Macromolecular Studies in Lodz). He teaches at the Graduate School of the Jagiellonian University (Krakow) as an honorary professor. He has mostly contributed to the kinetics, thermodynamics, and mechanisms of the ring-opening polymerization, publishing over 300 papers in related areas. He was one of the first to observe living and controlled polymerizations in cationic and anionic ROP, including reversibility of deactivation of propagating species. Among other honors from Belgium, Japan, and Germany (the Warburg Prize), he is a member of the Polish Academy of Sciences and foreign member of German (Nordrhein) Academy, Dr *h.c.* of the Pierre and Marie Curie University in Paris and Dr *h.c.* of the Russian Academy of Sciences. He was a member of the International Union of Pure and Applied Chemistry (IUPAC) Bureau for two terms, and former president of European Polymer Federation.

Robert (Bob) Howard Grubbs' main interests in organometallic chemistry and synthetic chemistry are catalysts, notably Grubbs' catalyst for olefin metathesis and ring-opening metathesis polymerization with cyclic olefins such as norbornene. He also contributed to the development of so-called 'living polymerization'.

Grubbs has received many awards including Alfred P. Sloan Fellow (1974–76), Camille and Henry Dreyfus Teacher-Scholar Award (1975–78), Alexander von Humboldt Fellowship (1975), ACS Benjamin Franklin Medal in Chemistry (2000), ACS Herman F. Mark Polymer Chemistry Award (2000), ACS Herbert C. Brown Award for Creative Research in Synthetic Methods (2001), the Tolman Medal (2002), and the Nobel Prize in Chemistry (2005). He was elected to the National Academy of Sciences in 1989 and a fellowship in the American Academy of Arts and Sciences in 1994.

Hans-Werner Schmidt studied chemistry at the University of Mainz (Germany) and ETH Zürich (Switzerland). He received his diploma in chemistry and Dr. rer. nat. degree in macromolecular chemistry with Prof. Helmut Ringsdorf at the University of Mainz. After a stay at the DuPont Central Research in Wilmington, Delaware (USA), he moved to the University of Marburg to obtain his habilitation. From 1989 to 1994, he was Assistant and Associate Professor of Materials with tenure at the Materials Department, College of Engineering at the University of California, Santa Barbara. Since 1994, he has been Full Professor for Macromolecular Chemistry at the University of Bayreuth. He is director of the Bayreuth Institute of Macromolecular Research and founding member of the Bayreuth Centre for Colloids and Interfaces. Since 2009, he has been Vice President of the University of Bayreuth for research and since 2004 chairman of the 'Elite Study Program Macromolecular Science' (Elite Network Bavaria).

His research interest is focused on the synthesis and development of novel organic functional materials in the area of emerging technologies. This includes multifunctional polymers, molecular glasses, and supramolecular polymer additives and gelators. Combinatorial methods to efficiently synthesize and screen materials properties of polymer and supramolecular materials and functions of devices are an additional aspect.

Mitsuru Ueda received his BS and MS degrees in polymer chemistry from Chiba University in 1970 and 1972, respectively, and a PhD degree from Tokyo Institute of Technology in 1978. He joined Yamagata University in 1972 and was promoted to a professor in 1989. He moved to Tokyo Institute of Technology in 1999. His current research interests are the development of new synthetic methods for condensation polymers, polymer solar cells, fuel-cell membranes, photosensitive materials for microelectronics, and new advanced resist materials.

Axel H. E. Müller obtained his PhD in 1977 from Johannes Gutenberg University in Mainz, Germany, for the work on the kinetics of anionic polymerization with G. V. Schulz. Since 1999, he has been professor and chair of macromolecular chemistry at the University of Bayreuth. In 2004, he received the IUPAC MACRO Distinguished Polymer Scientist Award and since 2011, he has been a Fellow of the Polymer Chemistry Division of the American Chemical Society. He is senior editor of the journal *Polymer*. His research interests focus on the design of well-defined polymer structures by controlled/living polymerization techniques and on self-organized nanostructures and hybrids obtained from them. He has coedited five books and published over 400 research papers.

Karen L. Wooley holds the W. T. Doherty-Welch Chair in the Department of Chemistry at Texas A&M University, with a joint appointment in the Department of Chemical Engineering. She received a BS in chemistry from Oregon State University in 1988 and then studied under the direction of Professor Jean M. J. Fréchet at Cornell University, obtaining a PhD in polymer/organic chemistry in 1993. She began an academic career as an assistant professor of chemistry at Washington University in St. Louis, Missouri; was promoted in 1999 to full professor with tenure; and was installed as a James S. McDonnell Distinguished University Professor in Arts & Sciences in 2006. In 2009, she relocated to Texas A&M University. Research areas include the synthesis and characterization of degradable polymers, unique macromolecular architectures and complex polymer assemblies, and the design and development of well-defined nanostructured materials, for which she has received several awards, including an Arthur C. Cope Scholar Award, a Herman F. Mark Scholar Award, and awards from the National Science Foundation, the Office of Naval Research, and the Army Research Office. Karen serves as an editor for the *Journal of Polymer Science, Part A: Polymer Chemistry*. She directs an NHLBI-supported Program of Excellence in Nanotechnology and also serves on the Scientific Advisory Panel for the NIH Nanomedicine Development Centers and on the International Scientific Advisory Board for the Dutch BioMedical Materials Program.

Professor Eugenia Kumacheva is a Canada Research Chair in Advanced Polymer Materials. Her current research interests are in polymer micro- and nanostructured materials, hybrid materials, biomaterials, inorganic nanoscale materials, and microfluidics.

Thomas Russell is Silvio O. Conte Distinguished Professor, Polymer Science and Engineering Department; Director, Energy Frontier Research Center (EFRC), Polymer-Based Materials for Harvesting Solar Energy. His research interests are polymer-based nanoscopic structures, polymer-based nanoparticle assemblies, electrohydrodynamic instabilities in thin polymer films, surface and interfacial properties of polymers, polymer morphology; kinetics of phase transitions, and supercritical fluid/polymer interactions.

Professor Christopher K. Ober received his BSc in honours chemistry (co-op) from the University of Waterloo, Ontario, in 1978. He received his PhD in polymer science and engineering from the University of Massachusetts (Amherst) in 1982. From 1982 until 1986, he was a senior staff member at the Xerox Research Centre of Canada where he worked on marking materials. Ober joined Cornell University as an assistant professor in the Department of Materials Science and Engineering in 1986. He recently served as Interim Dean of the College of Engineering. He has pioneered new methods in photolithography and studies the biology materials interface. His awards include the 2009 Gutenberg Research Award from the University of Mainz, the 1st Annual FLEXI Award in the Education Category (for flexible electronics) awarded in 2009, the 2007 Humboldt Research Prize, the 2006 ACS Award in Applied Polymer Science, and the Photopolymer Science and Technology Award in 2004. He was elected an ACS Fellow in the 2009 Inaugural Class.

Professor Dr. Klaus Müllen obtained his PhD degree from the University of Basel, Switzerland, in 1972 where he undertook research with Professor F. Gerson on EPR spectroscopy of twisted π-systems. In 1972, he joined the group of Professor J.F.M. Oth at the Swiss Federal Institute of Technology in Zürich where he worked in the field of dynamic NMR spectroscopy and electrochemistry. He received his habilitation from the ETH Zurich in 1977. In 1979, he became a professor in the Department of Organic Chemistry, University of Cologne, and accepted an offer of a chair in organic chemistry at the University of Mainz in 1983. In 1988, he joined the Max-Planck-Society and in 1989 as one of the directors of the Max-Planck Institute for Polymer Research. His current research topics include new polymer-forming reactions, multidimensional polymers with complex shape-persistent architectures, dyes, chemistry and physics of single molecules, polymers for electronic and optoelectronic devices, materials for lithium or hydrogen storage, biosynthetic hybrids, and nanocomposites. In recent years, he has especially focused on the chemistry and physics of carbon-rich materials such as carbon nanotubes, graphenes, and nanographenes. He has received numerous prestigious awards such as the International Award of the Polymer Society of Japan (2009), the ACS Award for Polymer Chemistry (2011), the ERC Advanced Grant (2011), and the Tsungming Tu Award (2011). Since 2006, he acts as Associate Editor of the *Journal of the American Chemical Society* and in 2008 and 2009 he served as President of the German Chemical Society.

David A. Tirrell is the Ross McCollum-William H. Corcoran Professor of chemistry and chemical engineering at the California Institute of Technology. After earning the BS degree in chemistry at MIT in 1974, he enrolled in the Department of Polymer Science and Engineering at the University of Massachusetts, where he was awarded the PhD degree in 1978 for work done under the supervision of Otto Vogl. After a brief stay with Takeo Saegusa at Kyoto University, he accepted an assistant professorship in the Department of Chemistry at Carnegie Mellon University in the fall of 1978. He returned to Amherst in 1984 and served as director of the Materials Research Laboratory at the University of Massachusetts before moving to Caltech in 1998. He chaired the Division of Chemistry and Chemical Engineering at Caltech from 1999 until 2009. His contributions to chemistry and chemical engineering have been recognized by his election to the National Academy of Sciences, the National Academy of Engineering, the Institute of Medicine, and the American Academy of Arts and Sciences.

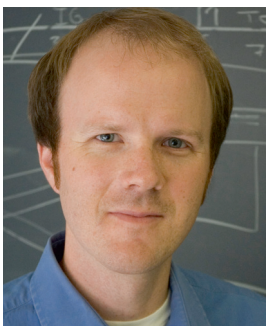
Robert S. Langer is the David H. Koch Institute Professor (there are 14 Institute Professors at MIT; being an Institute Professor is the highest honor that can be awarded to a faculty member). Dr. Langer has written nearly 1130 articles. He also has approximately 800 issued and pending patents worldwide. Dr. Langer's patents have been licensed or sublicensed to over 220 pharmaceutical, chemical, biotechnology, and medical device companies. He is the most cited engineer in history. He served as a member of the United States Food and Drug Administration (FDA)'s SCIENCE Board, the FDA's highest advisory board, from 1995 to 2002 and as its Chairman from 1999 to 2002.

Dr. Langer has received over 180 major awards including the 2006 United States National Medal of Science; the Charles Stark Draper Prize, equivalent of the Nobel Prize for engineers; the 2008 Millennium Prize, the world's largest technology prize; and the 2012 Priestley Medal, the highest award of the American Chemical Society. He is the also the only engineer to receive the Gairdner Foundation International Award; 72 recipients of this award have subsequently received a Nobel Prize. Among numerous other awards Langer has received are the Dickson Prize for Science (2002); Heinz Award for Technology, Economy and Employment (2003); the Harvey Prize (2003); the John Fritz Award (2003) (given previously to inventors such as Thomas Edison and Orville Wright); the General Motors Kettering Prize for Cancer Research (2004); the Dan David Prize in Materials Science (2005); the Albany Medical Center Prize in Medicine and Biomedical Research (2005), the largest prize in the United States for medical research; induction into the National Inventors Hall of Fame (2006); the Max Planck Research Award (2008); and the Prince of Asturias Award for Technical and Scientific Research (2008). In 1998, he received the Lemelson-MIT Prize, the

world's largest prize for invention for being 'one of history's most prolific inventors in medicine'. In 1989, Dr. Langer was elected to the Institute of Medicine of the National Academy of Sciences, and in 1992, he was elected to both the National Academy of Engineering and the National Academy of Sciences. He is one of very few people ever elected to all three United States National Academies and the youngest in history (at age 43) to ever receive this distinction.

Forbes Magazine (1999) and *Bio World* (1990) have named Dr. Langer as one of the 25 most important individuals in biotechnology in the world. *Discover Magazine* (2002) named him as one of the 20 most important people in this area. *Forbes Magazine* (2002) selected Dr. Langer as one of the 15 innovators worldwide who will reinvent our future. *Time Magazine* and CNN (2001) named Dr. Langer as one of the 100 most important people in America and one of the 18 top people in science or medicine in America (America's Best). *Parade Magazine* (2004) selected Dr. Langer as one of six 'Heroes whose research may save your life'. Dr. Langer has received honorary doctorates from Harvard University, the Mt. Sinai School of Medicine, Yale University, the ETH (Switzerland), the Technion (Israel), the Hebrew University of Jerusalem (Israel), the Universite Catholique de Louvain (Belgium), Rensselaer Polytechnic Institute, Willamette University, the University of Liverpool (England), Bates College, the University of Nottingham (England), Albany Medical College, Pennsylvania State University, Northwestern University, Uppsala University (Sweden), and the University of California–San Francisco Medal. He received his bachelor's degree from Cornell University in 1970 and his ScD from the Massachusetts Institute of Technology in 1974 (both degrees in Chemical Engineering).

James E. McGrath received his BS in chemistry from Siena College in New York (1956) and his MS (1964) and PhD (1967) in polymer science from the University of Akron, where he worked on emulsion and anionic polymerization of synthetic rubbers, ozone cracking, and triblock copolymer thermoplastic elastomers. After 19 years in industry (Rayonier (cellulose), Goodyear (synthetic rubbers), and Union Carbide (engineering thermoplastics, polyolefins)), he joined the Chemistry Department at Virginia Tech in 1975. He is now Ethyl Chair and a University Distinguished Professor. He was director of the first group of NSF Science and Technology Centers from 1989 to 2000 on Structural Adhesives and Composites and focused on high-temperature polymers including polyimides, polysulfones, and toughened epoxy polymeric matrix resins for carbon fiber composites. He has many contributions to the anionic and ring-opening polymerization of dienes, epoxides, and organosiloxanes. His current focus is on polymeric materials for carbon fibers and membranes, including fuel cells, reverse osmosis water purification and gas separation systems. He has 50 patents and over 500 publications and has received numerous awards, including election to the National Academy of Engineers (1994), The International SPE award, the Plastics Hall of Fame, and the ACS awards in Applied Polymer Science (2002) and Polymer Chemistry (2008). He has graduated more than 100 PhD chemists and engineers and remains one of the leaders in polymer science and engineering, with a current group (2011) of 13 students and postdoctoral fellows.



Michael A. Hickner received a BS in chemical engineering from Michigan Tech in 1999 and MEng in 2002 and PhD in chemical engineering from Virginia Tech in 2003. In graduate school, he worked under the direction of James E. McGrath and also spent time in the fuel cell group at Los Alamos National Laboratory developing novel aromatic proton exchange membranes for both hydrogen and direct methanol fuel cells. Before joining the Department of Materials Science and Engineering at Penn State in July 2007, he was a postdoctoral researcher and subsequently became a staff member at Sandia National Laboratories in Albuquerque, NM, where he conducted experimental investigations and modeling studies of liquid water transport in fuel cells and porous media and properties of ion-containing membranes, electrochemical reactors, and nanoporous membranes for water treatment applications. His research group at Penn State is focused on the synthesis and properties of ion-containing polymers, measurement of water–polymer interactions using spectroscopic techniques, and the study of self- and directed assembly of polymeric nanostructures for fast transport. He has ongoing projects in new polymer synthesis, fuel cells, batteries, water treatment membranes, and organic photovoltaic materials. He is currently an assistant professor and the Virginia S. and Philip L. Walker Jr. Faculty Fellow in the Materials Science Department at Penn State. Hickner's work has been recognized by a

Powe Junior Faculty Enhancement Award (2008), Young Investigator Awards from ONR and ARO (2008), a 3M Non-tenured Faculty Grant (2009), and a Presidential Early Career Award for Scientists and Engineers from President Obama in 2009. He has five US and international patents and over 60 peer-reviewed publications since 2001 that have been cited more than 2900 times as of 2011.

Rainer Höfer graduated in Inorganic Chemistry with Professor Oskar Glemser at the Georg-August Universität zu Göttingen in 1973 with work on sulfur–nitrogen–fluorine chemistry. He spent three years at the Technical University of Oran (ENSEP), Algeria, as Maître de Conférences and Directeur de l'Institut de Chimie before joining Henkel in Düsseldorf. With Henkel KGaA and then as Vice President Research & Technology with Cognis GmbH in Monheim, he has assumed global research and development, application technology, technical sales service, strategic business development, and technology scouting responsibilities in oleochemistry, polymer chemistry, and surfactant chemistry for the polymerization, coatings, graphic arts, adhesives, engineering plastics, agrochemical, synthetic lubricants, mining, and pulp and paper markets. He is founder of Editorial Ecosiris with consultancy and publishing activities in the domains of green chemistry, renewable resources, sustainable development, and interculturation.

PREFACE

Comprehensive Polymer Science was published in 1989 as a set of seven volumes and then supplemented by two additional volumes. This excellent print collection comprehensively covered the entire field of polymer science at that time. Much of the information is currently still as valuable as it was then, although some aspects are seen differently now. Those differences are important in order to understand the enormous development polymer science has taken since 1989. When we developed the concept for an entirely new edition of *Polymer Science: A Comprehensive Reference*, we intended not only to update and replace the original edition of *Comprehensive Polymer Science*, (we are pleased to announce that it will be soon available in electronic format) but also to focus on a widely observed transition of polymer science, from exploring only macromolecules, polymeric materials, and polymerization processes to become part of a comprehensive study on molecular soft matter science enabling advancements in other related disciplines.

In 1989, polymer science had just started a second stage of development after completing the scientific and technological evolution of its fundamental principles. This second stage has been driven by the continuously increasing understanding of the complexity in the structural organization of polymer materials and the challenge to understand and to master the fundamental underlying structure formation on exceedingly large length scales. Material functions based on molecular organization have been the focus of outstanding and highly recognized achievements, for example, new concepts for macromolecular architectures, self-assembling properties, electronically conductive polymers, ultrathin films, and hybrid structures or bioconjugates.

We are once again at the beginning of another step forward in the development of polymer science. Based on an increasing understanding of molecular processes, for example, advancements in mastering molecular self-assembly and the interfacing of bottom-up and top-down approaches to molecular organization, the tremendous progress in understanding the molecular basis of biological processes, and the growing ability to describe more and more complex systems with the rigorous approaches of physics, the traditional boundaries between these fields of science are being torn down. At the same time, the differentiation between materials and living organisms is becoming more and more indistinct, that is, machines are becoming biological and biology is becoming engineered. Already a new field of biofunctional materials is emerging, where 'biofunctional' represents the ability to activate and control a biological response. As a consequence, polymer science is facing a shift in paradigm from having been focused on itself, toward creating an enabling science that provides an understanding of a much broader base of 'molecular soft matter science' that reaches out and provides important contributions toward biology and information- and energy-related technologies. This development is seen in the increased worldwide interest in bioinspired materials engineering biomimetic materials and in the creation of smart nanostructures, as well as polymeric electronic and photonic devices.

The great progress that has been made in many areas of polymer science since 1989 is reflected in, and aided by, three major developments: (1) the advancements in precision polymerization and synthetic combination of well-defined (bio)macromolecular building blocks, for example, controlled polymerization processes, and new macromolecular architectures; (2) the progress in characterization methods spanning an enormous increase in length- and timescales, for example, single molecule imaging and spectroscopy that provides an improved insight on slow and cooperative relaxation and ordering; and (3) significant improvement in the understanding of complex macromolecular systems like polyelectrolytes and block and graft copolymers amplified

by the dramatically enhanced power of computational simulations. In addition, much interest has been focused on polymers and materials coming from biological sources, or those designed to serve specific functions in a biological system, which is partly driven by environmental and sustainability aspects, but also by the rising interest in smart biomimetic and bioactive materials. Besides the emergence of new biomaterials and biohybrid macromolecules, this also leads to a new interest in waterborne polymers and polymer synthesis in aqueous systems, for example, enzymatic polymerization.

The organization and outline of the ten volumes of this edition of *Polymer Science: A Comprehensive Reference* has been chosen to give consideration to these developments, but also to link the fundamentals of polymer science, as developed over almost 100 years, with the challenges of the ever more complex systems, and introduce connections that will dominate the future development of a polymer-based molecular soft matter science. Besides the classic print edition, this new edition of *Polymer Science: A Comprehensive Reference* is also provided as an e-version, enabled with efficient cross-referencing and multimedia. We invited the top world experts in polymer science to serve as volume editors and this 'dream team' has prepared a ten-volume set with 269 chapters covering both the fundamentals and the most recent advances in polymer science. Volumes 1–5 are directed toward the fundamentals of polymer science, that is, polymer physics and physical chemistry, advanced characterization methods, and polymer synthesis. In spite of the breadth of information collected in these five volumes, it has not been possible to cover all aspects of polymer science. In some cases, the reader must refer to the chapters in volumes 6–10 that address topical developments with a stronger material focus.

The progress in polymer science is revealed in essentially all chapters of this edition of *Polymer Science: A Comprehensive Reference*. In Volume 1, edited by Khokhlov and Kremer, this is reflected in the improved understanding of the properties of polymers in solution, in bulk, and in confined situations such as in thin films. Volume 2, edited by Spiess, Hashimoto, and Takenaka, addresses new characterization techniques that were not covered in the first edition, or did not even exist in 1989, such as high-resolution optical microscopy, scanning probe microscopy, and other procedures for surface and interface characterization. Volume 3, edited by Coates and Sawamoto, presents the great progress achieved in precise synthetic polymerization techniques for vinyl monomers to control macromolecular architecture: the development of metallocene and post-metallocene catalysis for olefin polymerization, new ionic polymerization procedures, atom transfer radical polymerization, nitroxide-mediated polymerization, and reversible addition-fragmentation chain transfer systems as the most often used controlled/living radical polymerization methods. Volume 4, edited by Penczek and Grubbs, is devoted to kinetics, mechanisms, and applications of ring-opening polymerization of heterocyclic monomers and cycloolefins (ROMP), as well as to various less common polymerization techniques. Polycondensation and non-chain polymerizations, including dendrimer synthesis and various 'click' procedures, are covered in Volume 5, edited by Schmidt and Ueda. Volume 6, edited by Müller and Wooley, focuses on several aspects of controlled macromolecular architectures and soft nanoobjects including hybrids and bioconjugates. Many of the achievements would have not been possible without new characterization techniques like atomic force microscopy (AFM) that allowed direct imaging of single molecules and nanoobjects with a precision only recently available. An entirely new aspect in polymer science is based on the combination of bottom-up methods such as molecularly programmed self-assembly with top-down structuring such as lithography and surface templating, as presented in Volume 7, edited by Kumacheva and Russell. It encompasses polymer and nanoparticle assembly in bulk and under confined conditions or influenced by an external field, including thin films, inorganic–organic hybrids, or nanofibers. Volume 8, edited by Muellen and Ober, expands these concepts, focusing on applications in advanced technologies, for example, in electronic industry and centers, in combination with the top-down approach and functional properties like conductivity. Another type of functionality that is rapidly increasing in importance in polymer science is introduced in volume 9, edited by Langer and Tirrell. This deals with various aspects of polymers in biology and medicine, including the response of living cells and tissue to the contact with biofunctional particles and surfaces. Volume 10, edited by Höfer, Hickner, and McGrath, is devoted to the scope and potential provided by environmentally benign and green polymers, as well as energy-related polymers. It discusses new technologies needed for a sustainable economy in our world of limited resources. Common to all approaches in this edition of *Polymer Science: A Comprehensive Reference* is the mastering of an increasing complexity of the polymer material structure needed for a change in focus

from commodities to materials for various advanced applications, related to energy, environment, and biomedicine.

We hope that this new edition of *Polymer Science: A Comprehensive Reference* will provide the readers with state-of-the-art coverage of all important and modern aspects of polymer science. We would like to thank all volume editors, contributing authors, and Elsevier personnel for their efforts, not only in completing the project in a timely fashion but also in ensuring the outstanding quality of the final product.

Martin Möller

FOREWORD

Polymer science has experienced a most impressive expansion in depth, breadth, and diversity through developments in its core domains as well as at the interfaces of polymer chemistry and physics with materials science, supramolecular chemistry, nanoscience, biophysics, and biology. These developments are reflected in the evolution from the original edition of *Comprehensive Polymer Science* to the present edition *Polymer Science: A Comprehensive Reference*. None of these areas can nowadays be envisaged without considering the contributions of polymer science to their own progress. At the same time and with increasing impact, scientists from the other fields contribute new findings and concepts to polymer science and many novel and topical approaches are rooted in the areas mentioned above.

The extension of the concepts and features of supramolecular chemistry from discrete species to polymolecular entities has opened novel perspectives in materials science. It defines a field of supramolecular materials that rests on the explicit implementation of intermolecular interactions and recognition processes for controlling the buildup, the architecture, and the properties of polymolecular assemblies as they emerge from their components through self-organization. Such spontaneous but directed self-assembly is of major interest for the supramolecular design, synthesis, and engineering of novel materials presenting novel properties.

Our own connection with polymer science stems from the introduction and progressive establishment of a supramolecular polymer chemistry built on entities generated by polyassociation between molecular 'monomeric' components through dynamic noncovalent interactions with molecular recognition between the components. The more recent development of dynamic covalent chemistry led to the investigation of dynamic covalent polymers formed by polycondensation through reversible reactions between subunits bearing suitable functional groups. The dynamic features of both these molecular and supramolecular polymers characterize dynamic polymers, dynamers, on both levels. Dynamers may be defined as constitutional dynamic polymers, that is, polymeric entities whose monomeric components are linked through reversible connections and have therefore the capacity to modify their constitution by exchange and reshuffling of their components. They may undergo constitutional variation by incorporation, decorporation, and exchange of components. These dynamic properties confer to dynamers the ability to undergo adaptation and driven evolution in response to physical stimuli or chemical effectors. Dynamers are thus constitutional dynamic materials resulting from the application of the principles of constitutional dynamic chemistry to polymer science. As such, they open wide perspectives toward adaptive materials and technologies.

By the nature and the size of its objects, polymer science plays a very important role in nanoscience and nanotechnology, both areas experiencing a profound mutual fertilization. Polymer science has also been subject to major developments at the interface with biology, by the incorporation of biological components into synthetic polymers, as well as by applying its own principles to the understanding of the features of biological macromolecules.

An extremely rich variety of novel architectures, processes, and properties have resulted and may be expected to further emerge from the blending of polymer science with the other areas of materials chemistry and physics, with ongoing developments in chemistry as well as with the investigation of complex molecular behavior in biological sciences.

Polymer Science: A Comprehensive Reference provides complete and up-to-date coverage of the most important contemporary aspects and fundamental concepts of polymer science. It will become the indispensable reference not only for polymer scientists but also for all researchers in disciplines related to macromolecular systems.

4.01 Introduction

S Penczek, Polish Academy of Sciences, Lodz, Poland
RH Grubbs, California Institute of Technology, Pasadena, CA, USA

Ring-opening polymerization (ROP) encompasses polymerization of cyclic compounds (monomers) with at least one heteroatom or a double bond in the molecules. Polymerization of the latter proceeds by the metathesis mechanism and is called ring-opening metathesis polymerization (ROMP). It has become customary to use the expression 'ROP' mostly for heterocyclic monomers. Both processes belong to the larger family of chain polymerizations. In this volume of Polymer Science: A Comprehensive Reference there are a few chapters that do not entirely belong to ROP.

The first chapters describe the general phenomena of ROP (and ROMP). For the first time, the mechanistic aspects of ROMP are presented, as they were not treated in the first edition of Comprehensive Polymer Science (CPS). These chapters will present a discussion of the history of development of 'living' ROMP and the key features that must be controlled to obtain narrow dispersity polymer samples with the desired molecular weight.

Thermodynamic features of polymerization of both classes of monomers are similar and the ring strain is mostly responsible for conversion of monomer into polymer unit. The origins of the ring strains are similar, namely distortion of the ring angles and stretching bonds. Nevertheless, certain differences in thermodynamics in the two groups of monomers stems from the conversion of the single bonds into single bonds in the former and the conversion of the double bond into a double bond in the repeating units in the latter. Then, if there is a sufficiently short distance, their interaction may influence the enthalpy of the chemical change.

Metathesis can be accomplished with ruthenium-based catalysis in water solvent, whereas ionic processes typical in the ROP exclude water as a reaction medium (there are a few exceptions: the most basic monomers, radical ROP as well as unusual ionic polymerization in water emulsions (cyclic siloxanes)).

Impressive progress has been made in stereospecific polymerization of cyclic ethers and cyclic esters since the first edition of *CPS* was published. A novel ROP phenomenon called stereocomplexation, which is especially important when it involves homochiral macromolecules, poly(*R*)- and poly(*S*)- polylactides, is analyzed in detail (chapter devoted to cyclic esters). A breakthrough in the stereoregulation of methyloxirane (propylene oxide) polymerization is the subject of a chapter on stereospecific polymerization of oxiranes.

Several chapters describe ROP of major classes of monomers such as cyclic ethers, acetals, esters, sulfides, amines, amides, oxazolines, and less common ones, like *N*-carboxyanhydrides (NCAs) of α-amino acids, leading to polypeptides or ROP of cyclic esters of phosphoric acid allowing synthesis of the backbones of DNA.

Novel phenomena are examined such as ROMP (metal-catalyzed ROMP of olefins) involving new classes of initiators (so-called metal free) and phosphorus compounds. Moreover, if one looks at the literature cited in the majority of chapters, then it becomes clear that at least half of the chapters are based on results published after the first edition of *CPS* appeared. Of course, there are established fields, like polymerizations of cyclic sulfides or cationic polymerization of cyclic acetals or several cyclic ethers (e.g., tetrahydrofuran (THF)). Therefore, in the corresponding chapters, the major facts of the past are recalled. However, in the chapters on mechanism of ROMP or cyclic esters, almost exclusively new data are set forth, like the polymerization of biobased monomers (e.g., lactides). The mechanism of the most often used catalytic system, based on $Sn(Oct)_2$, is novel and conditions for living and controlled polymerization of L-lactide polymer (PLA), which is called the 'polymer of the twenty-first century', are discussed in detail.

In the processes of chain ROP/ROMP, there are several phenomena not existing in the vinyl chain polymerizations. These include chain transfer to macromolecules with chain breaking, the most prominent in the polymerization of cyclic acetals (described Chapter **4.10** by Kubisa and Warren), where cationic active species may react with the repeating units of macromolecules with rate constants exceeding the rate constants of propagation.

Similar phenomena, although less effective, take place in the polymerization of all monomers leading to macromolecules with heteroatoms in the chains. A related phenomenon is chain transfer to the same macromolecule, called backbiting and bearing a resemblance to the intramolecular transfer in, for example, polymerization of ethylene. However, in the latter, branching results from 'backbiting' and in ROP/ROMP formation of cyclic molecules is the dominating process.

The theory of chain transfer with chain breaking is presented Chapter **4.11** by Duda. Zwitterionic ROP was studied already in the 1970s (initiation with strong bases – tertiary amines and phosphines), but this work has mostly been forgotten. Related classes of strong nucleophiles and carbenes have appeared and are discussed under the more appealing name 'no metal catalysts'. These are particularly important for cyclic esters due to the value of the final applications of the resulting polymers ranging from medicine to electronics. In addition, strong bases and acids, which perform equally well in some systems, also belong to this category of initiators/catalysts.

The second large group of chapters specifically describes the synthetic aspects of ROP/ROMP. In this section, the architecture of polymers prepared by ROMP, functionalization of poly(ethylene oxide), chain extension by ROP, nonlinear polyethers, as well as ROP in heterogeneous media are discussed. It also describes methods of polymerization that provide regular and mostly spherical particles, and gives for the first time a review of the kinetics and mechanism of this particular system that resembles emulsion vinyl polymerization. The chapter on polymerization in confined space (encompassing matrix polymerization) summarizes results that may open the way to the 'replica polymerization', a process that is typical for the matrix synthesis of biomacromolecules in nature.

Frontal polymerization and solid-state polymerization, which are found in separate chapters, are gaining practical importance. Solid-state polymerization is a useful tool to 'fight against thermodynamics'. Indeed, when polymerization is conducted at a relatively high temperature (e.g., polymerization of L-lactide), there is a high equilibrium monomer concentration. Changing from homogeneous to heterogeneous conditions may not change the equilibrium monomer concentration but changes the volume of the system in which polymer–monomer equilibrium takes place, reducing the amount of monomer left at equilibrium. Ring-chain equilibrium and copolymerization at equilibria are the subjects of separate chapters, giving the necessary theoretical background.

The next group of chapters is devoted to particularly important applications. In this section, a chapter on conducting polymers by ROMP describes advances in this popular area and several chapters are devoted to biomedical applications: biorelated polymers by ROMP, functional surfaces and supports prepared by ROMP, biological applications of polyphosphoesters by ROP, and the already mentioned chapter on functionalized poly(ethylene oxide) (PEO), devoted mostly to the preparation of PEO for further PEGylation, a process making bioactive macromolecules more stable toward biohydrolysis.

The final group of chapters describes either already existing general industrial methods of polymer synthesis (Chapter **4.32**) or polymerization methods specifically related to a given group (Chapters **4.30, 4.36, 4.37** and **4.39**). Under these general titles, there are several important specific ROP polymerizations, like ROP of cyclic ethers, where photochemical initiation converts thermally stable compounds into strong protonic acids initiating fast cationic polymerization. Nevertheless, radical photopolymerization is still the most important area of research, and the introduction of lasers now competes successfully with the ionizing radiation processes. High-pressure polymerization, mostly known as an industrial process of ethylene polymerization, is the subject of the last chapter of this volume. It provides up-to-date analysis of the radical high-pressure polymerization and stresses the importance of the high pressure in supercritical CO_2 (supercritical CO_2).

It could be assumed that the accumulated knowledge would also be used for monomers with structural features preventing them from polymerization under normal conditions (resulting in thermodynamic potentials that indicate 'nonpolymerizability'). Several cyclic compounds that might under high pressure successfully become monomers are considered.

Since the first edition of *CPS*, significant progress has been made in ROP and ROMP; the chapters of this section of the book were designed to emphasize these aspects and to put them in the context of prior work on ring-opening processes.

Biographical Sketches

Stanislaw Penczek is Professor of Polymer Chemistry at the Polish Academy of Sciences (Centre of Molecular and Macromolecular Studies in Lodz). He teaches at the Graduate School of the Jagiellonian University (Krakow) as an honorary professor. He has mostly contributed to the kinetics, thermodynamics, and mechanisms of the ring-opening polymerization, publishing over 300 papers in related areas. He was one of the first to observe living and controlled polymerizations in cationic and anionic ROP, including reversibility of deactivation of propagating species. Among other honors from Belgium, Japan, and Germany (the Warburg Prize), he is a member of the Polish Academy of Sciences and foreign member of the German (Nordrhein) Academy, Dr *h.c.* of the Pierre and Marie Curie University in Paris and Dr *h.c.* of the Russian Academy of Sciences. He was a member of the International Union of Pure and Applied Chemistry (IUPAC) Bureau, and former president of European Polymer Federation.

Professor Robert (Bob) Howard Grubbs' main interests in organometallic chemistry and synthetic chemistry are catalysts, notably Grubbs' catalyst for olefin metathesis and ring-opening metathesis polymerization with cyclic olefins such as norbornene. He also contributed to the development of so-called 'living polymerization'.

Grubbs has received many awards including Alfred P. Sloan Fellow (1974–76), Camille and Henry Dreyfus Teacher-Scholar Award (1975–78), Alexander von Humboldt Fellowship (1975), ACS Benjamin Franklin Medal in Chemistry (2000), ACS Herman F. Mark Polymer Chemistry Award (2000), ACS Herbert C. Brown Award for Creative Research in Synthetic Methods (2001), the Tolman Medal (2002), and the Nobel Prize in Chemistry (2005). He was elected to the National Academy of Sciences in 1989 and a fellowship in the American Academy of Arts and Sciences in 1994.

4.02 Thermodynamic and Kinetic Polymerizability

S Penczek, Polish Academy of Sciences, Lodz, Poland
K Kaluzynski, Center of Molecular and Macromolecular Studies, Lodz, Poland

4.02.1 Introduction

In the first edition of *Comprehensive Polymer Science*[1] the thermodynamics of cationic ring-opening polymerization (CROP) was discussed exclusively. The content of this earlier chapter is to some extent retained, although entirely rewritten, taking into account the IUPAC document 'Glossary of Terms Related to Kinetics, Thermodynamics, and Mechanisms of Polymerization' ('Glossary')[2] published in 2008 as well as some new literature data. In the 'Glossary' enthalpy and entropy of polymerization as well as ceiling and floor temperatures are defined.

Major references are given to monographs, textbooks, and review papers. Nevertheless, papers that mostly contributed to the thermodynamics of polymerization are duly quoted.

Thermodynamics of polymerization does not formally differ from that of any other chemical reaction if by 'polymerization' the propagation step is understood.

Then

$$\mathrm{M} \rightleftarrows 1/n\,\text{–}(\mathrm{m})_n\text{–}$$

where M is a monomer, –(m)– is the repeating unit, and n is the polymerization degree (P_n). Like in any other chemical reaction, the polymerization may occur if the Gibbs energy of polymerization (actually, propagation) is negative ($\Delta G < 0$).

4.02.2 Major Definitions

Thermodynamic functions of polymerization may depend on the polymerization degree (P_n) (length of the polymer chain). If P_n is large enough the influence of the chain ends and the translation entropy of the macromolecule as a whole could be neglected, and the thermodynamic functions practically do not depend on P_n.

According to the IUPAC definition, Gibbs energy (G) is defined as "Enthalpy minus the product of thermodynamic temperature and entropy": $G = H - TS$.[3] The corresponding definitions of enthalpy and entropy related to polymerization are given below and are copied from the 'Glossary'.[2]

4.02.2.1 (Molar) Enthalpy of Polymerization (ΔH_m or $\Delta_{ab}H_m$, SI Unit: J mol^{-1})

Change of enthalpy, in a 'chain polymerization' forming a homopolymer, is associated with the conversion of one mole of monomer into polymer under isobaric and isothermal conditions.

Note 1: Under defined standard conditions the enthalpy of polymerization is designated $\Delta H^\circ{}_m$.

Note 2: The subscripts a and b in $\Delta_{ab}H_m$ denote the state of the monomer and the state of polymer, respectively:
g: gaseous state (hypothetical in the case of polymer);

l: liquid state (must be specified in the case of a mesophase);
s: in solution (solvent and mesophases, if any, must be specified);
c: (condensed) amorphous, glassy states;
c′: crystalline or partly crystalline state;
for example, $\Delta_{lc}H_m$ means: from liquid state to amorphous or glassy state; and
$\Delta_{ss}H_m$ means: from monomer in solvent to polymer in solvent.

Note 3: The symbol ΔH_{ab}, in common usage in polymer chemistry, is discouraged as the IUPAC-recommended symbol is $\Delta_{ab}H_m$.

4.02.2.2 (Molar) Entropy of Polymerization (ΔS_m or $\Delta_{ab}S_m$, SI Unit: J mol^{-1} K^{-1})

Change of entropy, in a 'chain polymerization' forming a homopolymer, is associated with the conversion of 1 mol of monomer into polymer under isobaric and isothermal conditions.

Note 1: Under defined standard conditions, the entropy of polymerization is designated $\Delta S^\circ{}_m$; thus, if the standard state refers to standard concentration, and the monomer behaves ideally, $\Delta S_m = \Delta S^\circ{}_m + R\ln([M]_0/c^\circ)$, where $[M]_0$ denotes the starting monomer concentration and $c^\circ = 1\ \text{mol dm}^{-3}$ is the standard concentration.

Note 2: The a and b subscripts in $\Delta_{ab}S_m$ denote the state of the monomer and the state of polymer, respectively (see Section 4.02.2.1).

In the present chapter the subscript m is omitted and all the values are given for 1 mol. In place of dm^{-3} symbol l (allowed by IUPAC) is used.

To use the accepted IUPAC definitions and notations is necessary, since in many monographs and textbooks, particularly coming from various countries, similar phenomena are described by different terms. For instance, Gibbs energy (IUPAC-preferred term) is still called 'free energy' or 'free enthalpy'.[4] In the authoritative monograph *Kinetics of Polymerization Processes* published in Russia *G* is called 'thermodynamic potential',[5] although this term (not existing in the IUPAC Gold Book) describes all the major thermodynamic functions, namely Gibbs energy $G(T, P, n)$, enthalpy $H(S, P, n)$, internal energy $U(S, V, n)$, and Helmholtz energy $F(T, V, n)$. The letters in brackets have their usual meaning (n is the number of species). The relationship between these thermodynamic potentials is known to be given by Legendre transforms, defining the other thermodynamic potentials in terms of U minus variable as shown above for a given potential.[6] An understanding of the interrelation is important, since in some monographs and textbooks either ΔG or ΔF is used. As it is known, exclusively at constant P and V $\Delta G = \Delta F$.

Thermodynamic potentials should be known, as well as their change when polymerization occurs, in order to properly understand positions of equilibriums (thermodynamic polymerizability). These potentials, like potential energy in mechanics, give information about the most stable state of the system, related to polymerizability.

Moreover, when for a given system, for example, $\Delta_{ss}G > 0$, it does not mean that polymerization in bulk would not also be possible (or vice versa), since it may happen at the same P, V, and T, $\Delta_{lc}G < 0$.

Thermodynamic polymerizability of monomers may be described and compared in various ways. $\Delta_{ab}G$ at a given temperature is one of the possible approaches. However, the ceiling temperature of monomers in bulk (T_c(bulk)) appears as a useful candidate since this is the upper limit at which the polymer of a given monomer is thermodynamically stable.

4.02.3 Equilibrium and Ceiling (Floor) Temperatures (T_e and T_c/T_f)

The history of the term 'ceiling temperature' is described in the paper by Ivin[7] and this term was first used for copolymerization of olefins with SO_2, studied in Phillips Petroleum by Snow and Frey. Copolymerization proceeded only below a certain temperature, which the authors called 'ceiling temperature'.[8]

In several papers and textbooks there is no clear-cut distinction made between equilibrium temperatures (T_e) and this particular temperature – ceiling temperature (T_c) – above which high polymer may not exist.

The statements from some textbooks are for instance as follows: "The temperature at which propagation and depropagation rates are equal is called a ceiling temperature".[9] "The temperature at which this equilibrium occurs is called ceiling temperature".[10] In the Odian's textbook we find "Finally a temperature – the *ceiling temperature* T_c is reached at which propagation and depropagation notes are equal".[11] Actually $\Delta G = 0$ (or $\Delta F = 0$) is a necessary but not a sufficient condition to fulfill the IUPAC definition and the original meaning introduced by Dainton and Ivin.[12] At T_c no high polymer, according to IUPAC definition (cf. below), is formed, and Snow and Frey (*vide supra*) have indeed not observed any polymer formation. To make it clear, let us assume that monomer M is to be polymerized at a certain temperature T_1 in bulk at living polymerization conditions. Then, after addition of an initiator polymerization proceeds until equilibrium monomer concentration $[M]_e$ is reached. Thus the $\Delta_{ss}G = 0$ condition is fulfilled. At this $T_1 = T_e$, however, a certain amount of polymer (P) is produced. The total number of repeating units (P_n) is equal to $[M]_0 - [M]_e$. Polymerization of, for example, tetrahydrofuran (oxolane) in bulk ($[M]_0 = 12.5\ \text{mol l}^{-1}$) and at 298 K would stop eventually at this temperature. Equilibrium monomer concentration $[M]_e$ would be equal to $2.3\ \text{mol l}^{-1}$. When the temperature is increased further, finally at a certain temperature, called, according to the above definition, ceiling temperature, T_c, there will be no high polymer formed, and $[M]_e = [M]_c \approx [M]_0$ (here $\sim 12.5\ \text{mol l}^{-1}$). Thus, there is, when polymerization is conducted in bulk, an infinite number of 'pairs': equilibrium monomer concentration $[M]_e$ paired with the corresponding equilibrium temperatures T_e. For these conditions (bulk), there is, however, only one ceiling temperature T_c(bulk), which for THF ≅ 84 °C.

When polymerization is conducted in solution, in the ideal system, the polymerization started at $[M]_0$ would go to equilibrium at $[M]_e$, characteristic only for the temperature of polymerization: $[M]_e$ does not depend on $[M]_0$ although T_c does depend, as it follows from eqn [1]. If the temperature is

increased further, finally $[M]_e$ becomes equal to $[M]_0$, and only then there would be no high polymer formed. In the nonideal systems (Section 4.02.7) $[M]_e$ is a function of $[M]_0$ (cf. Figure 4). Thus, in these real systems there is an infinite number of pairs of $[M]_e$ and T_e for various $[M]_0$ and an infinite number of T_c for various $[M]_0$. The corresponding equation relating T_c and $[M]_0$ reads

$$\Delta G = 0 = \Delta H - T_c(\Delta S^\circ + R\ln[M]_0) \quad [1]$$

(Since the system is nonideal ΔS° may also depend on $[M]_0$.)

In eqn [1] and in some further equations the subscripts at ΔG, ΔH, and ΔS (existing in the IUPAC document) are omitted. Equations may be valid for any chosen conditions with a pertinent modification. Often the subscript 'p' is used in the literature (e.g., ΔH_p) indicating the polymerization process, particularly when a paper is published in journals of a more general scope. These are also omitted in this chapter. Finally, ΔH can be taken as equal to ΔH°, since practically it depends neither on temperature nor on monomer concentration, in contrast to ΔS.

If the standard conditions are used, when $[M]_0 = 1\ \mathrm{mol\,l^{-1}}$, then

$$\Delta G = 0 = \Delta H - T\Delta S^\circ;\ \text{therefore}\ \Delta H = T\Delta S^\circ\ (\text{in general}) \quad [2]$$

From this relationship, for polymerizations with negative ΔH the exothermicity of polymerization (propagation) is counterbalanced at equilibrium by a negative change of entropy. This simple thermodynamic condition could also be explained by kinetic approach. At any equilibrium (i.e., also at T_c) the forward reaction (propagation) may proceed all of the time, although it is counterbalanced by an equally fast depropagation.

In the present treatment it is assumed that high molar mass polymers are formed; therefore $\ldots(-m-)_n m^* \approx \ldots(-m-)_{n+1} m^*$ $= [P_i^*]$.

The rate constants can be expressed according to the theory of the transition state (rate constants are given at T_c):

$$k_p = A_p \exp(-E_p/RT_c) \quad [3]$$

$$k_d = A_d \exp(-E_d/RT_c) \quad [4]$$

At the ceiling temperature polymer (by definition) is not formed; therefore, at this particular equilibrium $[M]_e = [M]_c = [M]_0$.

The rate of propagation and the rate of depropagation are equal:

$$A_p \exp(-E_p/RT_c)[M]_0[P_i^*] = A_d \exp(-E_d/RT_c)[P_i^*] \quad [5]$$

It follows that

$$T_c = (E_p - E_d)/R\ln\{(A_p/A_d)[M]_0\} = \Delta H/(\Delta S^\circ + R\ln[M]_0) \quad [6]$$

remembering that $E_p - E_d = \Delta H$, $\Delta S^\circ = \Delta^{\neq}S_p^\circ - \Delta^{\neq}S_d^\circ = R\ln(A_p/A_d)$, and $\Delta^{\neq}S_p^\circ$ and $\Delta^{\neq}S_d^\circ$ are entropies of activation and A_p and A_d are probability factors of propagation and depropagation, respectively, and concentrations of species can be omitted.

There is also another strictly thermodynamic way to express T_c as the function of ΔH and ΔS.

As it is known from monographs on thermodynamics,[13,14] it could be shown by methods of chemical thermodynamics or statistical mechanics (both out of scope of this chapter) that Gibbs energy change and equilibrium constant are related in the following way:

$$\Delta G = \Delta G^\circ + RT\ln K;\ \text{at equilibrium}\ \Delta G = 0 \quad [7]$$

$$\Delta G^\circ = -RT\ln K;\ \text{since}\ K = k_p/k_d = 1/[M]_e (\text{for long chains}) \quad [8]$$

$$\Delta G^\circ = RT\ln[M]_e;\ \text{thus, at}\ T_c:\ \Delta G^\circ = RT_c\ln[M]_0 \quad [9]$$

Thus

$$\Delta G^\circ = \Delta H - T_c\Delta S^\circ = RT_c\ln[M]_0 \quad [10]$$

After rearranging

$$T_c = \Delta H/(\Delta S^\circ + R\ln[M]_0)\ (\text{cf. eqns [1] and [6]}) \quad [11]$$

At particular conditions, when $[M]_0 = 1\ \mathrm{mol\,l^{-1}}$

$$T_c = \Delta H/\Delta S^\circ \quad [12]$$

(Superscript over ΔH may be omitted for reasons presented above.)

The higher the ceiling temperature of a given monomer, the higher its thermodynamic polymerizability. T_c could be calculated from ΔH and ΔS° and the extensive scale of T_c for various monomers could thus be tabulated.

Since

$$\ln[M]_e = \Delta H/RT_e - \Delta S^\circ/R \quad [13]$$

the experimentally accessible plot of $\ln[M]_e$ versus $1/T_e$ gives from the intercept and slope ΔS° and ΔH, respectively.

In Figure 1 this plot is shown for polymerization of L-lactide (L-LA).[15] The calculated values are $\Delta H = -22.9\ \mathrm{kJ\,mol^{-1}}$ and $\Delta S^\circ = -25\ \mathrm{J\,mol^{-1}\,K^{-1}}$. In this particular instance, as in many others, T_c is higher than the temperature at which the polymer would start to degrade.

In the extensive paper by Duda and Kowalski, published in 2009, a large number of ΔH, ΔS°, and $[M]_e$ at 298 K are tabulated.[16]

4.02.3.1 The IUPAC Definitions for Ceiling and Floor Temperatures

The IUPAC definitions taken in extenso from the IUPAC 'Glossary'[2] are given below.

4.02.3.1.1 Ceiling temperature (T_c, SI Unit: K)

Temperature above which, in a given 'chain polymerization', polymer of high molar mass is not formed.

Note 1: A ceiling temperature is only observed for enthalpy-driven *chain polymerizations* in which $\Delta H_m < 0$ and $\Delta S_m < 0$, where ΔH_m and ΔS_m are, respectively, the enthalpy and entropy change per mole of monomer reacted.

Note 2: For most *chain polymerizations*, $\Delta H_m < 0$ and $\Delta S_m < 0$.

Note 3: Below T_c, ΔG_m $(= \Delta H_m - T\Delta S_m) < 0$; at T_c, $\Delta G_m = 0$; and above T_c, $\Delta G_m > 0$.

Note 4: Because $\Delta G_m = 0$ at the ceiling temperature, $T_c = \Delta H_m^\circ/\Delta S_m^\circ$. If ΔH_m° and ΔS_m° are the enthalpy and entropy

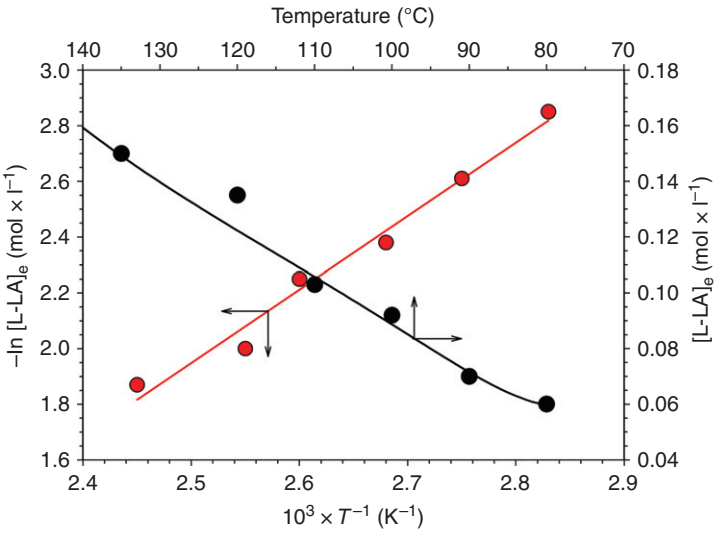

Figure 1 Dependence of the equilibrium concentration of L-lactide on the reciprocal of the absolute temperature.

changes in the standard state, and the monomer behaves ideally, then $T_c = \Delta H_m^\circ / \{\Delta S_m^\circ + R \ln([M]_0/c^\circ)\}$, where $c^\circ = 1$ mol dm^{-3} is the standard concentration and $[M]_0$ is the initial monomer concentration. Thus, T_c depends on the initial monomer concentration.

Note 5: The symbol $T_c(c^\circ)$ is used to denote the ceiling temperature when the initial monomer concentration, $[M]_0$, is equal to c°.

Note 6: The symbol T_c(bulk) is used to denote the ceiling temperature when the initial monomer concentration is equal to its undiluted concentration.

4.02.3.1.2 Floor temperature (T_f, SI Unit: K)

Temperature below which, in a given 'chain polymerization', polymer of high molar mass is not formed.

Note 1: A floor temperature is only observed for entropy-driven 'chain polymerizations' in which $\Delta H_m > 0$ and $\Delta S_m > 0$, where ΔH_m and ΔS_m are, respectively, the enthalpy and entropy change per mole of monomer reacted.

Note 2: Examples of 'chain polymerizations' for which $\Delta H_m > 0$ and $\Delta S_m > 0$ are polymerizations of larger cyclic monomers, for example, elemental sulfur (S_8) and octamethylcyclotetrasiloxane (2,2,4,4,6,6,8,8-octamethyl-1,3,5,7,2,4,6,8-tetraoxatetrasiloxane), proceeding via ring-opening mechanisms.

Note 3: Above T_f, ΔG_m ($= \Delta H_m - T\Delta S_m$) < 0; at T_f, $\Delta G_m = 0$; and below T_f, $\Delta G_m > 0$.

Note 4: Because $\Delta G_m = 0$ at the floor temperature, $T_f = \Delta H_m / \Delta S_m$. If ΔH_m° and ΔS_m° are the enthalpy and entropy changes in the standard state, and the monomer behaves ideally, then $T_f = \Delta H_m^\circ / \{\Delta S_m^\circ + R \ln([M]_0/c^\circ)\}$ where $c^\circ = 1$ mol dm^{-3} is the standard concentration. Thus, T_f depends on the initial monomer concentration.

Note 5: The symbol $T_f(c^\circ)$ is used to denote the floor temperature when the initial monomer concentration, $[M]_0$, is equal to c°.

Note 6: The symbol T_f(bulk) is used to denote the floor temperature when the initial monomer concentration is equal to its undiluted concentration. In this chapter subscript 'm' is omitted.

4.02.4 Methods for Determination of T_c (or $[M]_e$)

For living polymerizations a simple method could be to measure the monomer concentration as a function of temperature (e.g., NMR, GC, SEC) and determine the temperature at which $[M]_e = [M]_0$, that is, there is no polymer in the system. This method may be impractical for several cyclic monomers with highly exothermic polymerization, since their T_c, particularly in bulk, may be too high and decomposition would come first.

Ceiling temperatures T_c and floor temperatures T_f of polymerizations in bulk are usually reported for $\Delta_{lc}G$ or $\Delta_{lc'}G$ for polymerizations of liquid monomers (subscript l) to amorphous (subscript c) or crystalline (subscript c') polymers. Polymerization in solution is usually referred to as the polymerization of a 1 mol l^{-1} monomer solution (subscript s) to a dissolved polymer (subscript s), that is, $\Delta_{ss}G^\circ = 0$. Ceiling temperatures in bulk (T_c(bulk)) are always higher than ceiling temperatures in solution.

Another method would be based on the determination of ΔH and ΔS° first from studies of dependence of $[M]_e$ on $1/T$, as shown in Figure 1.

How large are differences between T_c(bulk) and T_c(25 °C) is shown for a few examples in Table 1.

4.02.5 Factors Affecting Polymerizability: Enthalpy of Polymerization

Any factor that lowers the enthalpy or raises the entropy of a particular species in a system will shift the equilibrium to favor that species.

Table 1 Comparison of ceiling temperatures (T_c): determined for bulk – lc or (lc′) and ss conditions (the former for bulk, the latter for $[M]_c = ([M]_0) = 1\ mol\ l^{-1}$)[17]

	T_c (°C)

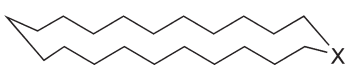
Undecano-11-lactam	12	–2.1
Dodecano-12-lactam	13	2.9

4.02.5.1 Ring Strain

In polymerization at normal pressure, the $P\Delta V$ term in $\Delta H = \Delta E - P\Delta V$ is negligible and the enthalpy change is almost equal to the change in the internal energy of the monomer. Thus, the heat of polymerization may be used as a measure of the strain energy in the cyclic compound, which reflects well the thermodynamic polymerizability of the monomer. The major sources of ring strain are (1) bond-angle distortion (angular strain); (2) bond stretching or compression; (3) repulsion between eclipsed hydrogen atoms (conformational strain, bond torsion, bond opposition); and (4) nonbonded interaction between atoms or substituents attached to different parts of the ring (transannular strain, compression of the van der Waals radii).

In some groups of monomers, there are additional sources of strain, such as inhibition or reduction of amide-group resonance in lactams.[18] The contribution of each type of strain depends on the chemical structure of the cyclic monomer, ring size, and its substitution.

Distortion in bond angles is the major source of the ring strain in three- and four-membered cyclic monomers. In five-membered cyclic compounds, the strain is mostly due to bond opposition forces, arising from eclipsed conformations. Tetrahydrofuran is an example. In medium-sized rings, strain arises primarily from nonbonded interactions and bond oppositions. Any kind of strain, including transannular interactions, can be removed completely in very large rings by arranging the ring atoms into two almost parallel chains.[19]



ΔH as a function of the ring size in cyclic ethers and for lactams are given in Table 2 and Table 3, respectively.

The normal angles between the four valences of a tetrahedral carbon atom are assumed to be 109°28′, that is, the valences are equally spaced about the atom: then, in three- and four-membered rings, severe valence angles must be involved. Thus, if rings are considered to be planar (which is, however, not true for majority of heterocyclic monomers), the distortion [0.5 × (normal valence angle minus actual angle between bonds)] from normal valence angle would be the number of atoms in the ring, and distortion, given in this order, is 3, 24°44′; 4, 9°44′; 5, 0°44′; and 6, -5°16′. Thus, the angle strain is quite severe in the three- and four-membered rings. It is much lower for the five- and six-membered rings (minimum of strain). Cyclic esters are exceptions from this rule, due to the presence of the >C=O group. Comparison of conformations of the five- and six-membered lactones and five-membered THF is given in Figure 2. There is a repulsion between the H atoms in the six-membered lactones, which is practically not present in the five-membered rings. Therefore, the six-membered ester is known to polymerize, whereas the five-membered is not. In the same figure a model of tetrahydrofuran, a polymerizable five-membered cyclic ether, is shown and opposition of H atoms is seen.

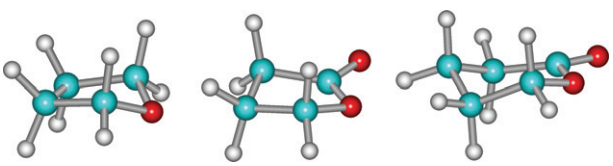


Figure 2 Comparison of conformations of five-membered cyclic ether (tetrahydrofuran) and the five- and six-membered lactones.

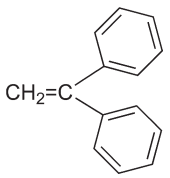
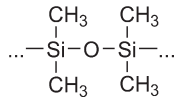
4.02.5.2 Side Groups' Interaction

Bulky side groups attached to the polymer chain can destabilize a polymer relative to monomer or cyclic oligomers. The presence of small substituents may have no influence on the repulsion in monomer and polymer, which can be negligible. On the other hand, the presence of large substituents may practically make polymerization impossible. For vinyl monomers the best known example is 1,1-diphenylethene:

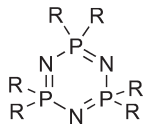


In polymerization of cyclic siloxanes (cf. Chapter 4.17 in this comprehensive), even in poly(dimethylsiloxane), there is 87% of linear polymer at equilibrium and the rest consists of cyclics:



When larger substituents are present, then monomer and cyclic oligomers are further favored and thermodynamic polymerizability is lowered.[22]

Allcock[23] gives corresponding examples for cyclophosphazenes:



For R = Cl the polymer is stable up to 350 °C whereas when R = OCH_2CF_3 or OC_6H_5 substantial depropagation takes place at much lower temperatures.

In the monograph on ring-opening polymerization (ROP) by Ivin and Saegusa[24] over 170 various cyclic compounds, five-, six-, and seven-membered (plus bridged ones), are tabulated and their ability to polymerize is described in the chapter on polymerization thermodynamics. In another comprehensive treatment ΔH, $\Delta S°$, and $[M]_e$ data for 25 more common monomers (mostly at 298 K) are compiled.[16]

On the other hand, in Allcock's textbook several T_c(bulk) are given and unsaturated monomers are compared, showing that, for example, for tetrafluoroethene T_c(bulk) equals 1100 °C whereas for acetaldehyde it is as low as −40 °C. For cyclic monomers these differences may also be quite high. It is understandable that for a strained ethylene oxide it would have been ~1000 °C whereas for THF it is equal, as mentioned above, to ~84 °C (T_c(bulk)).

4.02.5.3 Independent Determination of ΔH and ΔS

As it follows from the 'Glossary' document,[2] it is necessary for the purpose of tabulation and comparison of, for example, $[M]_e$ to choose standard states such as 25 °C, 1 mol l^{-1} of monomer in the inert solvent, converted to 1 mol l^{-1} of repeating units, that is, to $1/n$ mole of polymer with an average degree of polymerization n in the same solvent.

Standard enthalpies of polymerization $\Delta H°$ (ΔH) are most generally obtained by direct comparison of the results of calorimetric measurements of the amount of monomer converted to polymer with the determined amount of heat evolved. The heat of combustion of monomer and polymer give standard enthalpies of formation for the monomer ($\Delta H_f°(M)$) and polymer unit ($1/n\ \Delta H_f°(P_n)$) respectively. The difference (Eqn 14) is equal to the standard enthalpy of polymerization.

$$\Delta H^\circ = 1/n\Delta H_f^\circ(P_n) - \Delta H_f^\circ(M) \quad [14]$$

Standard entropies of polymerization $\Delta S°$ are generally calculated from the absolute entropies of the monomer and polymer:

$$\Delta S_f^\circ = 1/nS^\circ(P_n) - S^\circ(M) \quad [15]$$

The absolute entropies are determined in turn from calorimetric measurements of the heat capacities of the monomer and polymer over a wide temperature range using the expression

$$S^o(T) = \int_0^T \left(\frac{C_p}{T}\right) dT \quad [16]$$

where C_p is the molar heat capacity at constant pressure and T is the absolute temperature.

Quite often ΔH and ΔS are determined at the temperature of the process and then ΔG has to be known at standard conditions, that is, at $T = 298$ K. Thus, the dependence of ΔH and ΔS on temperature should be known:

$$\Delta H_T = \Delta H_{298} + \int_{298}^T \Delta C_p dT \quad [17]$$

and

$$\Delta S_T = \Delta S_{298} + \int_{298}^T (\Delta C_p/T) dT \quad [18]$$

where ΔC_p is the change of heat capacity.

Although it is generally accepted that ΔH and ΔS do not substantially depend on temperature, Berlin *et al.* calculated this dependence for polymerization of gaseous formaldehyde to crystalline polymer.[5] Such a calculation could seldom be found in the polymer monographs and textbooks.

The experimentally determined $\Delta_{gc}H = 70.4$ kJ mol^{-1}. The temperature range for calculations was chosen from 26 to 72 °C. Values of C_p of monomer and polymer in the given states are known, being equal to 43.2 and 34.8 J mol^{-1}, respectively.

Thus, $\Delta C_p = 8.4$ J mol^{-1} K^{-1} and

$$\int_{298}^T \Delta C_p dT \approx \Delta C_p \Delta T \approx 0.2 \text{ kJ mol}^{-1} \quad [19]$$

The average temperature of experiment is equal to 48 °C, that is, correction for $\Delta T = 23$ °C has to be introduced. The measured value is equal to 70.4 kJ mol^{-1} and the correction for the temperature change would only be 0.2 kJ mol^{-1}. Similar comparison of measured and calculated values of ΔS_T (the measured ΔS_T for the same temperature interval) equals −178.9 J mol^{-1} K^{-1} and correction for every 10 K is equal to ~0.24 J mol^{-1} K^{-1}. Therefore, if T_c is calculated or determined

for a certain monomer at a temperature that differs from 298 K it can be compared with T_c of other monomers, taking as an average corrections as calculated above. However, when $|\Delta H|$ and $|\Delta S|$ have low absolute values this correction may have a much larger influence.

When $\Delta_{gg}H$ is known by calculations (gaseous monomer gives hypothetical gaseous polymer), then, to find, for example, $\Delta_{sc}H$, that is, formation of the crystalline polymer from monomer in solution, it is necessary to calculate heat of monomer dissolution (interaction with solvent), dissolution of polymer, and polymer crystallization.

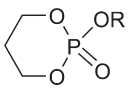
4.02.6 Entropy-Driven Polymerization

Polymerization driven by entropy may only proceed if $|\Delta H| \leq |T\Delta S|$, that is, $|\Delta H| \leq |T(\Delta S^\circ + R \ln[M])|$ (since $\Delta H > 0$). Thus, $\Delta G < 0$.

The best known example is polymerization of sulfur (cyclooctasulfur). Cyclooctasulfur monomer is an eight-membered, crown compound with restricted rotational and vibrational freedom. The eight-membered ring is not strained; however, polymerization is possible, since at high enough temperature (above the floor temperature T_f) the entropic factor ($T(\Delta S^\circ + R \ln[M])$) outweighs the positive or near to zero ΔH value. Entropy of polymerization is positive as polymer units have more freedom (rotational, vibrational) than in S_8 ring, in spite of losing the translational entropy. The sulfur polymerization and its copolymerization with selenium had been used by Tobolsky and Eisenberg[25,26] for detailed analysis of thermodynamics of homopolymerization and of equilibrium copolymerization. These works, together with works of Dainton and Ivin,[12] are the milestones of polymerization thermodynamics.

Later, a general solution of equilibrium copolymerization in living conditions was developed by Szwarc[27] and Szymanski (cf. Chapter 4.04 in this comprehensive).

In the polymerization of the six-membered cyclic esters of phosphoric acid (dioxaphosphorinanes)



it was observed that polymerization is entropy driven (in contrast to the five-membered cyclic triester, cf. Figure 3). These monomers are puckered and vibration as well as rotation is easier in linear chains. These apparently contribute sufficiently to a positive change of entropy of polymerization. The larger the exocyclic group the higher the contribution to a positive change of entropy as it follows from the dependence of ΔH on ΔS° shown in Figure 3.[28,29]

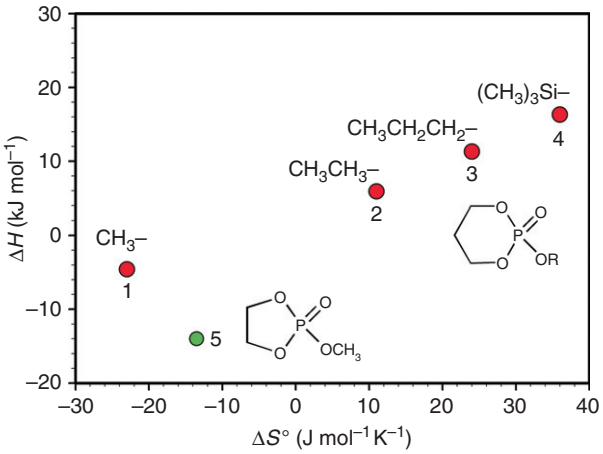


Figure 3 Isoequilibrium dependence for 2-alkoxy-2-oxo-1,3,2-dioxaphosphorinan-2-ones (six-membered) substituted in position 2. Exocyclic substituents are indicated in the figure. Point 5: 2-methoxy-2-oxo-1,3,2-dioxaphospholan-2-one (five-membered) for comparison.[28]

4.02.6.1 Polymerization of Cyclic Oligocarbonates

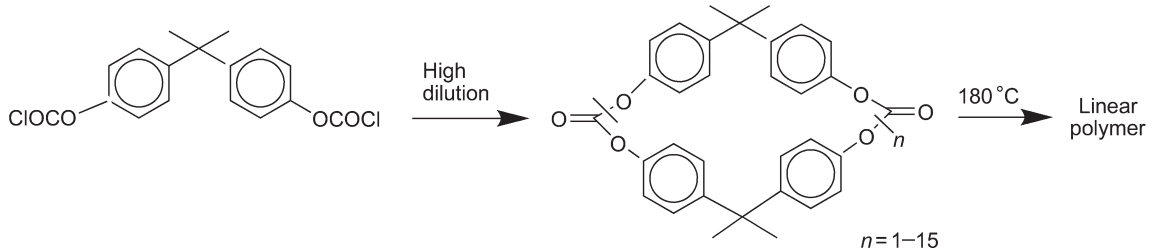
An interesting case of the entropy-driven reaction is the polymerization of cyclic oligocarbonates.[30] The monomer consisting of a mixture of cyclic oligocarbonates is made by the pseudo-high dilution method (Scheme 1). Bisphenol A bis (chloroformate) was added slowly to a mixture of $(C_2H_5)_3N$, aqueous NaOH, and CH_2Cl_2. The selectivity for cyclics versus linear oligomers was 10 000:1.0.

On polymerization by ring opening at 180 °C a linear polymer is formed containing less than 1% of cyclic oligomers at equilibrium. The actual entropy change depends on the value of n and on the dilution, but at the used conditions $T\Delta S$ is much greater than $-\Delta H$, which is close to zero.

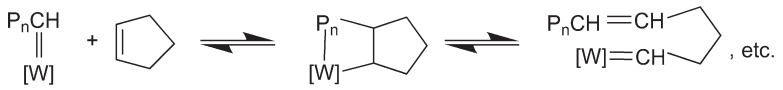
4.02.6.2 Ring-Opening Metathesis Polymerization

Besides the heterocyclic monomers, mostly discussed in this chapter, this volume is also devoted to the ring-opening metathesis polymerization (ROMP). This polymerization is initiated and propagated by metal carbene complexes and metallacyclobutane complexes as shown in Scheme 2.

This reaction is reversible and back reactions can lead to cyclic oligomers as well as the starting monomer. The



Scheme 1 Formation of cyclic oligocarbonates by the pseudo-high dilution method.



(P_n is a polymer chain, W stands for wolfram)

Scheme 2 Ring-opening metathesis polymerization of cyclopentene.

Table 4 Polymerizability of substituted cyclopentenes[31,32]

High conversion:	
Some conversion:	No conversion:	
polymerizability of some substituted five-membered cycloalkenes is illustrated in Table 4 taken *in extenso* from Reference 7.

For norbornene and its derivatives, as indicated by Ivin,[7] the opening of the bicyclic structures results in a considerable release of ring strain when double bond is cleaved during polymerization and monomers polymerize to high conversion. The metathesis reaction of the double bonds in the initial monomers is much less thermodynamically favorable but finally could lead to cross-linked polymers (Scheme 3).[7]

4.02.7 Nonideal (Real) Systems

When the conversion of a monomer into a polymer unit is measured in bulk or at high $[M]_0$, the monomer–polymer interaction cannot be neglected. The same is true when the measurements are made in a solvent interacting differently with the monomer and polymer. Under these conditions, the corresponding interactions have to be taken into account. If the molar mass of the polymer is high enough, the following semiempirical equation can be used to determine ΔG:

$$\Delta G = RT[\ln\Phi_1 + 1 + \chi(\Phi_1 - \Phi_2)] \qquad [20]$$

where Φ_1 and Φ_2 are the volume fractions of the monomer and polymer, respectively, and χ is the polymer–monomer interaction parameter according to the Flory–Fox theory. At these conditions either $\Delta_{lc}G$ or $\Delta_{ss}G$ is determined.[33]

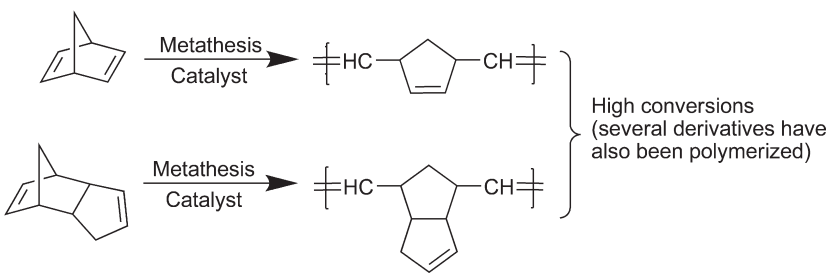
The relationship between these two functions is as follows: $\Delta_{lc}G = \Delta_{ss}G + \Delta_1G - \Delta_2G$, where Δ_1G and Δ_2G are the related Gibbs energies of dissolution of the monomer and polymer in the given solution. In an inert solvent $\Delta_1G \approx \Delta_2G$ and then $\Delta_{lc}G \approx \Delta_{ss}G$, indicated above simply as ΔG.

4.02.7.1 Influence of Initial Monomer Concentration

It was observed in the polymerization of THF in benzene solvent that the equilibrium monomer concentration $[THF]_e$ depends linearly on $[THF]_0$. A method was elaborated to determine $\Delta_{lc}H$ and $\Delta_{lc}S°$ from the experimental data for such nonideal thermodynamics.

It has also been observed that the extent of dependence of $[THF]_e$ on $[THF]_0$ is a function of the acidity of the solvent used.[34] This is shown in Figure 4 (Reference 1), where $[THF]_e$ is plotted as a function of $[THF]_0$ for CCl_4, C_6H_6, CH_2Cl_2, and CH_3NO_2 solvents. Some of these solvents interact with THF, making its polymerization more difficult. This is because THF is a stronger base than its open-chain counterpart and, thus, interaction with polymer units is relatively weaker. These dependences can be envisaged: THF behaves as if its actual instantaneous concentration available for polymerization were lowered by a fraction of complexed monomer, provided that the complexed monomer propagates less rapidly and requires preliminary desolvation. Indeed, the heat of mixing of THF with CCl_4 is only $-2.9\ kJ\ mol^{-1}$, whereas the heat of mixing of THF with CH_2Cl_2 is $-5.0\ kJ\ mol^{-1}$.

1,3-Dioxolane (DXL) is much less basic than THF and, besides, in contrast to THF, DXL is slightly less basic than its polymer, although the difference is not as great as in the THF/polyTHF system. It follows that the dependence of its equilibrium



Scheme 3 Ring-opening metathesis polymerization of the bicyclic monomers (norbornene and its derivatives).

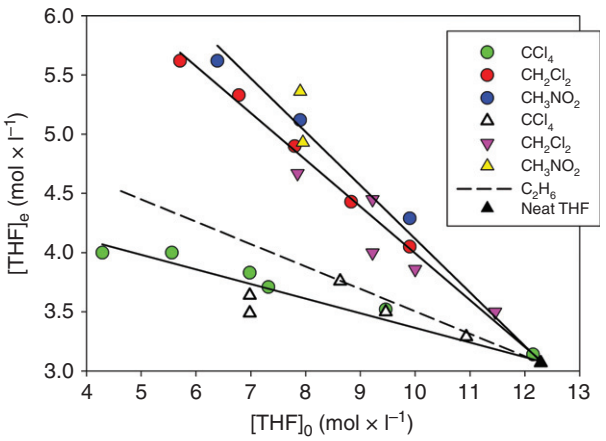


Figure 4 Dependence of the equilibrium monomer concentration $[THF]_e$ on initial monomer concentration $[THF]_0$ at 25 °C; ●, NMR; ▲, gravimetrically. Solvent: CCl_4, C_6H_6, CH_2Cl_2, CH_3NO_2 (References 1 and 34).

concentration $[DXL]_e$ on $[DXL]_0$ and solvent acidity is much smaller than in the polymerization of THF.[35] In the monograph published in 2008 this system is analyzed in great details on the basis of the series of papers published earlier mostly by Berlin *et al.* (cited in the monograph).[36] This is the most comprehensive coverage of the monomer–solvent–polymer system in the ROP (like α-methylstyrene analyzed by Szwarc in the anionic vinyl polymerization).[37] According to these studies the equilibrium monomer concentration $[M]_e$ is practically a linear function of $[M]_0$ (i.e., like for THF as above), although this dependence, at least for CH_2Cl_2 solvent, is indeed much less pronounced than for THF. The dependence of $\ln[M]_e$ on $1/T$ in this series of works agrees well with the earlier data of Plesch[35] and leads to $\Delta_{lc}H = -23.0$ kJ mol^{-1} and $\Delta_{lc}S^\circ = -62.9$ J K mol^{-1}.

Knowledge of the dependence of $[M]_e$ on $[M]_0$ is of primary importance in the studies of kinetics of polymerization. The use of a wrong value of $[M]_e$ may lead to erroneous values of k_p, especially when polymerization is studied starting from $[M]_0$ close to $[M]_e$. Therefore, the studies of equilibrium polymerization, when $[M]_e$ is relatively high, require determination of $[M]_e$ for every run.

4.02.8 Influence of Degree of Polymerization

The equilibrium monomer concentration $[M]_e$ depends on P_n for shorter chains because, in the neighborhood of the end groups, the thermodynamic potentials of the polymer units are different from those in the middle of the chain.

These relationships, described by Tobolsky and Eisenberg,[25] have been confirmed experimentally for THF polymerization by Fukuda and Hirota.[38]

For low polymerization degrees,

$$P_n = \frac{\sum_{n=1}^{\infty} n[P_n^*]_e}{\sum_{n=1}^{\infty}[P_n^*]_e} = \frac{\sum_{n=1}^{\infty} nK_1K_p^{n-1}[I]_e([M]_e)^n}{\sum_{n=1}^{\infty} K_1K_p^{n-1}[I]_e([M]_e)^n} = \frac{1}{1 - K_p[M]_e} \quad [21]$$

(when $K_1 = K_p$, where K_p is an equilibrium constant at any polymerization degree). Fukuda studied the polymerization of THF at high dilution. At these conditions it was observed that $[M]_e$ 'increased' with increasing $[M]_0$ which was contrary to the dependence shown above in Figure 4, when the interaction of the monomer and polymer with solvent has to be taken into account.

This observation is described for the sake of completeness of information, although it is of minor importance, since for $P_n = 10$, K_p differs from $1/[M]_e$ only by 10% and usually $[M]_e$ is determined for much higher P_n. This is true, however, only when the equilibrium constant K is the same for all the propagation/depropagation steps, including the first one, namely, the reaction of initiator with the monomer.

When the equilibrium constants are not the same, they can be determined by Szwarc's treatment, based on the reduction of the number of steps.[39] Heitz *et al.*[40] have studied the cationic oligomerization of THF and established that only the first equilibrium constant K_0 differs from K_n, that is, the equilibrium constant for every next step. Thus, $K_0 = 1.7$ l mol^{-1} and $K_n = 0.25$ l mol^{-1}. This study has been made possible by using high-resolution HPLC, allowing measurements of the concentrations of all of the chains involved. It is also based on the assumption that the distribution of the growing chains is the same as that of the dead macromolecules.

4.02.9 Influence of Phase Separation

When a liquid monomer in solution is converted into an insoluble polymer, the following possibilities arise: (1) solid amorphous polymer precipitates out of the saturated solution; (2) solid crystalline polymer precipitates from the saturated solution; and (3) polymerization proceeds in the crystalline state and the monomer is supplied from solution.

Only polymerization proceeding in the crystalline state differs thermodynamically from the polymerization of the same monomer in homogeneous solution. In the first two instances, the growing species may still remain in solution and $[M]_e$ would be the same for both homogeneous and apparently heterogeneous systems. However, this does not mean that the polymer yield would be the same. Although $[M]_e$ remains the same, in the precipitating system the total volume of the liquid polymer–monomer mixture becomes smaller, so the amount of monomer at equilibrium is smaller anyway when the polymer precipitates.

The change in the Gibbs energy of the polymerization proceeding in the crystalline state differs from that taking place in the homogeneous solution by the heat of crystallization. Therefore, we have

$$[M]_{e,s}/[M]_{e,ss} = \exp\Delta G_{cryst}/RT \quad [22]$$

It follows from this equation that the $[M]_e$ observed in the homogeneous polymerization may be greatly reduced by performing polymerization under conditions when the propagation step proceeds at the crystalline sites of a solid polymer.

Cationic polymerization of 1,3,5-trioxane (TXN) takes place in the crystalline state. The hypothetical equilibrium monomer concentration calculated for the homogeneous polymerization is $[TXN]_e = 2.5$ mol l^{-1} (CH_2Cl_2, 20 °C),[41] whereas $[TXN]_e$ for the polymerization from the dissolved monomer directly to the crystalline polymer is 0.11 mol l^{-1} (at 25 °C). Thus, if one starts from a 30% solution of TXN (~3.3 mol l^{-1}), then, in the homogeneous solution, 72% of the monomer would be

left at equilibrium, whereas the real polymerization, proceeding in the crystalline state, leaves only ~3% of the unreacted monomer.

The only ROP process in industry, using conversion of a liquid monomer into an insoluble, crystalline polymer, is cationic polymerization of TXN. Although in this process no solvent is used, there was also elaborated polymerization of TXN in cyclohexane solvent with the formation of insoluble, crystalline polymer. Therefore, it was of interest to compare the dependence of $[M]_e$ on the solvent properties. Some data[5] (formula of solvent and $[TXN]_e$ in $mol\,l^{-1}$) follow in this order (for 20–30 °C): $C_6H_5NO_2$: 0.14; CH_2Cl_2 : 0.11; C_7H_{16} : 0.03. From the thermodynamic viewpoint the higher the difference between the polarity (dielectric permittivity was taken as a measure) of solvent and monomer the higher then the chemical potential of the system.

Summarizing the thermodynamic polymerizability, some data of ΔH ($kJ\,mol^{-1}$) and $\Delta S°$ ($J\,K^{-1}\,mol^{-1}$) for cyclic monomers are given below, according to Ref. 42 and from the more recent compilation by Duda and Kowalski, giving ΔH and $\Delta S°$ as well as $[M]_e$ at 25 °C.[16]

Ceiling temperatures (T_c) can be calculated from the corresponding values of ΔH and $\Delta S°$ from Table 5.

4.02.10 Final Remarks on the Thermodynamic Polymerizability

It might look like a paradox that in this part of the chapter the thermodynamic polymerizability has mostly been determined by the critical temperature of the given monomer (the best is T_c (bulk)) or the change of enthalpy and entropy as measured in polymerization. This could indicate that the information on the range of polymerizability requires preformation of the polymerization itself. It is true in the sense that in this way the structure and polymerizability of monomers could be correlated, which then allow the prediction of the polymerizability of a novel monomer taken for polymerization. However, in such an instance the thermochemical measurements (calorimetry) may also be of help and a certain model of the not yet existing polymer could be taken as a standard. Then, if the thermodynamic polymerizability is established, the proper mechanism (initiator/catalysts) has to be chosen.

4.02.11 Kinetic Polymerizability

Thermodynamic polymerizability is of major importance. If a monomer to be studied had (for $\Delta H < 0$) a very low T_c(bulk), as determined thermochemically or calculated, then its polymerization is hopeless. If it looks thermodynamically polymerizable then it could be expected that the mechanism would be found for successful polymerization. The accumulated experience allows to reasonably choose the corresponding conditions of polymerization.

A large majority of cyclic monomers polymerize by one of the ionic or coordination (so-called pseudoionic) mechanisms. Moreover, kinetic polymerizability and the difference in the rates of polymerization depend on the used conditions and may vary dramatically. In CROP there is no difference between the reactivities of ions and ion pairs, but in anionic polymerization (e.g., of ethylene oxide) ions are much more reactive than ion pairs. In a solvent (e.g., in 1,4-dioxane, poorly solvating ions) there may occur no polymerization, whereas in, for example, hexamethylphosphorotriamide (HMPTA) (highly solvating, helping dissociation) there could occur a fast polymerization. Cyclic esters, for example, ε-caprolactone (CL) or lactides, polymerize by cationic, anionic, and coordination polymerizations. For the same conditions (monomer concentration, active species concentration, and solvent) the difference between the rates of propagation can be 1000-fold.

In the propagation step some active species could reversibly be converted into the inactive species, like, for instance, in the polymerization of lactides initiated by aluminum alkoxides, when unimers propagate and their aggregates do not. For all these reasons there is no simple way to compare kinetic reactivities of various monomers and construct the table comparing kinetic reactivities – in contrast to the thermodynamic reactivities, when some of the thermodynamic potentials give an absolute measure and could be correlated with monomer structure (ring size, heteroatoms present, substituents). The thermodynamic activation parameters of the rate constants of propagation, namely $\Delta^{\neq}G$, $\Delta^{\neq}H$, and $\Delta^{\neq}S$, also have different values, depending on the structure of the active species (i.e., initiator/catalyst used). Therefore, these parameters can reasonably be compared only for a given monomer and various active species or for a given active species (e.g., anionic pair with a defined cation) for various monomers. This kind of experimental data is almost nonexistent. Besides, some authors determine the dependence of the rate of polymerization (not propagation!) on the reciprocal of the absolute temperature and are erroneously calling the temperature coefficient determined in this way merely temperature coefficient – as activation parameters. For CROP there was an attempt to correlate rate constants of propagation with basicities of different heterocyclic monomers. This dependence taken from Reference 43 is tabulated in Table 6.

Thus, the data above indicate that the highest rate constant is observed for the monomer of lowest basicity. This 'correlation' is rather rough but, indeed, more basic monomers are slower, even if the bridged four-membered ring is compared with the five-membered THF.

The proper correlation analyses of the reactivities of given species (i.e., monomers or active centers) requires comparing additions of various monomers to the same active species as well as the addition of the same monomer to different active species.

The methyloxonium cation derived from THF was used as a model of cationic active centers and triflic ester as a model of the covalent ones (Scheme 4).[43]

The values of the corresponding rate constants determined in this way are given in Table 7. In this series higher rate constants were observed for monomers of higher basicity.

These data indicate that the rate constants for reactions of various monomers and model active species, both ionic and covalent, are the function of monomer basicity.

In order to correlate the reactivities of various onium ions (active species) within their structures, the reaction of ions, modeling different active species, and the highly nucleophilic monomer conidine was studied. The corresponding rate constants are given in Table 8.

Table 5 Summary of thermodynamic polymerizability: ΔH and $\Delta S°$ data for the most often polymerized cyclic monomers

No	*Monomer*	*Conditions*	*ΔH*	*ΔS°*	*Method*
1	 Ethylene oxide	gl	–140	–174	Semiempirical calculation
2	 3,3-Bis(chloromethyl)oxetane	lc	–84.5	nd	Experimentally measured heats of polymerization
3	 β-Propiolactone	lc	–80.5	nd	Experimentally determined heats of formation
4	 Pivalolactone	lc	–92.0	nd	As above
5	 Tetrahydrofuran	lc	–12.5	–41.0	From $[M]_e = f(l/T_e)$
6	 1,3-Dioxolane	ss	–21.3	–77.8	As above
7	 γ-Butyrolactone (butano-4-lactone)	lc	5.1	–29.9	Thermochemical
8	 ε-Caprolactone (hexano-6-lactone)	lc′	–28.8	–53.9	From $[M]_e = f(l/T_e)$
9	 1,3,5-Trioxane	lc′	–28	nd	From heats of formation
10	 Hexano-6-lactam	lc	–12.5	+5.4	As above
11	 Ethylenemethylphosphate	ss	–14.0	–13.5	From $[M]_e = f(l/T_e)$
12	 Trimethylene-*H*-phosphonate	ssls	5.4 – 0.64	7.1 – 5.8	As above
13	Sulfur	ls	13.2	19.4	

In this series a reverse order of reactivities is observed: active species from more basic monomers are less reactive. Thus the observed order of reactivities in homopropagation is parallel to the order of reactivities in the reaction of standard monomer with different active species and reverse to that observed in the reaction of different monomers with standard active species.

Table 6 Rate constants of propagation and basicities of different heterocyclics

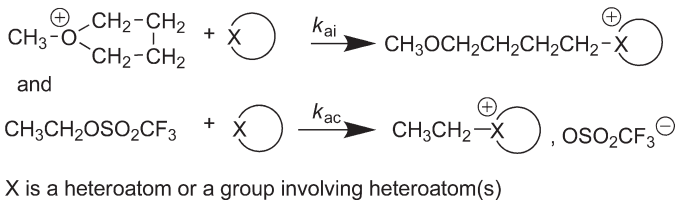
Monomer					k_p ($mol^{-1}\,l\,s^{-1}$)	$\sim 10^4$	4×10^{-2}	$\sim 10^{-8}$	5×10^{-5}	7×10^{-3}
pK_a	−6.5	−2.0	1.2	3.4	11



X is a heteroatom or a group involving heteroatom(s)

Scheme 4 Models of cationic and covalent active centers: methyloxonium cation of THF and triflic ester, respectively.

Table 7 Rate constants for the addition of heterocyclic monomers to the model active species ($C_6H_5NO_2$, 35 °C), shown in **Scheme 4**[43]

Monomer	*(Ionic)* k_{ai} *($mol^{-1}\,l\,s^{-1}$)*	(Covalent) k_{ac} *($mol^{-1}\,l\,s^{-1}$)*	*pK_a*
	4.5×10^{-3}	4×10^{-5}	−7.3
	10^{-4}	6×10^{-5}	−6.5
	4×10^{-2}	2×10^{-4}	−2.0
	20	4.4×10^{-2}	1.2
	120	4×10^{-1}	3.4
	500	170	11

Table 8 Rate constants of addition of conidine to various onium ions, differing in heteroatoms ($C_6H_5NO_2$, 35 °C)[43]

Active center	k_{add} *($mol^{-1}\,l\,s^{-1}$)*
	5×10^2
	1×10^{-3}
	9×10^{-2}
	7×10^{-3}

This is a clear demonstration that in passing from the ground state to the transition state the bond-breaking is more advanced than the bond-making.

With a further shift in the direction of still more advanced breaking of the bond within active species this borderline S_N2 mechanism could eventually convert into the S_N1 mechanism. This should be promoted by the presence of a stabilizing group located close to the carbenium ion (like in the polymerization of cyclic acetals) and/or high ring strain (like in the three-membered rings). Indeed, contribution of the S_N1 mechanism in both cases has been postulated for polymerization of 1,3-dioxolane and isobutylene oxide (2,2-dimethyloxirane) but there is still no clear-cut evidence for its operation. This is probably the reason for high kinetic polymerizability of these monomers.

Cationic polymerization of heterocyclic monomers can proceed not only by the S_N2 mechanism involving onium ions located at the chain end, and analyzed in this chapter, but also by another S_N2 mechanism involving an activated monomer, adding to the neutral chain ends.

4.02.12 Kinetic Polymerizability versus Macroions and Macroion Pairs in Propagation

Kinetic polymerizability depends on the actual conditions of polymerization, having no influence on thermodynamic polymerizability. There are a few systems for which equilibrium constants of dissociation (K_D) were determined in order to establish the proportions of macroion pairs and macroions. Then, the rate constants of propagation for these species were determined and in this way the kinetic reactivity of various forms of active species could be compared. In the cationic polymerization of THF, oxepane (OXP), and more recently conidine, it has been shown that $k_p^{\pm} = k_p^{+}$.[44] This was explained by assuming weak interactions of counterions within the ion

Table 9 Rate constants of propagation in anionic polymerization of heterocyclic compounds

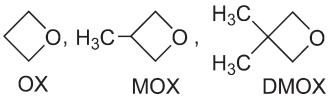
Monomer polymerization conditions	*Active species*	$k_p^{\pm}$ *(mol^{-1} l s^{-1})*	k_p^{-} *(mol^{-1} l s^{-1})*	*Reference*
 THF, 20 °C	…–$CH_2CH_2O^-K^+$	4.8×10^{-2}	–	45
	…–$CH_2CH_2O^-Cs^+$	1.22×10^{-1}	–	45
	…–$CH_2CH_2O^-K^+$[2.2.2]-cryptand	2.5×10^{-2}	1.67	45
 THF, –30 °C	…–$CH_2CH(CH_3)S^-Na^+$	2.5×10^{-3}	3.8	45
	…–$CH_2CH(CH_3)S^-Cs^+$	2.3×10^{-1}	–	45
 Benzene, 20 °C	…–$Si(CH_3)_2O^-Li^+$[2.1.1]-cryptand	1.4	–	45
 CH_2Cl_2, 25 °C	…–$CH_2CH_2COO^-K^+$DB-18-C6	7.0×10^{-4}	1.6×10^{-1}	46
 THF, 20 °C	…–$C(O)(CH_2)_5O^-K^+$	4.7	–	47

pairs, due to delocalization of the positive charge in the components of onium ions, as well as by the stereochemical course of the propagation step, in which the approaching monomer hardly requires the pulling apart from the anion.

In the anionic polymerization there are three monomers only that have been studied in more detail, namely ethylene oxide, propylene oxide (methyloxirane), and β-propiolactone (propano-3-lactone). In the anionic active species, like alcoholate anions, the negative charge (in contrast to onium cations) is localized almost exclusively on one atom. Therefore, dissociation constants are much lower and the differences in reactivity of ions and ion pairs are much more pronounced (**Table 9**).

Comparison of kinetic reactivities of the monomers provides interesting observations. Oxirane (EO) is more strained than CL, but $k_p^{\pm}$ for the … $-O^-,K^+$ ion pairs is ~100 times higher for CL than EO. Presumably, this is because the higher ring strain of EO, in comparison with that of CL, outweighs the higher reactivity of the ester linkage (lower bond energy).

The kinetic polymerizability of monomers belonging to the same class of compounds and studied at similar conditions could be compared using thermodynamic activation parameters. Actually, these parameters are determined from the dependence of the rate constants of elementary reactions (ln k_p) on $1/T$; in several instances comparison of k_p could be sufficient. Comparison of $\Delta^{\neq}H$ and $\Delta^{\neq}S$ is more subtle since it provides information on the genuine source of differences in k_p and therefore on kinetic polymerizabilities. A good example of such a comparison for CROP of oxetane, 3-methyloxetane, and 3,3-dimethyloxetane is given in a classical work by Saegusa and Kobayashi.[48]



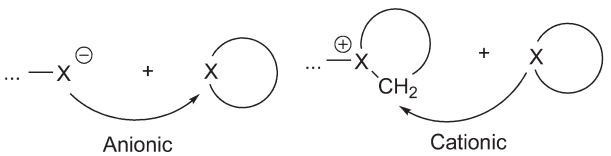
In this work rate constants were determined from the slope of the linear dependence of $\ln([M]_{t1}/[M]_{t2})$ on

$$\int_{t_1}^{t_2}[P^+]dt \qquad [23]$$

and the change in $[P^+]$ was determined by ion trapping. Then, the dependence of ln k_p on $1/T$ provides the thermodynamic parameters of activation. These are given in the following order: monomer, k_p (at –20 °C; in mol^{-1} l s^{-1}), $\Delta^{\neq}H$ (in kJ mol^{-1}), and $\Delta^{\neq}S$ (in J mol^{-1} K^{-1}): OX: 0.18, 44.8 and similarly, –77.9; MOX: 0.92, 47.3, –61.1; DMOX: 3.4, 50.7, –35.6.

Thus cationic polymerizability could only be related to the entropy of activation as described in this chapter for cyclic esters of phosphoric acid. Most probably substituents and the related polymer linear units are getting enhanced statistical probability of states in the transition state. One could expect dependence on basicity, but the known basicities are almost the same and do not change monotonically (given in ΔD_γ (m^{-1})): OX: 103; MOX: 106; DMOX: 99.[48] Thus, like in polymerization of cyclic esters of phosphoric acid, where the thermodynamic reactivity is governed by entropy change, this is the kinetic reactivity depending on the change of entropy of activation.

Summarizing the kinetic ring-opening polymerizability/reactivity it should be stressed that there are a larger number of monomers polymerizing cationically than anionically. This can be understood when the cationic and anionic propagation steps are compared:



Thus, in the cationic process the (usually) strained onium ion is attacked, whereas in the anionic polymerization the neutral cyclic species is attacked, which is less prone to ring opening. There are a few monomers that are able to polymerize exclusively by cationic mechanism (cyclic amines, phosphazenes) and all monomers polymerizing anionically are also able to polymerize cationically (**Table 10**).

Table 10 Monomers, catalysts, and polymerizability in ROP (taken in part with some modifications) from Reference 49

Class	*Ring structure*	*Ring size*[a]	*Catalyst type*[b]*/mechanism*
Olefin		4, 5, 8	ROMP
Ether		3, 4, 5, 7	Anionic, cationic (including activated monomer)
Thioether		3, 4	Anionic, cationic
Amine		3, 4, 7	Cationic
Lactone		4, 6, 7, 8	Anionic, cationic, coordinate
Thiolactone		4–8	Anionic, cationic
Lactam		4–8 and higher	Anionic, cationic (including activated monomer)
Disulfide		4–8 and higher	Radical
Anhydride		5, 7, 8, and higher	Anionic, cationic
Carbonate		6, 7, 8, 20, and higher	Anionic, cationic, coordinate
Formal		5, 7, 8, and higher	Cationic
Siloxane		6, 8, 10, and higher	Anionic, cationic
Phosphazene		6	Cationic
Oxazole		5	Cationic
Phosphonite		3, 5, 6, 7	Cationic
Dioxaphosphorinanes(cyclic phosphates)		5, 6	Anionic, cationic, coordination

[a]Ring sizes affording high molar mass polymers.
[b]Covalent nucleophilic mechanisms may include alkylating agents (e.g., benzyl chloride) and organometallics (e.g., R_3-Sn-X).

4.02.13 Outlook

Major principles governing thermodynamic and kinetic polymerizabilities in ROP/ROMP are already established. Angular strain, transannular interactions leading to strain, translational, vibrational, and rotational entropies in polymerization, as well as other factors were described in the past for several systems in polymer monographs and handbooks. Principal definitions of thermodynamic parameters and ceiling (and floor) temperatures have been formulated by IUPAC. Nevertheless, the general theory in the form of the algorithm encompassing constitutive elements of monomer structures and polymerizabilities does not exist since the data are scattered and not sufficient. On the other hand, all new monomers are polymerized and thermodynamic equilibrium data as well as thermodynamic activation parameters are being determined for those novel systems.

Biographical Sketches

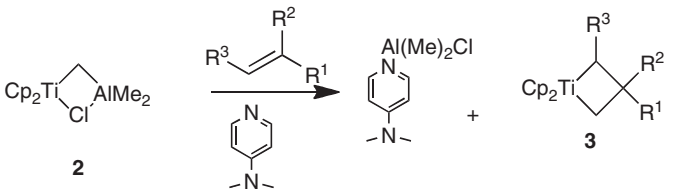
Stanislaw Penczek is professor of polymer chemistry at the Polish Academy of Science (Centre of Molecular and Macromolecular Studies in Lodz) and teaches at the Graduate School of the Jagiellonian University (Krakow) as honorary professor. He mostly contributed to the kinetics, thermodynamics, and mechanisms of the ROP, publishing over 300 papers in the related areas. He was a member of the first group to observe living and controlled polymerizations in cationic and anionic ROP, including reversibility of deactivation of propagating species. Among other honors from Belgium, Japan, and Germany (the Warburg Prize), he is a member of the Polish Academy of Science and a foreign member of the German (Nordrhein) Academy, dr *h.c.* of the P. M. Curie University in Paris and dr *h.c.* of the Russian Academy of Science. He was a member of the IUPAC Bureau for two terms, and a former president of European Polymer Federation.

Krzysztof Kaluzynski is currently working in the Center of Molecular and Macromolecular Studies of Polish Academy of Sciences, Lodz, Poland. He received his MS (1969) from the Technical University in Lodz and PhD (1988) from the Center of Molecular and Macromolecular Studies under the supervision of professor Stanislaw Penczek. In 1989–1990 he worked with professor Hisaya Sato in the Graduate School of Bio-Applications and Systems Engineering of Tokyo University of Agriculture and Technology as a scientific researcher. The main research interests of K. Kaluzynski are mechanisms and kinetics of polymerization of cyclic phosphates. He is a co-author of over 50 original papers and reviews and three patents. He has twice received group Awards of Scientific Secretary of Polish Academy of Sciences. Krzysztof Kaluzynski is a longtime co-worker of professor Stanislaw Penczek.

4.03 Living Ring-Opening Olefin Metathesis Polymerization

RH Grubbs, California Institute of Technology, Pasadena, CA, USA

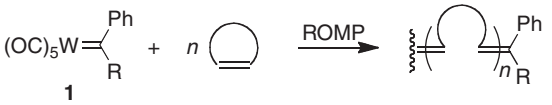
Calderon was the first to find a catalyst system that would initiate both ring-opening polymerization of olefins (subsequently named ROMP by Tim Swager when he was a student at Caltech) and acyclic metathesis of simple olefins.[1] Up until his findings, most catalysts for acyclic metathesis were heterogeneous systems, and metal salts were used to polymerize strained olefins such as norbornenes.[2] Beautiful work was carried out using the poorly defined systems to work out the stereochemistry and mechanism of metathesis. This beautiful work provides an excellent backdrop for the work described here.[3] This section will focus on the use of well-defined complexes as initiators for the living polymerization of cyclic olefins.



Although metathesis polymerization was well known from previous work using ill-defined catalysts, it was only with the introduction of single component catalysts that well-defined polymerizations using ring-opening metathesis polymerization (ROMP) became possible.

As with any living system, an initiator is needed which will polymerize without termination or chain transfer.[4] In addition, to obtain well-controlled polymer molecular weight and polydispersity, the initiation and quenching of the growing polymer must be controlled. The mechanism of olefin metathesis provides this potential and with an understanding of the mechanistic steps, each of the three requirements can be regulated.

The first use of a well-defined initiator was by Katz[5] in which he used the Fisher-type carbenes as prepared by Casey and Burkhardt[6] for the polymerization of strained olefins such as norbornene and cyclobutenes.



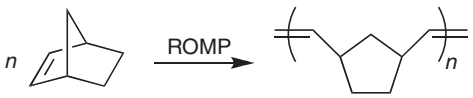
These systems gave poor control of molecular weight, but showed some of the characteristics of a living system such as the ability to prepare blocky polymers and the incorporation of an ill-defined initiator fragment in the resulting polymer.

The work of Fred Tebbe, of Dupont, provided a good starting point for the creation of living ROMP initiators where each of the critical features could be controlled. Tebbe and co-workers[7] demonstrated that the titanocene methylene complex would undergo a metathesis exchange with terminal olefins. This provided one of the earliest examples of a well-defined metal alkylidene complex undergoing a clean exchange with an olefin. The Caltech group demonstrated that a kinetically competent metallacyclobutane could be isolated from this system.[8]

The isolated metallacyclobutane would also undergo exchange with an olefin and provided a model for metathesis and a clean system for systematic mechanistic study.[9] The Tebbe reagent also reacted with carbonyl compounds such as ketones and esters to exchange an oxygen from the organic for the methylene of the complex. This reaction has become an often used transformation for organic synthesis.[10]

 doi:10.1016/B978-0-444-53349-4.00093-5

Since metathesis is a reversible reaction, monomers must be chosen so that the monomer should be more reactive than the double bond in the polymer. If this is not the case, the polymer will compete with the monomer for reaction and will result in a chain transfer reaction. Consequently, norbornenes have been used in most cases, although other less readily available strained monomers such as cyclobutenes, cyclopropenes, and transcyclooctenes have also been used in living ROMP.[11]

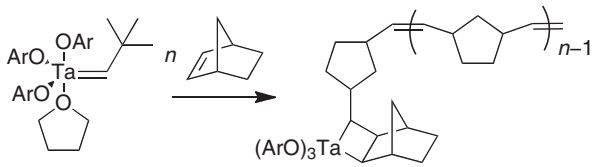


The reaction of the Tebbe reagent with a base and norbornene gave an isolated metallacycle.[12] When the isolated metallacycle was heated with monomer, polymerization initiated at 60 °C and cooling to room temperature stopped the reaction. The resulting polymer containing the metallacycle end group could be isolated and the polymer could be released from the metal by the addition of acetone that undergoes a Wittig-type reaction to replace the metal with a dimethyl group. These polymers were living – that is, termination was much slower than polymerization, and the resulting polymer was relatively stable with the initiator at the terminus. However, the polydispersity was near 1.5.

The titanium initiators were used to demonstrate many of the features of living systems such as the formation of block systems[13] and the ability to use the chain end to initiate other polymerization reactions.

An amusing application of this system was the use of the alkylidene to produce a living polymer that was converted to a system with the polymer attached to the metal through a single bond. This complex could be used to initiate polymerization of ethylene to generate a block[polynorbornene-polyethylene].[14]

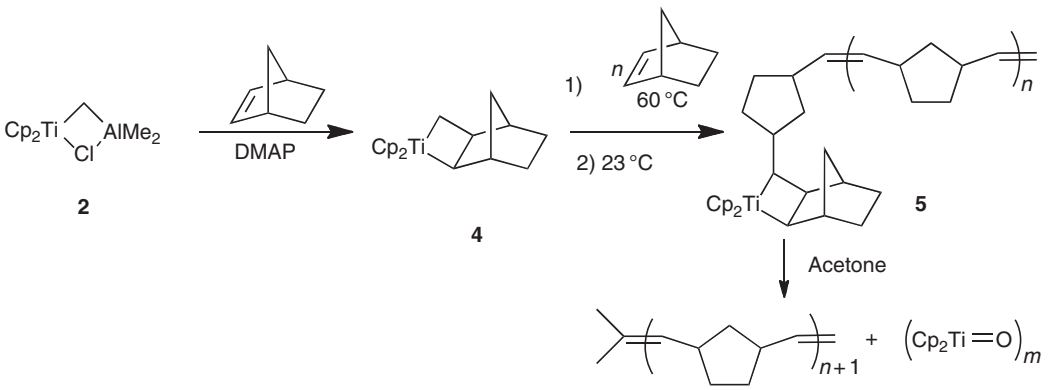
Later the Schrock group[15] demonstrated that Ta complex **7** showed similar reactivity to the titanium system.



7, Ar = 2,6-diisopropylbenzene

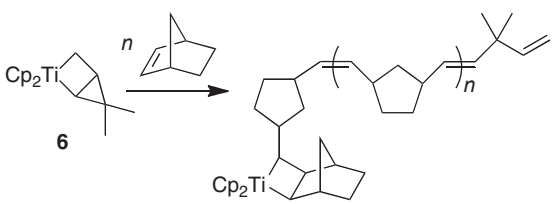
The thermal and functional group sensitivity of these complexes limited their application in functional polymer synthesis

As better initiators became available,[16] there was little further research utilizing these very early Ti and Ta complex initiators. However, these early studies provided the foundation for living ROMP. With the titanium systems, it was demonstrated that:



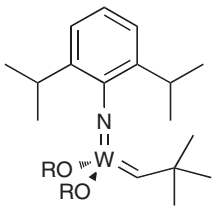
1. Well-defined initiators resulted in a general living metathesis polymerization system with strained olefin (a limited number were known at the time). Stable initiators produced stable propagating species.
2. Control of initiator structure was required to obtain low polydispersity indices (PDIs). Standard organometallic principles could be used to balance the rates of initiation and termination.
3. The 'Wittig'-like activity of these systems provided a clean termination process.

The final feature needed was an increase in the initiation rate. The starting metallacycle is a disubstituted metallacycle, while the propagating metallacycle is trisubstituted. Steric interactions will destablize the trisubstituted metallacycle relative to the disubstituted – that is, propagating species is more reactive than the initiator. To solve this problem, a more reactive initiator was required. It was found that the addition of dimethylcyclopropene to the Tebbe reagent in the presence of a base resulted in the formation of a stable metallacycle. The ring strain of the cyclopropene-derived metallacycle resulted in a very reactive initiator and the polynorbornene resulting from this initiator was near 1.1.

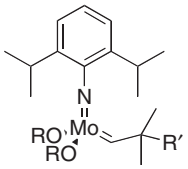


Many new applications were opened with the advent of much more active and stable tungsten and later molybdenum and ruthenium initiators. A number of these applications will be discussed in other sections. In this chapter, we will limit the discussion to those points directly related to the use of these systems in the synthesis of well-defined, low PDI, living polymers.

While Schrock was on sabbatical at Caltech, we initiated a collaboration to examine the living nature of other metathesis active complexes. The highly active tungsten-based metathesis catalysts that were the focus of this study opened the next chapter in living ROMP. The high activity of these systems required the development of additional methods of control. If the catalysts were too active, termination and backbiting reactions destroyed the livingness of the systems. Schrock had found that the activity of these tungsten systems could be controlled by the structure of the alkoxy ligands. The hexafluoro-*t*-butanol complex (**8c**) was much more active than that of the *t*-butoxy complex (**8a**). The less active complex gave lower polydispersities since the more active complex reacted with the polymer in competition with monomer.[17] In addition, the lower activity of the **8a** catalyst resulted in a much better balance in the initiation–propagation rates such that low PDIs of less than 1.1 were produced.



8a, R = *t*Bu
8b, R = $C(CH_3)_2(CF_3)$
8c, R = $C(CH_3)(CF_3)_2$

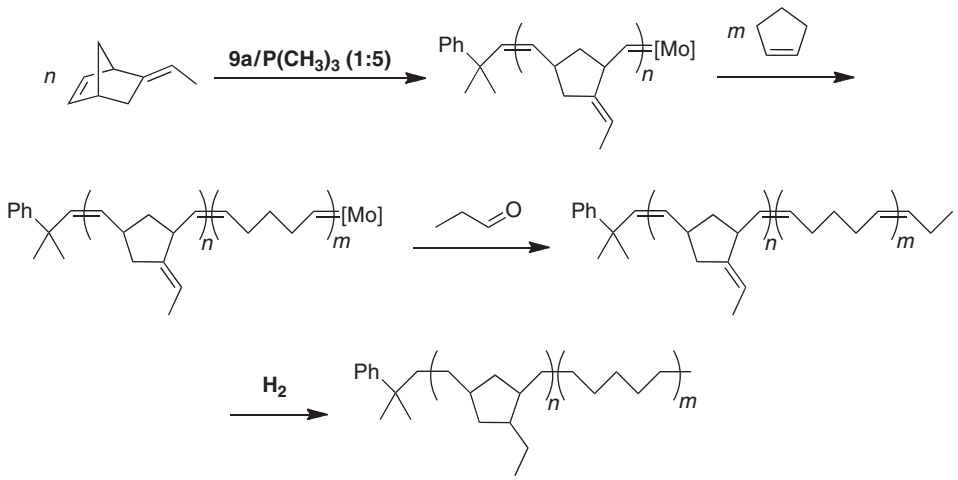


9a,R = *t*Bu
9b,R = $C(CH_3)_2(CF_3)$
9c,R = $C(CH_3)(CF_3)_2$
(R′ = CH_3 or Ph)

By controlling the ligands and additives, these systems opened the way to the synthesis of a wide array of homo and block polymers of well-defined structures. Polymers with PDIs of less than 1.1 that contained a variety of functional groups were routinely prepared using these initiators.

The Mo-based systems are used in a wide variety of applications. However, for the present discussion, the principles developed during these studies were as follows:

1. The activity of the catalyst must be controlled by ligands to prevent backbiting into the growing polymer chains.
2. Systems can be controlled by the addition of reversible inhibitors to control the propagation rate by reversible termination as in ATRP.
3. Highly active, functional group-tolerant initiators can be used to prepare a wide array of functional homo and block polymers with well-controlled structures.[20]

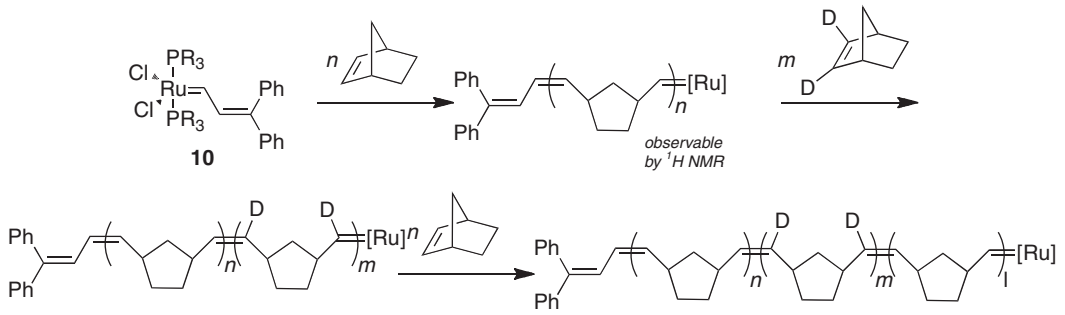


The second method of controlling the polymerization of these systems was the addition of phosphine, an inhibitor, to the system that stabilized the intermediate, decreased the reactivity of the chain end, and resulted in much narrower polydispersity.[18] The additives appeared to operate by the reversible termination principle that is the basis for atom transfer radical polymerization (ATRP). As was the case with the Tebbe systems, the tungsten alkylidenes reacted cleanly with aldehydes or ketones. Consequently, the living systems could be terminated by the addition of an aldehyde or ketone.

A related series of Mo-based complexes were more controlled and functional group tolerant than were the corresponding W-based systems. In a similar way, the structure of the alkoxide ligand controlled the catalyst activity.[19]

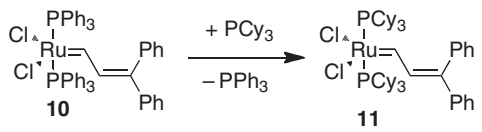
Based on work with aqueous ruthenium-based metathesis systems, stable, active, and well-defined ruthenium metathesis catalysts were developed. As will be demonstrated, the early promise of broadly functional group-tolerant and water-tolerant initiators based on ruthenium have been realized. The first complex, **10**, was not particularly reactive, but would polymerize norbornene and its derivatives. These complexes were much more stable to functional groups, water, and oxygen than prior systems. It was demonstrated that these systems would give a living polymer with norbornene and could be used to form block polymers.[21]

The usual quenching conditions that had been developed for earlier metal-based ROMP systems, the addition of an aldehyde, ketone, or acid, did not provide a clean cleavage of the metal from



the polymer chain with the Ru initiators. It was found that the addition of a vinyl ether cleaved the chain and produced a 'Fisher' carbene that is less reactive than the initiating complex. Polymers with PDI of less than 1.2 could be obtained with these systems.

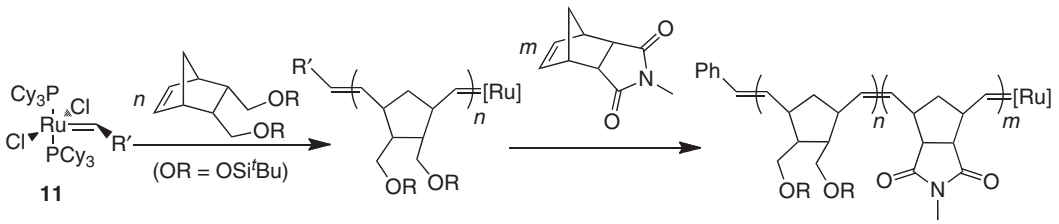
In contrast to the Mo and W systems, where electron-withdrawing groups increased the activity of the catalysts, it was found in the ruthenium systems that addition of the more electron-rich tricyclohexylphosphine to the original triphenylphosphine complexes resulted in the formation of a much more reactive complex.[22]

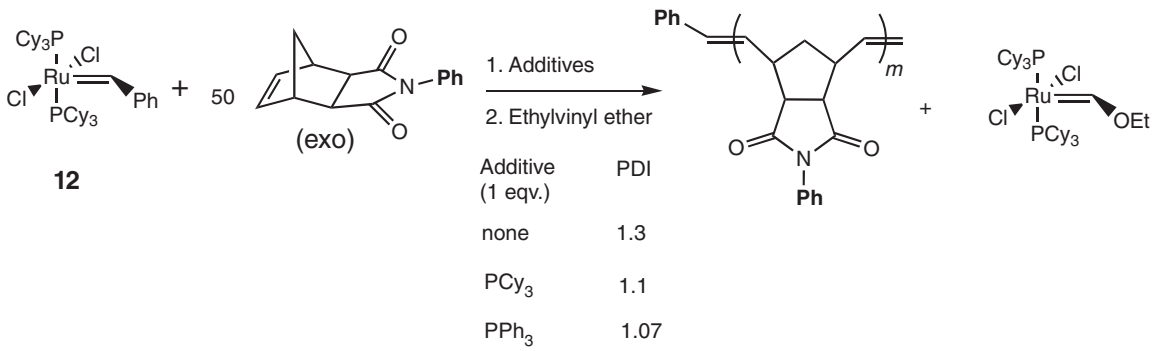


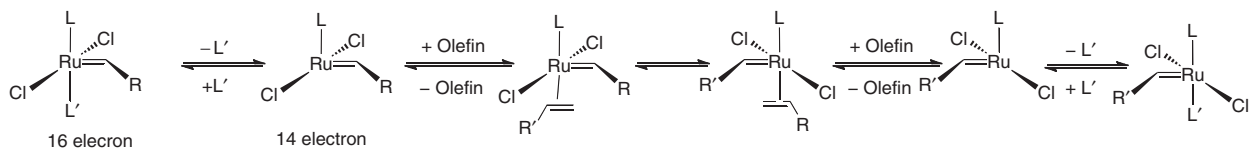
The complex **11** gave low polydispersity polymers, below 1.2, but additives were required to obtain narrow dispersity blocks and homopolymers.[23] As had been demonstrated with the Mo and W systems, a reversible inhibitor could be used to control the system.

The added excess phosphine slows the rate of polymerization. Addition of more than one equivalent gives good control of the PDI without completely shutting down the reaction. To understand the effect of added phosphine and to guide further changes in ligands, the mechanism of the activity of these systems in general metathesis reactions was examined.

The rate of reaction in most cases appears to be controlled by the loss of one of the neutral ligands to produce the active 14-electron species.







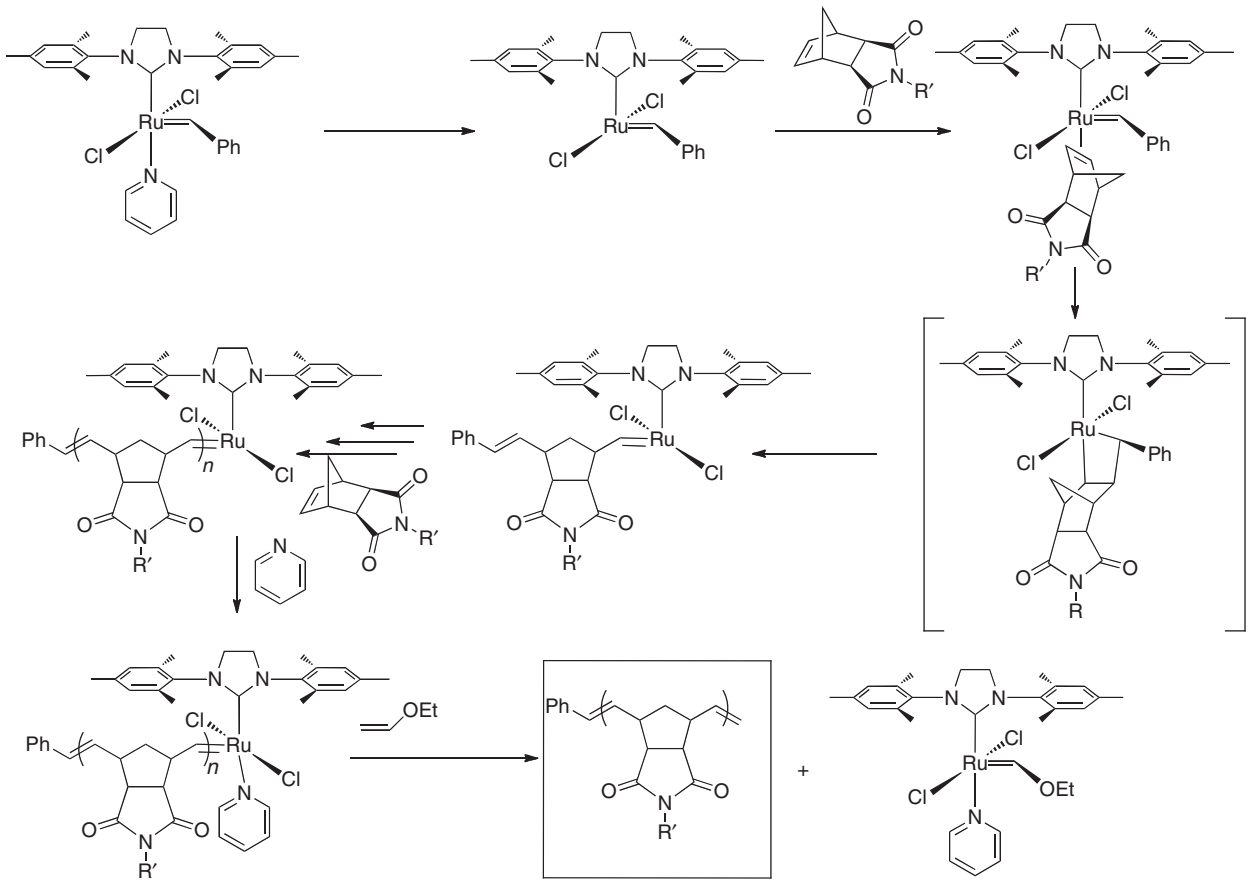
Under normal operating conditions, the 14-electron species is not detected. Only the 16-electron species that are the chain-carrying species in the reaction are observed. Buildup of significant concentrations of the reactive 14-electron complex leads to decomposition. In polymerization terms, the generation of the 14-electron species is initiation and the metathesis step is propagation. The addition of excess phosphine balances the initiation/propagation rates. Using these systems, well-defined homo and block polymers could be prepared. However, to obtain good control and rates, the less available *exo* isomers of the norbornene derivatives were required.

As a result of examining more electron-rich ligands, the *N*-mesityl family of *N*-heterocyclic carbene complexes was developed.[24] These complexes appear to operate by the same basic mechanism as the bisphosphine complexes with the initiation step slower and the propagation faster. As a result, these systems gave polynorbornenes with high PDIs. However, the higher activity did result in excellent rates of polymerizations with endo norbornenes. Attempts to control the PDI by the addition of excess phosphine resulted in some narrowing of the dispersity, but they remained unacceptably broad to be used to prepare well-controlled polymers. Apparently, the initiation of these systems is too slow relative to the propagation rate to be controlled by the addition of phosphine. A new derivative was needed.[25]

As part of a study to explore the role of phosphine structure on initiation, other phosphine derivatives of **12** were prepared from the bispyridine complex **13**. Complex **13** precipitated when **12** was dissolved in a pyridine solution. Mixing **13** with a solution of the desired phosphine and pumping off the solvent and pyridine resulted in the clean production of the desired new complex.[26] Although some of these initiated more rapidly, it was found that the bispyridine complex itself initiated at a very rapid rate.[27] Complex **13** could be used to prepare a wide variety of new well-defined homo and block polymers with PDIs less than 1.1.[28] In some cases, the PDI is lower than the standard polystyrenes used in calibration of gel permeation chromatography (GPC).

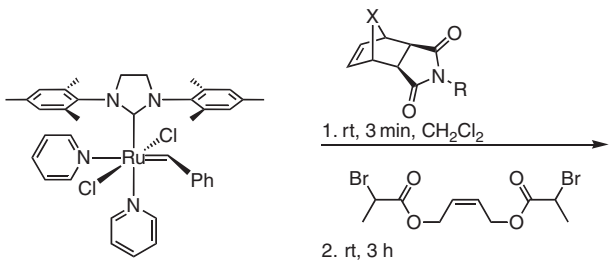
Initially, the *meta*-bromopyridine complex **13b** was used since it initiated at a very rapid rate. However, it was found in subsequent studies that the slower initiating pyridine complex **13a** was more stable and still provided good control.[29]

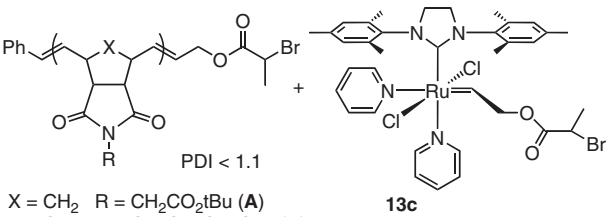
Polymerization with **13a** could be carried out under nitrogen in standard equipment and the reactions to produce well-defined polymers in the 100 K range were completed in tens of minutes.



In a recent example of the control of polymer structure that is made possible utilizing these initiators, a family of brush polymers was prepared. Brush polymers have been explored by many groups due to their interesting topology and are prepared using macromers–monomers that are short oligomers containing a polymerizable end group.[30] The special features of these materials

result from the collapse of these macromers along the backbone to produce rigid systems with high persistence lengths. However, it has proven difficult to prepare them with well-controlled structures by other living systems due to the steric hindrance around the end group induced by the high molecular weight of the monomers. Living radical systems are limited due to the instability of the propagating species[31] and the steric congestion resulting from the close proximity of the side groups. The ROMP systems have proven to be particularly useful for the preparation of well-defined brush polymers due to the stability of the propagating alkylidene as well as the broader displacement of the side groups resulting from the greater spacing resulting from opening of a norbornene monomer.[32]



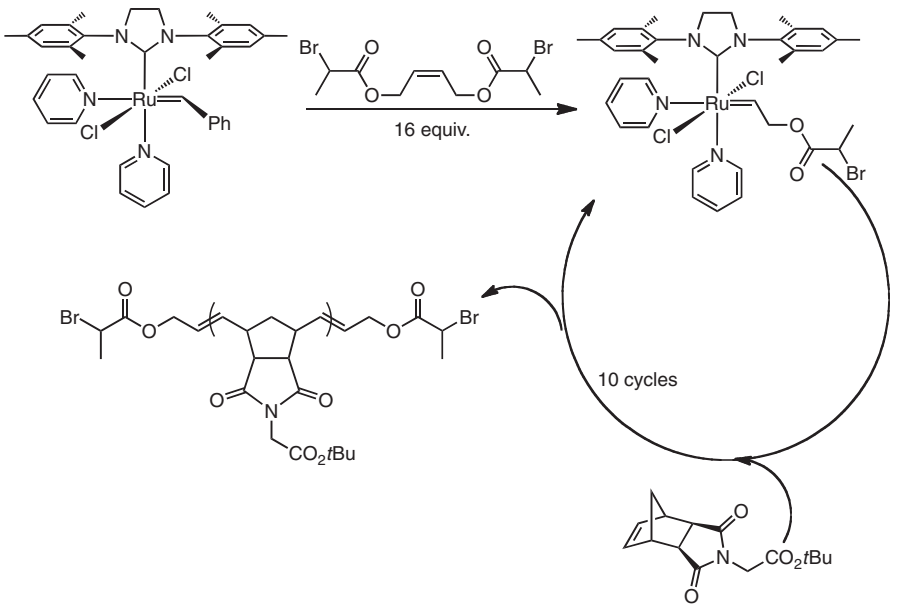


A variety of well-defined macromers with PDIs of less than 1.1 could be prepared by the use of ATRP or the living opening of lactides. Using these macromers, high-molecular-weight polymers could be prepared with PDIs of less than 1.1. Atomic force microscope (AFM) images demonstrated that these polymers dispersed on a surface with highly extended structures. The lengths demonstrated that the backbones were consistent, with all the C–C bonds being fully transoid and extended.[33] Bulk samples of block brush copolymers demonstrated facile and well-defined periodic structures resulting from phase separation of the blocks.[33]

A major limitation of all living systems is the requirement that one initiator produces only one chain. In ROMP, the initiators are rather complex and have high molecular weight. To solve this last limiting problem, pulsed living polymerization was developed. This approach was based on the observation that living systems could be terminated cleanly using *cis*-olefins.[34] The following terminations were carried out to prepare polymers that contained an end functionality that could be used to grow block polymers where the second block was prepared by ATRP.[35]

The key to these reactions was the higher rate of reactivity of the *cis*-olefin relative to the double bonds in the polymer. The predominantly *trans* stereochemistry of the polymer and the allylic substituents slow the reaction of the polymer double bonds relative to those in the *cis* acyclic olefin. In subsequent reactions, it was found that the *cis*-olefin could be present from the beginning of the reaction, that is, the stained norbornene reacted much faster than the *cis*-olefin. Since the complex resulting from the termination of the polymers with the acyclic

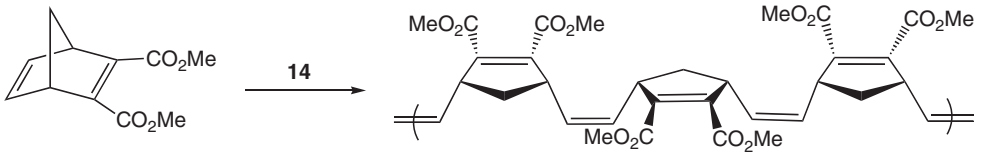
Cycles	Mn(GPC)×10^3	PDI
1	13.2	1.10
2	11.3	1.09
3	12.7	1.09
4	12.6	1.08
5	12.6	1.11
6	12.4	1.11
7	14.2	1.12
8	14.3	1.11
9	15.3	1.14
10	13.7	1.13



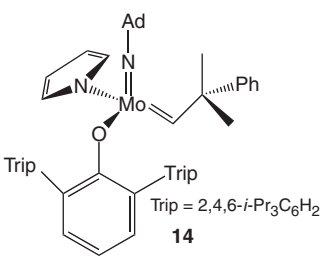
olefin is also an initiator, the system is perfectly set up to continue a second polymerization on addition of a pulsed addition of a new bolus of monomer.

The reaction was carried out in 10 vials using a robot to add more monomer at the appropriate times. Each vial contained monomer, initiator, and an excess of the *cis*-olefin terminator. At the end of each 30 min cycle, a second addition of monomer was added to vials 2–10. On each subsequent monomer addition, another vial was eliminated so that at the last time period, only the 10th vial received an injection of monomer. As can be seen in the table, even after 10 additions of monomer, the polymer was near 1.1 in PDI and near the predicted molecular weight. The increase in PDI and molecular weight are a result of loss of initiator in each step due to decomposition during the slow reaction with the terminator. Subsequent reactions could be run so that the amount of monomer was decreased slightly in each cycle to maintain the appropriate molecular weight and PDI.

At this stage, all of the steps of ROMP were demonstrated to produce polymers of well-defined and low PDI homo and block polymers. The last remaining issue is the control of the stereochemistry of the double bonds in the resulting polymer. Traditional molybdenum- and ruthenium-based catalysts give polymers with high levels of E geometry. However, it had been observed with some special ill-defined catalysts that high E or high Z polymers could be produced depending on the catalyst structure, although most of the ill-defined catalysts gave near equilibrium ratios of E and Z double bonds.[36] Some of the earliest well-defined tungsten catalysts give high Z stereochemistry. No explanations for these observations were given.[15] However, the ability to rationally control the stereochemistry and tacticity of the resulting polymer has recently been demonstrated for a well-defined catalyst. The Schrock and Hoveyda groups[37] have prepared a family of molybdenum- and tungsten-based initiators that produce high percentages of the Z isomer in standard metathesis reactions. Some of these same catalysts will also polymerize norbornenes and cyclopropenes to produce high *cis* polymers. As was found with ill-defined catalysts that gave good control of the double-bond geometry, these catalysts also provided excellent control of the tacticity of the resulting polymers. For example, it was found that the polymerization of the norbornadiene derivative with catalyst **14** gave a stereoregular polymer that was highly *cis* and syndiotactic.[38] The stereochemistry of the polymer is explained by addition of the norbornadiene on the *exo* face with the methylene pointing toward the adamantly group. If the norbornadiene always adds in that direction, *cis* polymer is obtained. The addition of the monomer to opposite faces of the growing polymer as a result of the chirality of the complex results in the *syntio*tactic structure.



> 99% *cis*, >99% syndiotactic



Although ROMP of norbornenes and related strained monomers has been known since the 1960s, the development of well-defined catalysts/initiators for this reaction over the past 25 years has resulted in the ability to prepare polymeric structures that have controlled length and block structures. Only recently have well-defined catalysts been prepared that produce polymers with defined double-bond geometry and tacticity which can be easily assigned based on the catalyst structure.

As a result of this control, the promise of olefin metathesis as a polymerization method has been realized. The controlled ROMP techniques, combined with ATRP and other living polymerization methods, provide the ability to produce polymeric materials of high molecular weight with unprecedented control.

Biographical Sketch

Professor Robert (Bob) Howard Grubbs' main interests in organometallic chemistry and synthetic chemistry are catalysts, notably Grubbs' catalyst for olefin metathesis and ring-opening metathesis polymerization with cyclic olefins such as norbornene. He also contributed to the development of so-called 'living polymerization'.

Grubbs has received many awards including Alfred P. Sloan Fellow (1974–76), Camille and Henry Dreyfus Teacher-Scholar Award (1975–78), Alexander von Humboldt Fellowship (1975), ACS Benjamin Franklin Medal in Chemistry (2000), ACS Herman F. Mark Polymer Chemistry Award (2000), ACS Herbert C. Brown Award for Creative Research in Synthetic Methods (2001), the Tolman Medal (2002), and the Nobel Prize in Chemistry (2005). He was elected to the National Academy of Sciences in 1989 and a fellowship in the American Academy of Arts and Sciences in 1994.

4.04 Ring–Chain Equilibria in Ring-Opening Polymerization

R Szymanski, Polish Academy of Sciences, Lodz, Poland

4.04.1 Phenomenon of the Ring–Chain Equilibria in Ring-Opening Polymerization

The general scheme of a ring-opening polymerization (ROP) contains, besides initiation and propagation, additional processes. Putting transfer reactions, termination, and other transformations of active species aside, the most important reaction involved often in polymerization processes of cyclic monomers is depolymerization. Formation of cyclic oligomers and polymers, macrocycles, is chemically similar to this reaction. Macrocycles can act as monomers in polymerization processes and their formation can be regarded as depolymerization of macrocycle polymerization. As all these reactions can in many systems be simultaneously reversible (polymerization and depolymerization of monomer and macrocycles), the ring–chain equilibria are important in many ROPs, playing positive or negative roles, depending on the aim of a given ROP.

Main reactions constituting the ring–chain equilibria in ROP are shown in a simplified scheme (**Scheme 1**).

The interchain segmental exchange reactions were not included in the scheme because they do not directly influence the ring–chain equilibria, although the reactions of the active chain-end (ACE) with the repeating units resulting in breaking of the polymer chain are similar to the backbiting reaction leading to macrocycles. However, although neglected here, they influence the kinetics of attaining the ring–chain equilibria by broadening the dispersity of linear polymer, usually doing it much faster than depolymerization and cyclization alone. Consequently, when the interchain segmental exchange is very effective, the system reaches the equilibrium faster and the kinetic enhancement in cyclic or linear polymer, the phenomena discussed in Section 4.04.5, can be less pronounced or not observed at all.

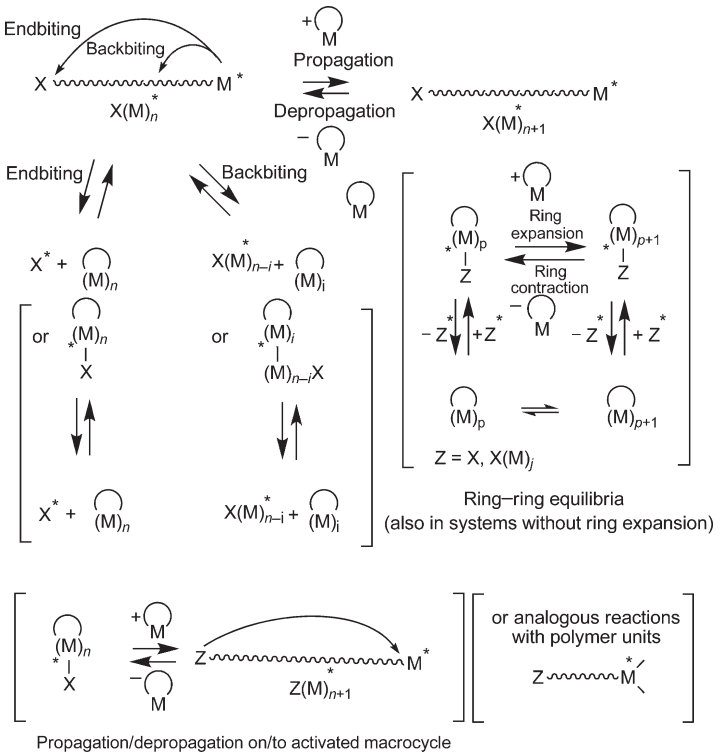
Cyclic oligomers can be formed mainly in the so-called end- and backbiting reactions shown in the scheme. The first of them is a reaction of active species of polymerization, located on one of the growing chain-ends, with the end group formed in polymerization initiation (or in chain transfer reactions). Quite often reactivities of these end groups in relation to active species are higher than reactivities of repeating units of the growing chain (backbiting reactions – see **Scheme 1**). It can stem from chemical differences of reacting groups (end group differing from the corresponding group of the repeating unit), but steric hindrance alone often also favors endbiting over backbiting. Depending on the considered ROP system, back- and endbiting reactions can lead either directly to macrocycles and shorter living chains (backbiting) or initiator/activator molecule or ion (endbiting), or activated macrocycles are formed first as intermediates (cf. **Scheme 1**). Free macrocycles can next be formed as a result of other reactions, for example, as shown in the scheme via breaking of the exocyclic bond connecting the activating group to the cycle.

If endbiting is very effective, it can be mistaken for ring-expansion reaction, also shown in **Scheme 1**.

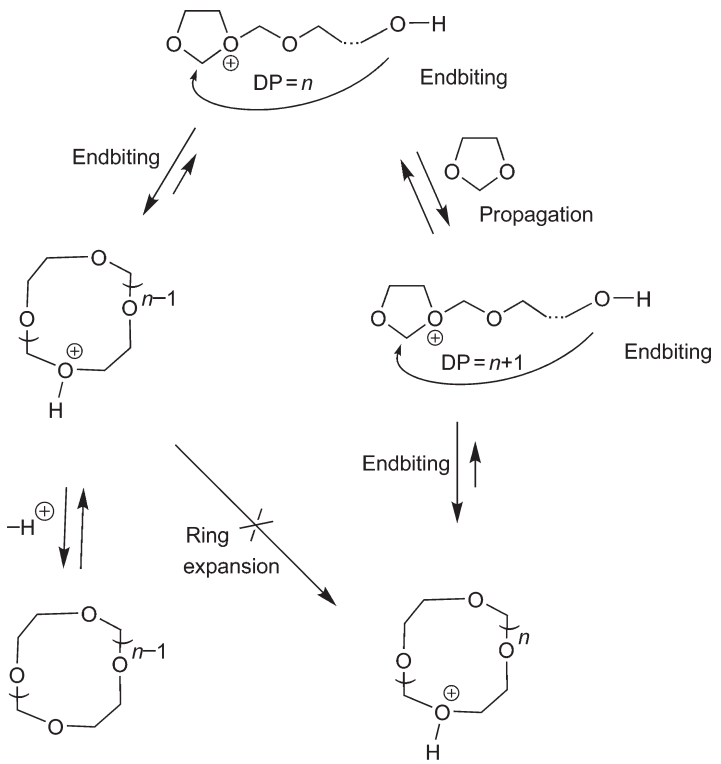
Such a situation existed in polymerization of cyclic acetals. After observing in many systems the formation of exclusively cyclic polyacetals, Plesch and Westermann[1] argued that no linear propagation accompanied by cyclization can explain this situation. Consequently, they proposed the ring-expansion mechanism of polymerization of cyclic acetals operating on cationated monomer and macrocycles.

However, as discussed by Szymanski *et al.*,[2] ring-expansion mechanism can be excluded on the basis of the presence of a fraction of linear polymer in polymerization systems as well as on the basis of some model reactions and computer simulations. Arguments presented by the authors prove that endbiting reaction accompanying linear propagation together with other reactions of ring–chain equilibria can explain experimental results and it is not necessary to assume ring-expansion reaction.

Thus, if endbiting is very effective and reversible, and activated macrocycles can react as active species with monomer giving normal linear growing chain, the net result can be very similar to ring expansion. **Scheme 2** shows this possibility, explaining Plesch's results of observing only macrocycles in some polymerizations of cyclic acetals (here 1,3-dioxolane



Scheme 1 Reactions constituting ring–chain equilibria in ROP (simplified scheme). In brackets, a variant with hyper-bonded structures, for example, with oxonium cations or catalyst coordinated (activated) compounds, is shown. Z denotes an initiator originated end group (X–) or a linear fragment of polymer (X(M)$_i$–). Reversible ring-expansion/contraction reactions were added to this general scheme, although they are usually possible and/or important only in some coordination ROP polymerizations.



Scheme 2 Formation of macrocycles in polymerization of 1,3-dioxolane initiated with protonic acids. Backbiting neglected, ring expansion route rather improbable.[2]

polymerization system is shown), although ring expansion can be usually excluded.

It is worth stressing that the existence of ring–chain equilibria in polymerization results automatically in the existence of the chain–chain and ring–ring equilibria even if direct routes in some systems are absent (like direct ring interconversions rarely observed in ROP). On the other hand, the ring–chain equilibrium can in some systems be reached faster via the direct ring–ring interconversions if these reaction routes are present and are kinetically favored (fusion/fission reactions – the simplest reactions constituting the ring–ring equilibria).

Nevertheless, the ring-expansion reaction (and generally ring–ring interconversions) are postulated for some systems with heteroatoms having 3d or higher orbitals, including systems with catalyst capable of incorporation itself into the monomer ring. In such systems, ring expansion is possible via concerted reaction of insertion of monomer molecules (and/or macrocycles) into the corresponding bond of the hybrid cycle. Some examples are shown in the following sections.

However, it is worth noting that the equilibrium in real ring-expansion systems, without linear chains, should rather give higher equilibrium concentrations of macrocycles than in systems in which linear chains are formed. It stems from the mass balance not including the absent linear polymer fraction (see a short discussion in the next section), but it has not yet been verified experimentally.

4.04.2 Thermodynamics of the Ring–Chain Equilibria in ROP

Equilibrium in ROP accompanied by macrocyclization reactions is described by an infinite set of equations:

$$-\mathrm{M}_y- \underset{}{\overset{K_x}{\rightleftharpoons}} -\mathrm{M}_{y-x}- + (\mathrm{M}_x) \qquad [1]$$

$$K_x = \frac{[\text{c-M}_x][-\mathrm{M}_{y-x}-]}{[-\mathrm{M}_y-]} \qquad [2]$$

where K_x is the cyclization equilibrium constant for formation of x-size ring (monomer, cyclic oligomers and polymers, cyclo-M_x); x, $y = 1, 2, 3, \ldots$ are the numbers of repeating units in a (macro)cycle and linear polymer (eqn [1]), respectively.

Jacobson and Stockmayer[3] analyzed such types of equilibria and formulated a theory describing dependence of the cyclization equilibrium constants on the ring size.

It is assumed, that K_x is independent of the polymer length, that is, $y > x$ in eqns [1] and [2].

As K_x is a thermodynamic function, it is independent of the reaction routes (see, e.g., **Scheme 1**) leading to the state described by eqns [1] and [2].

Although Jacobson and Stockmayer analyzed mainly the polycondensation systems, their results are also valid for ROP.

In ROP, K_x is equal to the ratio of the rate constants of backbiting and polymerization (addition) of macrocycle

$$-\mathrm{M}_y^* \underset{k_{px}}{\overset{k_{bx}}{\rightleftharpoons}} -\mathrm{M}_{y-x}^* + (\mathrm{M}_x) \qquad [3]$$

$$K_x = \frac{k_{bx}}{k_{px}} \qquad [4]$$

Analogously it can be defined by rate constants of endbiting reactions or any other set of reactions of the full reaction scheme (e.g., reactions of **Scheme 1**).

Because distribution of lengths of linear polymer in equilibrium is usually the most probable one, the ratio of concentrations of chains differing by x repeating units can be expressed as p^x,

$$p^x = \frac{[-\mathrm{M}_{y+x}-]}{[-\mathrm{M}_y-]} \qquad [5]$$

where p is the ratio of concentrations of chains differing by one repeating unit (eqn [6])

$$p = \frac{[\mathrm{M}_{y+1}-]}{[-\mathrm{M}_y-]} = 1 - \frac{1}{\mathrm{DP}_n} \qquad [6]$$

(DP_n is the number average degree of polymerization) being close to unity for a large average length of linear polymer chains.

Consequently, from eqns [2] and [5], we get the equation relating the equilibrium concentration of macrocycle with the corresponding cyclization equilibrium constant and parameter p describing the linear polymer

$$[\text{c-M}_x] = K_x p^x \qquad [7]$$

One can easily observe that the cyclization equilibrium constants are in fact reciprocals of the equilibrium polymerization constants of macrocycles, regarded as monomers of linear homopolymerization.

The sum of monomer units incorporated into cyclics is in the equilibrium dependent on p, that is, in fact on the average length of linear polymer:

$$[-\mathrm{M}-]_{\text{cyclic}} = \sum_{i=1}^{\infty} i[\text{c-M}_i] = \sum_{i=1}^{\infty} iK_i p^i = \sum_{i=1}^{\infty} iK_i \left(1 - \frac{1}{\mathrm{DP}_n}\right)^i \qquad [8]$$

This relationship gives the so-called critical monomer concentration, also called a critical cyclics concentration or a cutoff point (calculated from the above equation for $p = 1$), being the total equilibrium concentration of cyclics (monomer and macrocycles), expressed in monomer units, in the systems with linear polymer of infinite average length. For initial monomer concentration larger than this critical concentration, we can have the linear high-molar-mass polymer and macrocycles, while for lower initial monomer concentrations practically all the monomer above its equilibrium concentration is converted into cyclic oligomers. This critical monomer concentration is not a sharp borderline (cutoff point) because in fact the equilibrium concentrations of macrocycles depend on DP_n of linear polymer (eqn [7]). Consequently, in real systems, with not very low initiator concentrations, the fraction of linear oligomers gradually decreases in equilibrium with decreasing initial monomer concentration from values close above to values below the critical value. The computed dependence of cyclic fraction in equilibrium systems of 1,3-dioxolane polymerization initiated irreversibly with two different concentrations of initiator is shown in **Figure 1**.

For higher initiator concentration ($0.01\ \mathrm{mol\,l^{-1}}$) the maximum fraction of macrocycles in polymerization product at

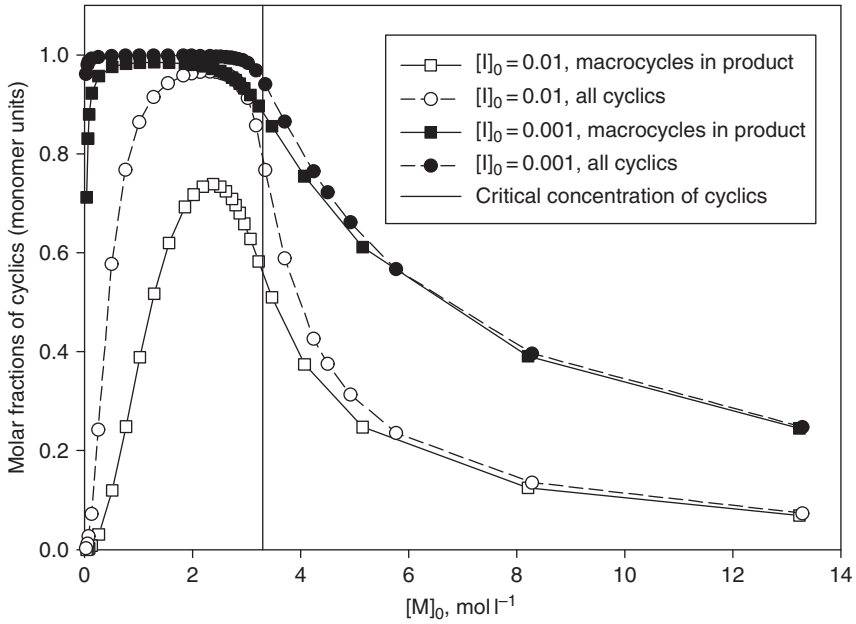


Figure 1 Contributions of cyclics in the equilibrium system of 1,3-dioxolane computed[4] for various initial concentrations of monomer and two concentrations of initiators: 0.01 and 0.001 mol l^{-1}. All-cyclics plots include monomer both in cyclics and in total mass of the systems. Equilibrium constants are taken from Andrews, J. M.; Semlyen, J. A. Polymer, **1972**, *13*, 142.[5]

equilibrium is about 74%, while the maximum fraction of cyclics, including monomer, reaches 96.5%. For 10 times lower concentrations of initiator (0.001 mol l^{-1}), the corresponding numbers are 98% and 99.8% and the critical monomer concentration borderline at about 3.3 mol l^{-1} is pronounced a bit more sharply. It is worth noting that at low initial monomer concentrations close to zero, the fraction of cyclics drops to zero due to the assumed irreversible initiation and decreasing the average length of linear oligomers to unity (consequently, the parameter p from eqns [5]–[8] limiting the equilibrium concentrations of cyclics, attains zero).

Jacobson and Stockmayer[3] analyzing the density of distribution of segments of linear polymer formulated a theory relating the distribution function of the end-to-end vector $\mathbf{r}$ for linear polymer composed of x units ($W_x(\mathbf{r})$), per unit range in $\mathbf{r}$, with the equilibrium constant of cyclization for systems without ring-strain and other enthalpic factors (equilibrium governed only by entropic factors):

$$K_x = \frac{W_x(\mathbf{0})}{N_A \sigma_{Rx}} \qquad [9]$$

where N_A is the Avogadro constant and σ_{Rx} the symmetry number for macrocycle of size x.

The above equation was derived assuming, besides no heat of cyclization, that the probability of cyclization is proportional to the fraction of polymer conformations at which the ends are close to each other and that reactivity of terminal groups are independent of the chain length.

Consequently, Jacobson and Stockmayer came to the conclusion that K_x is proportional to x raised to the power –5/2.

Flory and Semlyen[6] contributed to the original Jacobson–Stockmayer (J-S) theory assuming that for sufficiently long chains $W_x(\mathbf{r})$ should be Gaussian to an adequate approximation, fulfilling the relationship

$$W_x(\mathbf{0}) = \left(3/2\pi \langle r_x^2 \rangle\right)^{3/2} \qquad [10]$$

where $\langle r_x^2 \rangle$ is the mean-square end-to-end length averaged over all configurations of the real linear chain of size x. Additionally, as an approximation, they identified $\langle r_x^2 \rangle$ with the unperturbed mean-square end-to-end length $\langle r_x^2 \rangle_0$ as, for instance, in dilute theta solvent.

The unperturbed mean-square end-to-end length $\langle r_x^2 \rangle_0$ appears to be approximately proportional to the ring size x:

$$\langle r_x^2 \rangle_0 = C_x v x l^2 \qquad [11]$$

where C_x is the characteristic ratio of linear x-mer, l the average length of skeletal bonds, and v the number of these bonds in repeating unit.

For large x, C_x can be replaced with the limiting value of the characteristic ratio

$$C_\infty = \left(\frac{\langle r_x^2 \rangle_0}{v x l^2}\right)_{x \to \infty} \qquad [12]$$

Combining eqns [9]–[11], we get the relationship

$$K_x = \frac{\left[3/(2\pi C_x v x l^2)\right]^{3/2}}{N_A \sigma_{Rx}} \qquad [13]$$

which allows a prediction of the equilibrium constants of macrocyclization for nonstrained macrocycles on the basis of geometric features of polymers.

This equation does not take into account in a visible way the conformational restrictions (although they can be partly accounted for, hidden in the value of the characteristic ratio C_x). Conformational constraints are especially important for rigid chains. For instance, the equilibrium concentration of cyclics in poly(butylene isophthalate) is ~3 times higher than in poly(butylene terephthalate), because the former has a bent rigid structure.[7]

As the symmetry number for macrocycle σ_{Rx} is proportional to the ring size, for instance, cyclic x-mers of poly(dimethylsiloxane) is equal to $2x$, the cyclization equilibrium constant for larger macrocycles is, according to Flory and Semlyen, proportional to the ring size to the power −2.5 ($\sim x^{-5/2}$), similarly as was predicted in the original version of J-S theory.

This relationship was verified experimentally for many systems.

Any deviations from the predicted relationship could be explained by the ring strain of smaller macrocycles, not theta solvent or insufficient dilution, or by other factors.

An example of the experimentally determined dependence of the cyclization equilibrium constants on the ring size, indicating the observed deviation from the J-S theory, is shown in Figure 2.[8]

The fraction of macrocycles in the overall polymer at equilibrium conditions is, however, usually overestimated by the J-S theory and some of its improvements. There are several reasons for that, but the most important, besides the ring strain of smaller macrocycles, is insufficient approximation of the polymer segments distribution by the Gaussian density distribution function. Some factors, such as the polymer excluded volume, important for larger macromolecules, are not taken correctly into account due to lack of sufficiently good models. Also, the geometric restrictions for ring closure (orientational factor) can not always be correctly taken into account. One of the possible solutions to these problems is using Monte Carlo simulations to determine, for instance, the fraction of chain conformations for which both ends meet inside a small sphere and have the correct orientations. One of the models, most often used in these computations, is the rotational isomeric state model.[9]

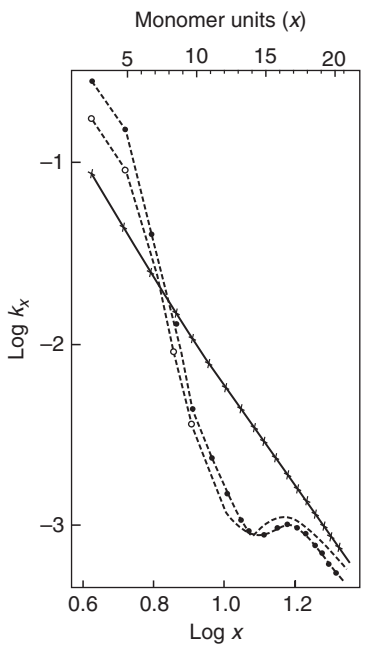

Figure 2 Molar cyclization equilibrium constants K_x for cyclics $((CH_3)_2SiO)_x$ at 383 K for a bulk equilibrate (open circles) are compared with a solution equilibrate (filled circles) and with values calculated (x) according to the J-S theory. K_x values are in mol l^{-1}. Reproduced with permission from Semlyen, J. A. *Adv. Polym. Sci.* **1976**, *21*, 41.[8]

From the formal equilibria for ring–chain interconversions (eqns [2]–[7]), we also get equations for the ring–ring equilibria.

The equilibrium constants for these reactions, derived from the ring–chain equilibria relationships, are also valid, being the real thermodynamic functions, for systems without reaction routes leading to linear polymers. In other words, they are also valid for systems in which ring expansion and ring contraction operate, but there are no reactions for formation of linear polymer.

Taking into account eqn [2], we get the relationships [14]:

$$K_{x,y} = \frac{[\text{c-M}_{x+y}]}{[\text{c-M}_x][\text{c-M}_y]} = \frac{K_{x+y}}{K_x K_y} \qquad [14]$$

indicating that the equilibrium constants of ring–ring equilibria are functions of the macrocyclization equilibrium constants.

Assuming that sufficiently large homogeneous macrocycles are considered (nonstrained and with approximately equal characteristic ratios $C_x \approx C_y \approx C_{x+y} \approx C_\infty$) and that the symmetry numbers for macrocycles are proportional to the ring size, $\sigma_{Rz} = az$, we get, combining eqns [13] and [14], a simple equation relating the ring–ring equilibria constants with the ring sizes

$$K_{x,y} = \frac{K_{x+y}}{K_x K_y} = N_A a \left(\frac{x+y}{xy}\right)^{-5/2} [\, 3/(2\pi C_\infty v l^2)\,]^{-3/2} \qquad [15]$$

where a is a proportion coefficient relating the symmetry number of macrocycles with their size ($\sigma_{Rz} = az$).

This relationship differs from the one given by Kricheldorf, who assumed that the dependence of the equilibrium constants of ring–ring equilibria on the equilibrium constants of ring–chain equilibria can be neglected and that independence of the ring–ring equilibrium constants of the sizes of rings describes the ring–ring equilibrium systems sufficiently well ($K_{x,y} = K_{\text{cyclo}}$, for any x and y).[10]

Moratti[11] criticized the Kricheldorf's paper indicating that this assumption of all ring–ring equilibrium constants being similar is incorrect. Nevertheless, Kricheldorf in the later paper repeats his treatment, extending the simplifying assumption to the kinetically controlled distribution of macrocycles.[12]

One more aspect of ring–ring equilibria can be noted. When no linear polymer can be formed and the system reaches the ring–ring equilibria, the mass–balance relationship without terms for linear polymer has to be held:

$$[\text{M}]_0 = [\text{c-M}_1]_0 = \sum_{i=1}^{\infty} i[\text{c-M}_i] \qquad [16]$$

As can be easily derived from eqn [7], the concentration of any ring at equilibrium is proportional to the ring–chain equilibrium constant and to the corresponding power of the parameter $p = [\text{M}]/K_1$ (defined here on the basis of eqn [7], not in relation to linear polymer as it is not present)

$$[\text{c-M}_i] = K_i \left(\frac{[\text{c-M}_1]}{K_1}\right)^i = K_i \left(\frac{[\text{M}]}{K_1}\right)^i = K_i p^i \qquad [17]$$

Combining eqns [16] and [17], we get the equation relating the initial concentration of monomer to the ring–chain equilibrium constants and the parameter p

$$[\mathrm{M}]_0 = \sum_{i=1}^{\infty} i[\mathrm{c\text{-}M}_i] = \sum_{i=1}^{\infty} iK_i p^i \qquad [18]$$

This parameter p resembles the analogous parameter for equilibrium systems of linear ROP in which p is equal to the ratio of concentrations of chains differing by one repeating unit and is always lower than 1 for such systems.

However, if formation of linear polymer is not possible, and the initial concentration of monomer is above the critical monomer concentration, then the ratio $p = [\mathrm{M}]/K_1$ becomes higher than 1. Otherwise the sum on the right-hand side of eqn [18] would be, at the most, equal to the critical cyclic concentration (cf. eqn [8]), and the eqn [18] would not hold.

Thus, p in systems without linear polymer and initial monomer concentration larger than the critical value is larger than 1 and consequently the total concentration of macrocycles in equilibrium ring-expansion systems without reaction routes leading to linear polymer, is higher than in systems of ring–chain equilibria.

Moreover, we can prove that the J-S theory of ring–chain equilibria, or rather its simplification giving the known dependence of the cyclization equilibrium constants on the ring sizes, is not correct for macrocycles of sizes attaining infinity. Namely, otherwise the infinite sum, defining the total concentration of monomer units in all cyclics (eqn [18]), attains infinity for any $p > 1$

$$[\mathrm{-M-}]_{\mathrm{cyclic}} = \sum_{i=1}^{\infty} i[\mathrm{c\text{-}M}_i] = \sum_{i=1}^{\infty} iK_i p^i = \sum_{i=1}^{\infty} Ai^{-1.5} p^i \qquad [19]$$

where A is a factor stemming from the simplified expression of the macrocyclization equilibrium constants being, according to the J-S theory, proportional to the ring size raised to the power −2.5 (deviation of smaller rings from the general relationship was neglected).

The conclusion is only one: at least for very large macrocycles, the cyclization equilibrium constants have to decrease with the ring size i faster than $i^{-2.5}$. Thus, the slope of log K_x versus log x for at least very large macrocycles has to increase (in absolute value) gradually giving the slope parameter less than −2.5, the value predicted by the J-S theory. This can be associated with not taking correctly into account the exclusion volume factor by the J-S theory or its extensions for very large polymers.

4.04.3 Thermodynamics of Ring–Chain Equilibria in Copolymerization

The J-S theory describing the ring–chain equilibria in systems of nonstrained cyclics can be applied also to copolymerization. However, due to possible differences of comonomers in their structures, including the number and type of atoms, bond lengths, and bond angles, the eqn [13] cannot be applied directly. We have to take into account the equilibrium distribution of comonomer units in copolymer chains of different lengths. Szymanski[13] has proposed relating the copolymerization cyclization equilibrium constants to analogous constants for homopolymerization to simplify the treatment.

Combining the equilibrium constants formulated according to the Flory and Semlyen (eqn [13]) for homo- and copolymeric macrocycles, the following relationship can be obtained:[13]

$$K_{x\mathrm{A}n\mathrm{B}m} = \frac{\sigma_{Rx\mathrm{A}}^{n/x}\sigma_{Rx\mathrm{B}}^{m/x}}{\sigma_{R\mathrm{A}n\mathrm{B}m}K_{x\mathrm{A}}^{n/x}K_{x\mathrm{B}}^{m/x}W} \qquad [20]$$

where $K_{x\mathrm{A}n\mathrm{B}m}$, $K_{x\mathrm{A}}$, and $K_{x\mathrm{B}}$ are the cyclization equilibrium constants for formation of homo- and copolymeric macrocycles composed of x units, $x = n + m$, n, and m are the numbers of A and B units in copolymeric macrocycle, respectively, and σ are the symmetry numbers of macrocycles, W is a function of the mean-square end-to-end lengths of homogeneous and heterogeneous chains of size x

$$W = \left(\frac{\langle r_x^2\rangle_{\mathrm{A}n\mathrm{B}m}}{\langle r_x^2\rangle_{\mathrm{A}x}^{n/x}\langle r_x^2\rangle_{\mathrm{B}x}^{m/x}}\right)^{3/2} \qquad [21]$$

The coefficient W for copolymers of similar monomers can be predicted to be close to 1 and thus can be neglected. For other systems, it can be approximated by computation, for instance, assuming the model of free-joint chain with block distribution of units A and B

$$W = \left(\frac{\langle r_x^2\rangle_{\mathrm{A}n\mathrm{B}m}}{\langle r_x^2\rangle_{\mathrm{A}x}^{n/x}\langle r_x^2\rangle_{\mathrm{B}x}^{m/x}}\right)^{3/2} \approx \left\{\frac{(na-1)L_{\mathrm{A}}^2 + (mb-1)L_{\mathrm{B}}^2 + (L_{\mathrm{A}}^2 + L_{\mathrm{B}}^2)/2}{[(na-1)L_{\mathrm{A}}^2]^{n/x}[(mb-1)L_{\mathrm{B}}^2]^{m/x}}\right\}^{3/2} \qquad [22]$$

where L_{A}^2 and L_{B}^2 are the average squared bond lengths of units A and B, a and b the numbers of bonds in corresponding copolymer units, and the squared AB bond length was approximated by the mean squared length of homogeneous bonds $(L_{\mathrm{A}}^2+L_{\mathrm{B}}^2)/2$. If L_{A} and L_{B} differ much, and the squared length of the A–B bond differs significantly from the assumed value, the real microstructure of the chain corresponding to the given macrocycle (not the block structure assumed above) should be taken into account.

However, unlike in homopolymerization systems, the concentrations of macrocycles are not at equilibrium equal (or approximately equal for not infinitely long linear chains) to the macrocyclization equilibrium constants. It stems from the fact that various compositions and microstructures of chains can usually be obtained depending on the initial monomer feed and copolymerization equilibrium constants (of homo- and crosspropagations). The only exceptions are alternating copolymers for which macrocycle concentrations correspond to macrocyclization equilibrium constants like in homopolymerization systems.

Szymanski[13] formulated the equations for the equilibrium concentrations of copolymer macrocycles as functions of the equilibrium constants of macrocyclizations, homo- and crosspropagations, and equilibrium concentrations of comonomers. For dyad model copolymerization, the derived relationship is the following (eqn [23]):

$$[C_{\mathrm{A}n\mathrm{B}m\mathrm{AB}r}] = K_{\mathrm{A}n\mathrm{B}m\mathrm{AB}r}(K_{\mathrm{AA}}[A])^n(K_{\mathrm{BB}}[B])^m\left(\frac{K_{\mathrm{AB}}K_{\mathrm{BA}}}{K_{\mathrm{AA}}K_{\mathrm{BB}}}\right)^r \qquad [23]$$

where $C_{\mathrm{A}n\mathrm{B}m\mathrm{AB}r}$ denotes a copolymer macrocycle composed of n units A and m units B and containing r AB bonds (and r BA bonds; the number of heterogeneous bonds is $2r$), and with the

distinct symmetry number (depending on microstructure) determining (besides other parameters) the macrocyclization equilibrium constant $K_{AnBmABr}$ (cf. eqn [20]). The brackets are used for denoting the equilibrium concentrations.

Instead of the homo- and crosspropagation equilibrium constants and the equilibrium comonomer concentrations, we can use the experimentally determined ratios of corresponding sequences of linear copolymer. For instance, for dyad model copolymerization, the following equation can be obtained:

$$[C_{AnBmABr}] = K_{AnBmABr}\left(\frac{[-AA-]}{[-A-]}\right)^{n}\left(\frac{[-BB-]}{[-B-]}\right)^{m}\left(\frac{[-AB-][-BA-]}{[-AA-][-BB-]}\right)^{r} \quad [24]$$

Analyzing these equations, we can easily come to the conclusion that linear and cyclic polymers can at equilibrium differ in copolymer units composition and microstructure (e.g., contributions of various triads). Such a phenomenon was observed for some copolymerization systems, for example, the maleic acid units fraction in macrocycles and in linear polymer differ for poly(hexane-1,6-diyl maleate-*co*-hexane-1,6-diyl fumarate).[14]

Equation [24] (after rearrangement) can be used for computing the macrocyclization equilibrium constants in copolymerization on the basis of the determined equilibrium concentrations of macrocycles and linear copolymer microstructure.

The relationships presented for copolymerization systems can also be used for some homopolymerization systems in which polymer with irregular structures is formed, like one containing head-to-head and tail-to-tail sequences. This problem is discussed in Section 4.04.6.2.

When the cyclization equilibrium constants in copolymerization are known, the same eqn [24] can be used to predict the equilibrium concentrations of macrocycles provided the equilibrium composition and microstructure of linear copolymer is known. When the properties of the equilibrium linear copolymer cannot be determined, but the equilibrium constants of macrocyclization and copolymerization are known, the prediction of the equilibrium concentrations of macrocycles can still be accomplished, but only by formulation and solving the set of equations, taking into account besides eqn [23] the mass balance equations for comonomer units in linear and cyclic fractions.[13]

4.04.4 Effects of Pressure and Solvents on the Ring–Chain Equilibria

Smaller cyclic oligomers, due to conformational restrictions as well as changed bond lengths and angles often differ from the high polymer in densities and some other features, like the average dipole moment of repeating units. Consequently, we can expect the dependence of the cyclization equilibrium constants for these cyclics on pressure and the reaction medium, solvent, and dilution.

The effect of pressure on undiluted oligo(dimethylsiloxane) ring–chain equilibria was studied by Wright.[15,16] The author found that at 3500 atm, the weight content of smaller cyclics D_x, where D denotes the dimethylsiloxane unit and $x = 4$, 5, 6, decreases at equilibrium from 6.2, 3.8, 1.6, respectively, at 1 atm to 4.4, 2.8, 1.3, respectively, while the content of larger macrocycles remains unchanged. It is associated directly with the differences of densities of siloxane compounds: at 383 K, the values for cyclic tetramer, pentamer, and high polymer are equal to 0.853, 0.866, and 0.898 g cm^{-3}, respectively.

Wright and Semlyen[17] also observed an increase in the equilibrium constants of cyclization for small-ring cyclic dimethyl-, methyl-, and diethylsiloxanes diluted with diglyme and toluene. For instance, K_x, $x = 4$ and 5, are equal to 0.19 and 0.09 for the undiluted system at 383 K (898 g l^{-1} for dimethylsiloxane compounds) and to 0.21 and 0.13 in diglyme solution (212 g l^{-1}, 333 K), and 0.30 and 0.15 in toluene solution (224 g l^{-1}, 383 K). Consequently, while diluting the systems to the critical concentration (calculated from K_x values for the undiluted systems), the contents of cyclic fraction increases faster than expected.

Solvent also changes the density distribution function of the end-to-end vector $\mathbf{r}$ for linear polymer of x units ($W_x(\mathbf{r})$), influencing in this way directly the ring–chain equilibria. In a good solvent, this effect, associated with the excluded volume, change the power law of the dependence of K_x on the ring size x, making this dependence steeper: instead of −2.5 ($K_x \sim x^{-2.5}$) values −2.8 or even −2.9 are observed.[18,19]

The effect of solvent on the cyclization equilibrium constants was analyzed by Carmichael *et al.*[20] for dimethylsiloxane systems in xylene and diglyme solutions. They explained it from the viewpoint of 'good' (toluene, xylene) and 'poor' solvents (diglyme) and semiempirical parameters of the Flory–Huggins equations for three-component systems.[21]

4.04.5 Kinetics of the Ring–Chain Equilibria in ROP

Looking at the general reaction scheme of the ring–chain equilibria (**Scheme 1**), we can predict that the main factor determining the rates of formation of macrocycles, besides the chemical structures of ROP monomers and initiators/catalysts, is the distance between the reacting entities of linear macromolecule (cyclization).

If diffusion of polymer segments is much faster than the rate of reaction of reacting groups forming the ring closing bond, and the ring strain influencing the activation enthalpy of the reaction can be neglected, the rate of cyclization is proportional to the distribution function of the end-to-end vector $\mathbf{r}$ for linear polymer of x units at $\mathbf{r}$ close to 0 ($W_x(\mathbf{0})$). According to the J-S theory,[3] the chain conformations are governed by the Gaussian distribution of interunit vectors, giving $W_x(\mathbf{0})$ and consequently the rate of cyclization proportional to the ring size raised to the power −3/2 for sufficiently large cyclics.

As there are at least two distinguished routes of macrocycle formation: backbiting and endbiting, that is, the reaction of the ACE of growing macromolecule with the chemical group located inside the chain and with a group located at the second chain-end, the kinetics of macrocycle formation in ROP of the same monomer may differ, depending on composition of the analyzed system, not only quantitatively (different time scales of attaining the equilibrium) but also qualitatively. The groups inside the chains and located at the chain end differ at least in

accessibility (differences in steric hindrance) but often they are also chemically different.

Discussion of one of the possible situations is given in Section 4.04.6.2.

Qualitatively the results of differences in rates of cyclization proceeding via back- and endbiting reactions (the mentioned polymerization of cyclic acetals is just an example) can be described simplifying cyclizations to be one-step reactions.

The differences in end- and backbiting rates result in phenomena known as kinetic enhancement of macrocycles or linear polymer. The former occurs when endbiting is more effective than backbiting and manifests itself in formation of macrocycles during polymerization in concentrations higher than the equilibrium values.

It is observed, for instance, in many ROPs of cyclic acetals and ethers initiated with protonic acids. The hydroxy end group formed in initiation is more effective in cyclization than acetal or ether groups of polymer repeating units, giving as a result a kinetic product with increased concentration of macrocycles, as briefly discussed previously for polymerization of 1,3-dioxolane. When the system can be kept living for a longer time, it eventually reaches the ring–chain equilibrium but for intermediate times the enhancement in macrocycles is observed. Such behavior was modeled by Matyjaszewski *et al.*[22] who have shown, assuming cyclizations to be one-step reactions, that during polymerization in systems with endbiting rate constants larger than those of backbiting, the concentrations of macrocycles after reaching maxima decreases to the equilibrium values. When endbiting can be neglected the concentrations of macrocycles, according to the same paper, steadily increase from zero to the equilibrium concentrations.

Similar simulations were performed by Slomkowski,[23] who assumed that cyclizations via backbiting are one-step reactions while endbiting gives more stable macrocycles with active centers (cf. **Scheme 1**). These activated macrocycles can either react in the reverse reaction giving linear growing chains or react in the exchange reaction of the active center with other cyclics, including monomer. Reactions of activated (e.g., protonated) macrocycle with linear polymer were neglected as well as all reactions leading to its ring opening in reaction with monomer or other compounds.

Nevertheless, such approximation can be justified for some cyclic ethers and acetals, at least for the initial stages of polymerization. The simulations have proved that a high contribution of macrocycles in the kinetic product of polymerization can be expected for systems with effective endbiting, especially for lower initial monomer concentrations, and the ring-expansion mechanism proposed by Plesch and Westermann[1] for cyclic acetals is not necessary to explain the experimental evidence of dominance of cyclics in some polymerizations.

However, the authors of both simulation works mentioned above analyzed systems with high DP_n of linear polymer. When critical concentration (total equilibrium concentration of cyclics for infinite DP_n of linear polymer, expressed in monomer units) for a given monomer is high in comparison to the initial monomer concentration and the concentration of initiator DP_n is also relatively high, the resulting equilibrium linear polymer is of low DP_n. Consequently, the effect of kinetic enhancement of macrocycles, that is, passing of the macrocycle concentrations through maxima, is observed not only for systems with effective endbiting but also for systems with negligible endbiting. This was shown by Szymanski[24] in computer simulations and it stems from changing the molar mass distribution of linear polymer after reaching the maximum monomer conversion. This phenomenon exactly corresponds to the well-known slow decrease in the steady-state (pseudo-equilibrium) concentration of monomer in reversible polymerization, proceeding simultaneously with broadening of the dispersity of polymer chain lengths. The kinetic linear polymer can often have a low dispersity, which means that the concentration of chains of DP close to DP_n can, at these stages of polymerization, be much higher than in the equilibrium product. Consequently, the rates of macrocyclizations leading to rings of those sizes and smaller are much higher than in equilibrium. Consequently, the instantaneous, steady-state concentrations of them can be significantly higher than the equilibrium concentrations. Computer simulations performed for rate constants determined for ε-caprolactone polymerization have shown, for lower initial monomer concentrations, the predicted enhancement of macrocycles, although not confirmed yet experimentally (**Figure 3**).[24]

For systems with propagation rate constants significantly higher than the rate constants of macrocyclization, a phenomenon of kinetic enhancement of linear polymer is observed. When the differences in ring strain and/or other factors influencing reactivity, like steric effect, discriminating monomer from monomer units, are sufficiently large, it is often possible to find an initiator giving active centers of propagation reacting predominantly, almost selectively, with monomer. Reactions with polymer repeating units (macrocyclization or interchain exchange) are much slower. Consequently, in such polymerizations, monomer is converted initially almost exclusively to linear polymer, giving a product of low dispersity. Next, in a different time scale, sometimes practically not attainable, a

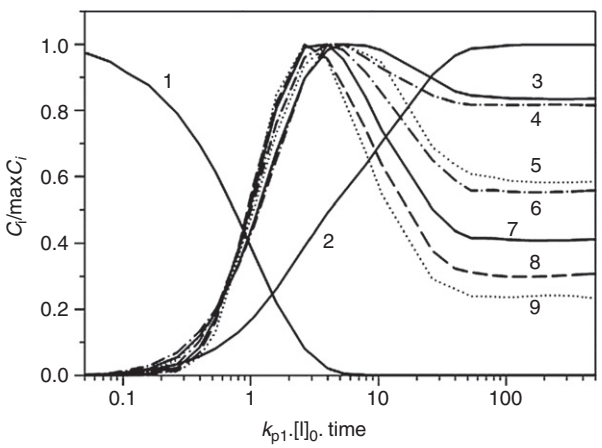

Figure 3 Kinetics of attaining the equilibrium concentrations of macrocycles of the size $x = 2$ to 9 in polymerization of ε-caprolactone computed for $[M]_0/[I]_0 = 22.7$ and the low initial monomer concentration $[M]_0 = 0.08\ mol\ l^{-1}$. The initial condition chosen to get a clearly visible effect of kinetic enhancement of macrocycles despite neglecting the endbiting reaction. Maximum concentrations of cyclics: 0.088 ($C_1 = [M]$), 0.0202 (C_2), 5.29×10^{-3} (C_3), 3.05×10^{-3} (C_4), 1.65×10^{-3} (C_5), 9.15×10^{-4} (C_6), 5.21×10^{-4} (C_7), 3.12×10^{-4} (C_8), 1.88×10^{-4} (C_9), all in $mol\ l^{-1}$. Reproduced with permission from Szymanski, R.; Baran, J. *Polimery (Warsaw)* **2003**, *48*, 758.[24]

macrocyclic product is slowly formed and interchain segmental exchange is also observed. Both these reactions lead to broadening of the molar mass distribution and the ring–chain equilibria can be reached after a much longer time than polymerization.

A special type of kinetic enhancement in linear polymer is observed when the polymerization is carried out via the activated monomer (AM) mechanism. Instead of active species located on the chain ends, the active species is located on some of the monomer molecules. Most often, such an activation proceeds via proton transfer reactions – protonated (cationic process) or deprotonated (anionic process) monomer can further react with the chain ends of linear polymer, increasing their lengths.

As the growing chain does not contain an active center, cyclization reactions are impossible or strongly hindered.

A case of AM polymerization of oxirane is briefly discussed in Section 4.04.6.2.

Specific kinetic enhancement in one type of macrocycle can sometimes be observed in enzymatically catalyzed processes. For instance, in lipase-catalyzed polycondensation of dimethyl terephthalate and diethylene glycol at first a series of cyclic oligomers is formed. Further, due to polymerization/depolymerization of them, almost exclusively a cyclic dimer is obtained[25] while the most stable oligomer is trimer.[26]

4.04.6 Ring–Chain Equilibria in Selected ROP Systems

A few ROP systems in which ring–chain equilibria are important are briefly discussed. No attempt was made to give a comprehensive review of various groups of ROP monomers but peculiarities of the ring–chain equilibria in each of the presented systems are indicated while describing their examples.

4.04.6.1 Ring–Chain Equilibria in Polysiloxane Systems

Polymerizations of cyclic siloxanes are systems in which ring–chain equilibria have been studied in detail for a long time. Following the usage of many authors, the dimethylsiloxane unit is denoted here as D, and consequently cyclic monomers of ring sizes 6, 8, 10, and so on, as D_3, D_4, D_5. Octamethylcyclotetrasiloxane (D_4) is the only significantly strained cyclic monomer of this group, polymerizing readily to a linear polymer (eqn [25]).

$$-P_n^* + D_4 \underset{k_{b4}}{\overset{k_{p4}}{\rightleftharpoons}} -P_{n+4}^* \qquad [25]$$

Depolymerization of poly(dimethylsiloxane) was postulated by Grubb and Osthoff[27] in 1955, but it was Scott[28] in 1946 who first determined the equilibrium concentrations of D_4, as well as of D_3 and several larger macrocycles (a few months earlier, the equilibration reaction between cyclic and linear polysiloxanes was reported by Wilcock[29]).

Polysiloxane systems were the most widely used by several authors to verify the theory of the ring–chain equilibria formulated by Jacobson and Stockmayer. This was because it was relatively easy to determine concentrations of macrocycles up to 200-membered rings and even larger.

Wright and Semlyen[17] have studied the effect of substituents in a polysiloxane system determining the equilibrium cyclization constants for cyclics $[R(CH_3)SiO]_x$, where R = H, Et, Pr, and $CF_3CH_2CH_2$.

There is a significant correlation between equilibrium cyclization constants K_x and the size of the substituent group R. The K_x values for the smallest nonstrained rings ($x = 4$ or 5) increase with the size of R: $H < CH_3 < CH_3CH_2 < CH_3CH_2CH_2 < CF_3CH_2CH_2$. However, the K_x values for the larger macrocycles decrease with increasing size of R and, for example, K_{12} for $[H(CH_3)SiO]_{12}$ is 10 times larger than K_{12} for $[CF_3CH_2CH_2(CH_3)SiO]_{12}$. Such a dependence on the substituent size can be explained by the steric interactions of R, influencing the numbers of possible low-energy conformations of the open-chain molecules. The cyclic tetramer and pentamer can adopt a number of strain-free conformations independently of the size of the studied range of substituents. However, as the group R increases, the number of low-energy conformations, which may be adopted by the corresponding linear chains are drastically reduced, resulting in the increase in the equilibrium cyclization constants K_x in the order of the increasing size of R. For larger macrocycles, which attain the prediction by the J-S theory proportionality of the equilibrium cyclization constants to the ring size in the power – 2.5, the key factor is the decrease in the 'flexibilities' of siloxane chains in the order

$$H > CH_3 > CH_3CH_2 > CH_3CH_2CH_2 > CF_3CH_2CH_2$$

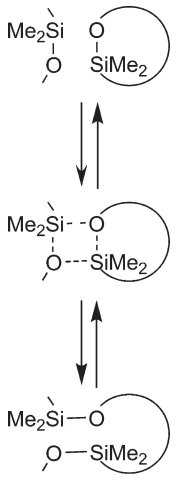
resulting in the parallel decrease in the chain end-to-end vector density $W_{12}(\mathbf{0})$. Consequently, the equilibrium cyclization constants decrease for larger macrocycles with the increase equilibrium in the substituent size.

Similarly, taking into account conformations of linear chains, Wright and Semlyen explain the observed differences in the characteristic minima observed in the log K_x versus log x plots for various R (an example of such a minimum can be seen in **Figure 2**). The minimum is not observed (only a slight inflection point at about $x = 12$) for R = H and for larger R it is shifted to higher values of x with the increase in the substituent size. Consequently, the plots show the limiting slope –2.5 for $x > 12$ and R = H but starting from $x > 25$ for $R = CF_3CH_2CH_2$.

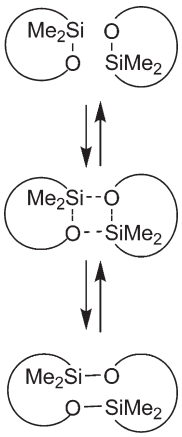
Thomas and Kendrick[30] observed the establishment of the ring–chain equilibria in systems of linear poly(dimethylsiloxane) at high temperatures without catalysts and interpreted their results as the effect of a siloxane-bond interchange reaction involving a four-center transition state. This reaction is in fact a ring-insertion/exclusion reaction (**Scheme 3**) (or ring-expansion/contraction reaction if only cyclic compounds are involved, cf. **Scheme 4**):

Bannister and Semlyen[31] studied an analogous reaction using both linear and cyclic oligo/poly(dimethylsiloxane)s as substrates at temperatures 623–693 K. When cyclic substrates were used, equilibration of the systems gave a product containing a typical cyclic fraction and a high-molar-mass product. The authors believed that the high-molar-mass polymer also had cyclic structure and was formed via siloxane-bond exchange reactions (ring-expansion/contraction reactions) (**Scheme 4**):

If only cyclic compounds are present, the reactions of ring expansion/contraction lead to ring–ring equilibria. However, the authors did not give any evidence that the high-molar-mass product had cyclic structure. Therefore, one cannot exclude that the high-molar-mass product observed by



Scheme 3 The ring-insertion/exclusion reaction proposed by Thomas and Kendrick[30] for thermal equilibration of poly(dimethylsiloxane) systems.



Scheme 4 The ring-expansion/contraction reactions proposed by Bannister and Semlyen[31] for poly(dimethylsiloxane) systems.

the authors is in fact a linear polymer formed from impurities or some degradation products acting as initiators of linear chains, and the ring-expansion/contraction reactions, if really operating in the systems, are only responsible for faster establishing of the ring–chain equilibria. The determined relatively low dispersity of the high-molar-mass polymer may be artificial because of a too low exclusion limit of the used chromatographic columns.

4.04.6.2 Ring–Chain Equilibria in Cyclic Acetals and Ethers Polymerizations

Cyclic acetals are very reactive in cationic conditions and both linear polymer and cyclic compounds are formed. Both types of cyclization (back- and endbiting) are important.

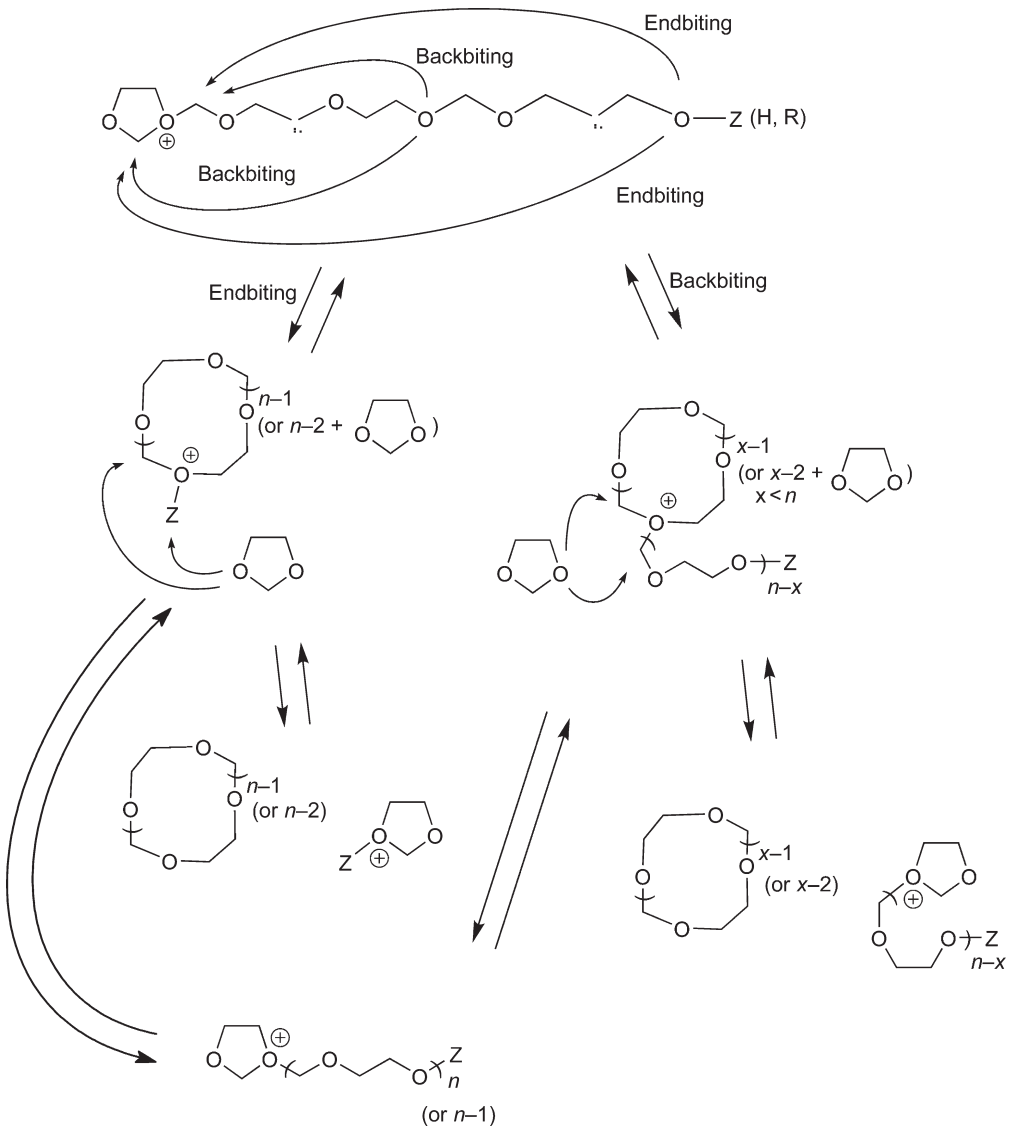
For instance, in polymerization of cyclic acetals the oxonium or oxocarbenium cation acting as the active center of propagation can react with the acetal groups located inside the polymer chain (backbiting) or with the end group, the nature of which depends on the used initiator. If polymerization was initiated with protonic acid, the end group is a hydroxy group. On the other hand, initiation with trialkyloxonium salts gives an ether end group. Both these groups are stronger bases than acetal groups, which causes that cyclization with their participation proceeds faster in comparison to the acetal groups located at the same distance from the active centers. Nevertheless, the kinetics of macrocyclization proceeds in these exemplary systems quite differently. The rates of both types of cyclization decrease with the cycle size proportionally to the probability of formation of the corresponding conformations of linear polymer (as discussed previously $k \sim x^{-3/2}$ for larger cycles). However, besides the relations between the rates of propagation, backbiting, and endbiting, other factors, such as the nature and kinetics of elementary reactions of two- or multistep cyclizations, determine as well the kinetic picture of polymerization.

The effects of the endbiting observed in polymerization of cyclic acetals can be explained as follows (Scheme 5). As an example of cyclic acetals, 1,3-dioxolane was chosen.

Because of low basicity of acetal oxygen atoms in comparison to the end groups in both systems, differing in the initiator used, cyclization involving end groups is faster than the analogous reaction (formation of rings of the same size) involving the acetal groups of polymer repeating groups. However, in order to get a free macrocycle, the intermediate macrocyclic oxonium cation has to react with any nucleophile present in the system (monomer, polymer unit, counter-ion, etc.), converting it to a free macrocycle. If the secondary oxonium cation is considered (protonated macrocycle) deprotonation as a proton transfer reaction is very fast, several orders of magnitude higher than the other possible reactions preventing formation of macrocycle. In Scheme 3, one of these side-reactions is shown, namely the reaction of an activated acetal methylene group (adjacent to the protonated oxygen atom) with monomer. Instead of monomer, shown as an example of a base for the proton transfer reaction, any other nucleophile present in the system, including polymer units or anion of the protonic acid used as initiator, can participate in such reactions. Consequently, as proton transfer reactions are very fast practically any macrocyclization reaction involving the hydroxy end group leads to a macrocycle released to the polymerization medium.

A different situation is when a tertiary macrocyclic oxonium cation involving the ether end group is formed. In order to get a free macrocycle, a reaction of nucleophile (monomer, polymer repeating unit, etc.) with the alkyl group from the end group is necessary. However, the acetal methylene group, also present at the tertiary oxonium atom, is much more reactive. Consequently, most cyclizations involving the ether end group are ineffective from the point of view of macrocycle formation, because predominantly they are followed by reactions of ring opening of the macrocyclic oxonium cation.

If reaction of backbiting is considered, involving the intrachain acetal group, the macrocyclic oxonium cation is about 50% converted to free macrocycle. This is because for nonstrained, sufficiently large cyclic oxonium cations, the reactivities of the two acetal methylene groups at the oxonium oxygen atom – endocyclic and exocyclic – are practically equal, which results in equal probabilities of endo- and exocyclic reactions. The exocyclic attack of monomer leads to free



Scheme 5 A simplified reaction scheme for 1,3-dioxolane polymerization initiated with protonic acid (Z=H) or an alkylating agent (Z=R). See text for differences in effectiveness of end- and backbiting in these systems.

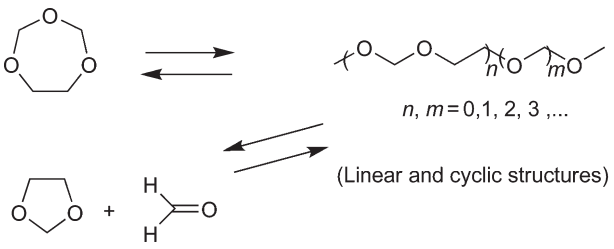
macrocycle and a shorter living linear chain, while the analogous endocyclic reaction leads to linear growing chain with the degree of polymerization increased by one unit in comparison to the macromolecule from which the macrocyclic oxonium cation was formed.

It is worth adding that because of at least two bonds (more in compounds with two or more acetal groups) which can be broken in monomer as well as in repeating units of polymer, the redistribution of polymer ends as well as the redistribution of polymer segments has to be considered in polymerization of cyclic acetals. If unsubstituted cyclic acetals with one acetal group, for example, 1,3-dioxolane, are considered only the effect of redistribution of chain ends and reshuffling of polymer segments leading to a faster attainment of the system equilibrium, can be observed. However, when an asymmetrically substituted monomer is polymerized, the effects of head-to-head and tail-to-tail structures and/or tacticity has to be additionally taken into account.

For instance, 4-methyl-1,3-dioxolane can be polymerized at low temperatures[32,33] giving macrocycles differing not only in sizes but also in their structure (structural and geometric isomers).

It is a special case of 1,3,5-trioxepane (TXP) as an example of a cyclic acetal monomer capable of creation of polymer segments as well as cyclic oligomers not being the simple multiplication of monomer units.[34] This monomer contains two acetal groups (and four acetal bonds, easily breakable in cationic conditions) and the real repeating segments in linear polymer and macrocycles, distributed statistically according to polymerization kinetics and the system thermodynamics, are oxymethylene groups (formally formaldehyde monomer units) and 1,3-dioxolane monomer units (Scheme 6).

Both formaldehyde and 1,3-dioxolane can be detected in the equilibrium besides monomer, polymer, and macrocycles. Polymer and macrocycles are composed of the mentioned repeating units, giving various microstructures and



Scheme 6 Equilibria in 1,3,5-trioxepane polymerization.

compositions. TXP can be considered as a composed monomer and the thermodynamic parameters for such a monomer cannot be determined simply on the basis of the measured equilibrium concentrations at several temperatures. Namely, the equilibrium monomer concentration (at high DP_n of linear polymer) is not equal to a reciprocal equilibrium constant of propagation (or to the equilibrium cyclization constant if the ring–chain equilibria are considered) but is also a function of the microstructure of linear polymer. The latter depends, for a given temperature, mainly on initial monomer concentration because the equilibrium concentration of 1,3-dioxolane constitutes a different fraction of the system of 1,3-dioxolane units depending on the system. As it was indicated first by Szwarc and Perrin,[35] and then the corresponding relationship corrected by Szymanski,[13] the equilibrium constant of propagation for 1,3,5-trioxepane K_{TXP} (equal to the reciprocal equilibrium constant of cyclization) can be computed, taking into account, besides the equilibrium concentration of TXP, the polymer composition:

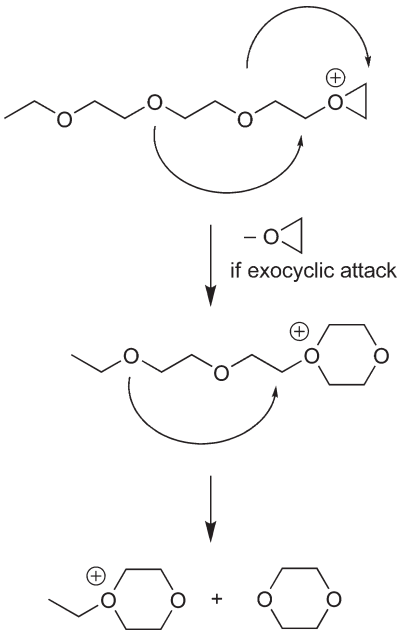
$$K_{TXP} = K_{cTXP}^{-1} = [TXP]^{-1} \frac{[-TXP-]^2}{[-E-]([-M-]-[-E-])} \qquad [26]$$

where K_{TXP} and K_{cTXP} are the equilibrium constants of TXP polymerization and of the corresponding cyclization, while –TXP–, –E–, –M–, denote TXP, oxyethylene, and formaldehyde units, respectively.

The general equation for determination of the equilibrium cyclization constants for the composed cyclics is in fact the one shown previously in Section 4.04.2 (eqn [24]), because the equilibrium in polymerizations of such monomers is the same as in copolymerization of corresponding simpler monomers (e.g., 1,3,5-trioxepane polymerization versus 1:1 copolymerization of 1,3-dioxolane and formaldehyde).

In ROP polymerization of cyclic ethers, oxiranes are the ones with the highest ring strain.[36] They can undergo the ring-opening reactions in anionic and cationic as well as in coordination processes. However, cyclization requires the reaction of the ether groups of linear polymer with active species and the only effective reaction proceeds with cationic species (and some dormant forms of them, like trifluoromethanesulfonate ester groups). As a result of fast cyclization, leading at first to nonstrained oxonium cations (preferably with six-membered rings when without bulky substituents), cyclic oligomers are formed (Scheme 7).

Consequently, linear polymer cannot be usually obtained because of kinetic enhancement in macrocycles connected with conversion of the active center of oxirane propagation to more stable nonstrained oxonium cations. Dale *et al.*[37] have observed that oligomerization of oxirane with BF_3 in



Scheme 7 Formation of 1,4-dioxane in cationic active chain-end (ACE) polymerization of oxirane. Larger cyclics can be formed in a similar way.

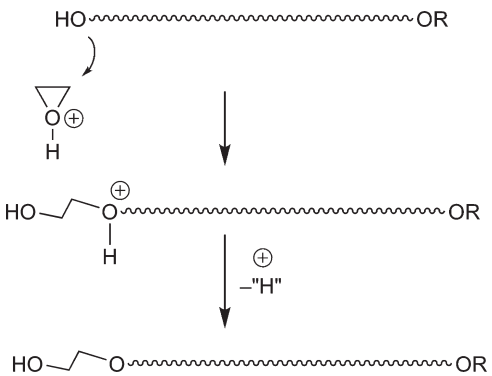
dichloromethane containing deuterated 1,4-dioxane gave after 8 h a product containing 85 wt.% of dioxane. Larger identified cyclic oligomers of oxirane were trimer to hexamer, in quantities, respectively: 1, 4, 1, 1 (wt.%), while still 8 wt.% of oxirane was unreacted. Linear product was not observed.

For bulky substituted oxiranes, the kinetic enhancement in cyclics are also observed but the main products of cyclization are tetramers.[38]

However, while applying the method of the AM polymerization, oxiranes can be polymerized to linear oligomers.

For instance, oxiranes in the presence of alcohols giving, as initiators, its hydroxy and alkyl groups to polymer chains can be polymerized via the AM mechanism while catalyzed with strong protonic acids (like $HAsF_6$, also generated *in situ* from, e.g., oxonium salts) (Scheme 8).

AM, reacting with the polymer hydroxy end group, forms intermediate secondary oxonium cation and after deprotonation a linear chain by one monomer unit longer. As the reactivity of hydroxy end groups toward AM is higher than toward ether groups of repeating units, linear oligomers can



Scheme 8 Activated-monomer polymerization of oxirane.

be obtained and such a polymerization can be treated as a process with kinetic enhancement in the linear polymer – ring–chain equilibria not reached in the polymerization time scale.

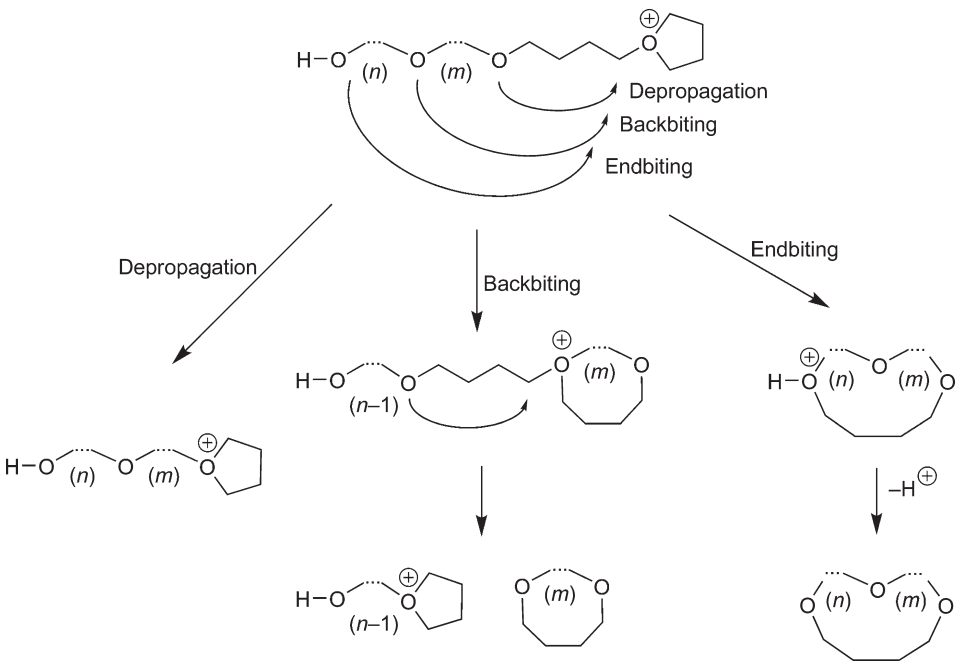
Formation of cyclic oligomers in cationic polymerization of highly strained four-membered cyclic ethers, oxetanes, seems to proceed in parallel with propagation and virtually stops when monomer is consumed.[39] The equilibrium is not attained probably because the active species of propagation are not stable and their terminated forms, like protonated polymer, formed after finished polymerization, are not effective in starting any cyclization reactions, unless a new portion of monomer is added.

Nonstrained cyclic ethers are much less reactive. Therefore, attaining the ring–chain equilibria takes much time despite the stability of active species (oxonium cations) in many systems. Nevertheless, formation of cyclic oligomers was reported for all common monomers belonging to this group.

Pruckmayr,[40,41] for instance, reported formation of cyclic oligomers in polymerizations of tetrahydrofuran (THF) initiated with both trialkyloxonium salts and trifluoromethanesulfonic acid (TfOH). As expected, more cyclic oligmers were observed in the systems with TfOH as initiator, although no kinetic enhancement in macrocycles was observed. It stems probably from higher reactivities of ether groups in polymer chain than of terminal hydroxy groups toward the exo- and endocyclic methylene groups of the five-membered oxonium cation – active center of THF polymerization. Additionally, a high effectiveness of backbiting leading to fast re-formation of the active center from the side-chain of the macrocyclic oxonium cation plays an important role in limiting the contribution of endbiting (see Scheme 9). In the scheme, cyclization reactions involve exocyclic methylene groups. However, formation of sufficiently large macrocycles via backand endbiting can also proceed with an attack on endocyclic methylene groups adjacent to oxonium atom (steric hindrance prevents this back attack breaking endocyclic O–C bond only in smaller rings).

4.04.6.3 Ring–Chain Equilibria in Cyclic Ester Polymerizations

In this section some systems of ROP of cyclic esters (of carboxylic acids, including carbonates) are reviewed from the point of view of importance of the ring–chain equilibria. All these monomers are capable of undergoing the ring-opening reactions involving the carbonyl group. The mechanisms of these reactions depend on the reagents used but independently of these mechanisms the eventual equilibria of linear polymer and cyclics, usually monomer and macrocycles, depend only on the structure of monomer and reaction conditions (dependences of the equilibrium concentrations of strained cyclics on temperature and of all cyclics on solvation phenomena). If monomer is significantly more strained than other cyclics, it is often possible to find an initiator creating an active center of polymerization reacting almost selectively only with monomer. Reactions with repeating units, either of its own chain, leading to macrocyclization, or of other macromolecules, resulting in reshuffling of polymer segments in and between chains, is much slower, sometimes negligible. In such systems, we have the kinetic enhancement in linear polymer, usually of low dispersity. The thermodynamic product containing macrocycles and the most probable distribution of chain lengths of linear polymer is not formed in applied polymerization times. An example of such a situation is polymerization of ε-caprolactone, which is strained only moderately ($\Delta H_{lc} = -28.8\ kJ\ mol^{-1}$)[42] and forms macrocycles easily while polymerized with most anionic, cationic, and coordination



Scheme 9 Macrocyclization in polymerization of THF initiated with strong protonic acids. The suspension points denote a number of repeating units (the numbers indicated in parentheses).

initiators. It can be polymerized to linear polymer of low dispersity when a coordination initiator creating active species with large steric hindrance is used.

Hofman *et al.*[43] presented a system of ε-caprolactone polymerization with suppression of macrocycle formation, observed when using $MeOAlEt_2$ as initiator. The authors explained the results by a high selectivity ratio of active species of propagation, reacting preferably with monomer, while cyclization reactions were much slower due to steric hindrance at the ACE. The following equation for the selectivity ratio, defined as the ratio of the propagation and cyclization rate constants ($k_{p1}/k_{c(n)}$), was derived:

$$\frac{\ln([M]/[M]_0)}{\ln\left(([C_n]_e - [C_n])/[C_n]_e\right)} = \frac{k_{p1}}{k_{c(n)}}[C_n]_e \qquad [27]$$

where k_{p1} is the propagation rate constant and $k_{c(n)}$ is the cyclization rate constant of formation of macrocycle of size n (C_n), brackets indicate concentrations of monomer and macrocycle, subscripts e indicate equilibrium values for high DP_n of linear polymer while 0 initial conditions (the equilibrium concentration of monomer is assumed to be close to zero).

This equation relates the concentrations of macrocycles in the polymerization system to monomer concentration. The higher the selectivity ratio ($k_{p1}/k_{c(n)}$), the lower is concentration of macrocycle at the given monomer concentration

$$[C_n] = [C_n]_e\left\{1-\left(\frac{[M]}{[M]_0}\right)^{\frac{k_{c(n)}}{k_{p1}[C_n]_e}}\right\} \qquad [28]$$

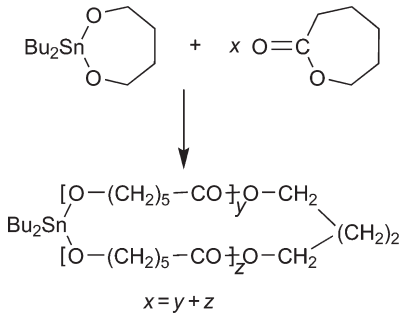
(equation obtained by rearrangement of eqn [27]).

Baran *et al.*[44] analyzed a series of initiators for polymerization of ε-caprolactone and found that for bulky active species in systems initiated with triisopropoxyaluminum the selectivity ratio, defined as the ratio of the propagation rate constant to the sum of cyclization rate constants (depropagation neglected), was equal to 3×10^5 while for anionic polymerization (sodium ethanolate) this ratio was equal only to 1.6×10^3.

Applying zinc octoate as initiator, forming also bulky active species, allowed high-molar-mass poly(ε-caprolactone) ($M_n \sim 4 \times 10^5$) to be obtained with no cyclic oligomers formed.[45]

Florczak and Duda,[46] while using as initiator aluminum alkoxide with a didentate, bulky ligand of the R or S configuration, 2,2′-[(1,1′-binaphthalene-2,2′-diyl)bis(iminomethyl)] diphenoxide, observed negligible formation of macrocycles not only in polymerizations of ε-caprolactone and L,L-lactide, but also in copolymerizations of these monomers. Additionally, applying enatiomerically pure R or S forms of the initiator or their mixtures they could get copolymers of various controlled microstructures.

Kricheldorf published a series of papers indicating that the ring-expansion polymerization of various monomers can be carried out when appropriate initiators are used (e.g., Reference 47 and references therein). Applying cyclic tin alkoxides, he managed to obtain tin-containing cyclic polyesters. For instance, when 2,2-dibutyl-1,3,2-dioxastannepane (2,2-dibutyl-2-stanna-1,3-dioxepane, DSDOP) was used as initiator in polymerization of ε-caprolactone the product was cyclic polymer formed by addition to the initiator ring a number of monomer molecules.[48] Although polymerization



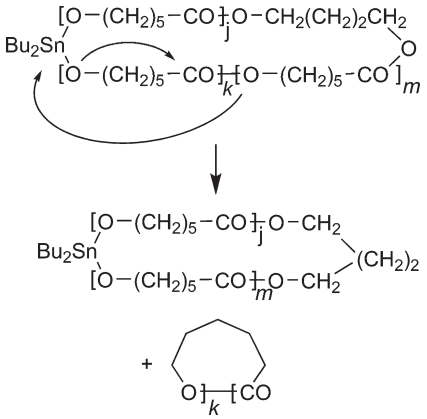
Scheme 10 Polymerization of ε-caprolactone via monomer insertion to cyclic dialkoxydialkyltin species.[48]

resembled a living process, the dispersity of the product was about 1.5, much higher than expected. If the ring–ring equilibrium is considered, the process can be treated as a kinetic enhancement in rings containing one initiator unit (Scheme 10).

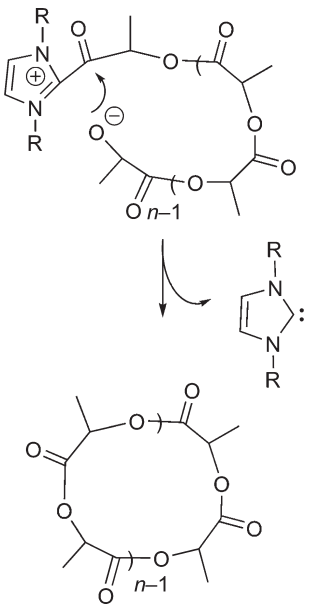
The thermodynamic product would contain oligomers of ε-caprolactone as well, formed in ring-contraction reactions (Scheme 11). Cyclics containing more than one tin atom, formed in statistically less frequent reactions of ring-expansion/contraction of tin-containing macrocycles.

If a reaction route leading to linear polymer were available, which cannot be excluded, the ring–chain equilibria should be considered as well. Unfortunately, no equilibrium was established in the studied systems and therefore no comparison with the ε-caprolactone ring–chain equilibria could be performed.

A special case of kinetic enhancement in macrocycles is observed when a zwitterionic polymerization of lactide was carried out. Waymouth and co-workers[49,50] have observed formation of cyclic polymer of M_n up to 3×10^4 and dispersity below 1.3 when polymerization was initiated by heterocyclic carbene (1,3-dimesitylimidazol-2-ylidene). It stems probably from propagation being much faster than cyclization and end-biting being much faster than backbiting. The latter can be explained by the reaction of oppositely charged chain-ends, located close to each other more frequently than can be expected for neutral chains (Scheme 12).



Scheme 11 The ring-contraction reaction of the tin-containing macrocycles of poly(ε-caprolactone) system leading to ε-caprolactone cyclic oligomers.



Scheme 12 Formation of macrocycles in zwitterionic polymerization of lactide.[49]

Kinetic enhancement in cyclics was also observed by Kricheldorf *et al.*[51] in polymerization of L-lactide with imidazole. The authors proposed the mechanism of formation of cyclics via endbiting, involving the increased reactivity of the carbonyl group of terminal polymer unit bonded to the imidazole moiety. However, the participation of the zwitterionic structures cannot be excluded here as well.

Macrocyclic oligoesters are often convenient monomers for preparation of high-molar-mass polymer. They have advantages over polycodensation monomers (e.g., diacid/diol monomers) because no by-product has to be removed during polymerization, the process can be carried out usually at lower temperatures, and the viscosity of the polymerization mixture is lower. Polymerization of macrocyclic oligoesters, as an entropy-driven process with often negligible enthalpic effect, has no technological limitations of the polymerization volume because of the heat transfer problems. The only important drawback of polymerization of macrocyclic oligoesters is their limited availability.

Ballone and Jones[52,53] studied ROP of cyclic oligomers of Bisphenol A polycarbonate using density functional calculations of the structure, potential energy surface, and reactivity of species. In their Monte Carlo simulations, the authors demonstrated that entropy in redistribution of interparticle bonds was the driving force for chain formation in the studied polymerization of macrocycles.

Several methods of preparation of such macrocyclic monomers, capable of polymerization to high-molar-mass polymers, were described in literature. Virtually all of them are reviewed in two sections of the 'Cyclic Polymers' book edited by Semlyen.[54,55] The most important two methods of them are:

1. high-dilution polycondensation of corresponding monomers, for example, preparation of macrocyclic carbonates in polycondensation of bis(chloroformate) of 4,4′-isopropylidenediphenol (BPA) with BPA (and its monochloroformate, both formed *in situ* from BPA dichloroformate);[56]
2. depolymerization of linear polyesters, for example, of poly(propane-1,3-diyl succinate) yielding a distillate containing 89% of cyclic dimer and 9% of cyclic monomer.[57]

Cyclic oligomers of poly(ethylene terephthalate) (PET) can be obtained by both mentioned methods.[58] The authors also studied polymerization of cyclic oligomers of PET and found that they readily polymerize if hydroxy-containing compounds are added. Without addition of such initiating species, cyclic tris(ethylene terephthalate) polymerizes extremely slowly even at temperatures up to 300 °C.

Preparation of high-molar-mass polyesters from cyclic oligomers seems to be a promising route. In literature, many such processes were described. For instance, many cyclic carbonates of bisphenols (mixtures of oligomers) could be polymerized to high-molar-mass polymers.[59,60]

Applications of macrocyclic oligomers of engineering thermoplastics (not only oligoesters) were reviewed by Brunelle.[61]

4.04.6.4 Ring–Chain Equilibria in Other ROP Systems

Ring–chain equilibria or reversible formation of cyclic oligomers were observed in ROP polymerizations of all other groups of ROP monomers. However, no detailed descriptions of the corresponding systems will be given in this section of the review, and many monomer groups will not be even mentioned. The interested reader can find the corresponding literature relatively easily.

In this section, only the most important groups of ROP systems, in which the ring–chain equilibria are important, but not discussed previously, are presented.

4.04.6.4.1 Cyclic oligomers of polylamides

The chain–ring equilibria are often observed in systems of polyamides. Independently of the route of preparation of polymers (polycondensation, polymerization of lactams, or other cyclic amides, including cyclic oligomers) the ring–chain interconversions are often important and cannot be neglected. However, the equilibrium conditions usually are not reached and often only kinetic distributions can be observed.

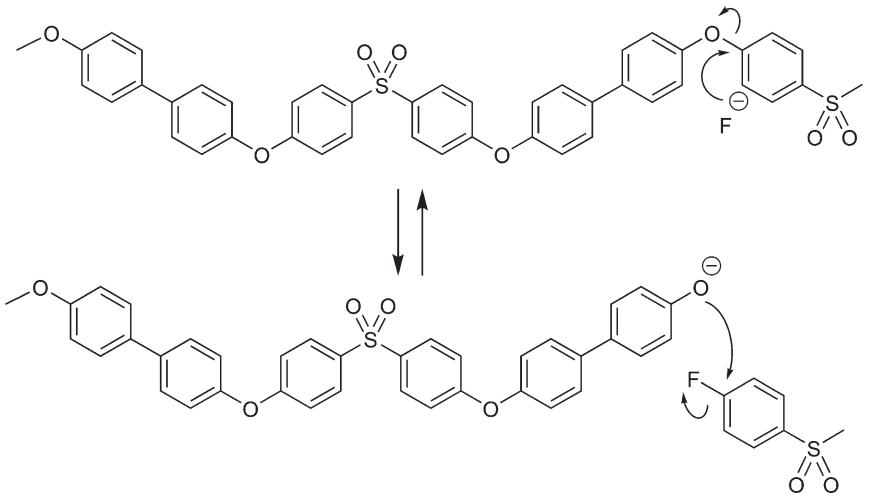
Oligo/macrocyclic polyamides are frequent contaminations of commercial polyamides, like various Nylons, and often have to be removed by extraction with hot water.[62–64]

According to Mori *et al.*,[65] the content of cyclics in polycaprolactam reaches about 10% (8% monomer), while in poly(dodecano-12-lactam) 1.5% (0.3% monomer).

Gupta *et al.*[66] simulated polymerization of caprolactam including all important reactions: reversible ROP, polycondensation, polyaddition, and cyclization reactions as well as the reaction with monofunctional acids and found that reactions constituting the ring–chain equilibria influence the molar mass distribution of product.

4.04.6.4.2 Cyclic poly(aryl ether)s

Cyclic poly(aryl ether)s containing electron-withdrawing groups, enabling nucleophilic substitution in aromatic rings, can be polymerized with nucleophilic initiators.[67–69] These oligomers are usually prepared by condensation, but the proposed mechanisms of polymerization and the often observed presence of cyclic oligomers in product suggest that polymerization is reversible and degradation of high-molar-mass

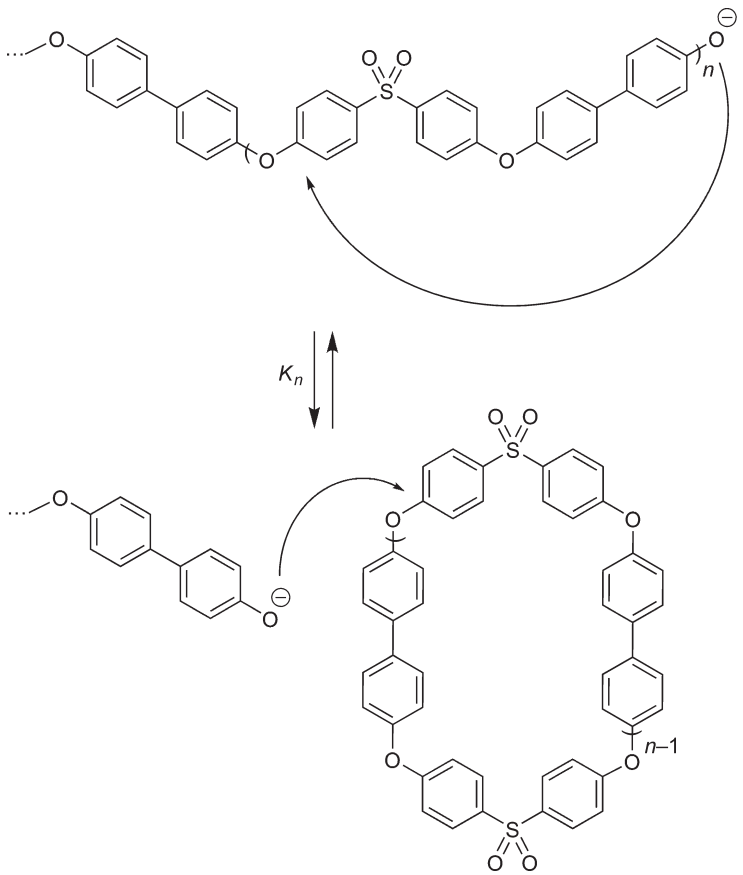


Scheme 13 Reversible initiation of cyclization processes with fluoride anion in poly(aryl ether) systems.[68]

polymer carried out in dilute solution could also give cyclic oligomers if a proper initiator was chosen.

Colquhoun *et al.*[68] managed to obtain cyclic oligomers from poly(ethersulfone), poly(oxybiphenyl-4,4′-diyloxy-1,4-phenylenesulfonyl-1,4-phenylene), by initiating the process with fluoride anion in dilute dimethylacetamide solution (Scheme 13).

After getting cyclic oligomers via cyclodepolymerization, the authors polymerized them using as initiator cesium salt of 4-benzoylbenzene-1-thiol getting linear polymer of rather high dispersity ($M_w = 151\,000$, $M_n = 26\,000$, and a level of residual macrocyclic oligomers of ~4%). Unfortunately, no studies have been performed to determine equilibrium constants of the ring–chain equilibria (Scheme 14).



Scheme 14 Cyclizations in poly(aryl ether) systems and polymerization of cyclic oligomers.

4.04.6.4.3 Metathesis ROP systems

Many cyclic hydrocarbons containing unsaturated bonds (double or triple carbon-to-carbon bonds) can undergo ROP via metathesis reaction. These processes are usually reversible and cyclic oligomers are often observed as kinetic or thermodynamic side-products. In this section, no details of polymerization processes will be given. The interested reader can consult some reviews on metathesis polymerizations[70–72] and original papers cited therein. Here, only some specific features of ring–chain equilibria in metathesis ROP (ROMP) are mentioned and briefly discussed.

Cycloolefins as well as resulting linear and cyclic oligomers and linear polymers can have *cis* and *trans* configurations at the C=C bond. Depending on the catalyst used and possible mechanisms of polymerization, we can expect various types of interconversions. Configuration of the C=C bond in monomer may be either preserved after incorporation into polymer chain or changed, or both possible configurations in polymer can be formed. Similar problems can be expected if cyclizations leading to cyclic oligomers are analyzed. Besides, if substituted cycloolefins are polymerized structural isomerism (head-to-tail and head-to-head structures) and/or tacticity has to be taken into account.

All these structural variations imply differences in linear chain conformation distributions depending on chain structure.

The observed dependence of the cyclization rate constants on the number of monomer units was often steeper than expected from the J-S theory ($K_x \sim x^{-2.5}$) and explained by nontheta solvent conditions. The exponent was usually expressed as $-(2+a)$, where a, the exponent of the Mark–Houwink relation between intrinsic viscosity and molecular weight, was found to be, for instance, 0.68 for cyclooctene oligomers in chlorobenzene,[72] 0.67 for poly(1-octene-1,8-diyl)/toluene,[73] and 0.72 for polybutadiene/toluene.[74]

The equilibrium cyclization constants in respect to *cis–trans*, as well as to structural or configurational isomerism in ROMP, was not studied in detail. However, after analyzing the distribution of *cis trans* configurations, Thorn-Csányi and Ruhland[75] observed that the proportion of ttt to ctt trimeric rings in the equilibrium of 1,4-polybutadiene system ($-CH_2CH{=}CHCH_2-$) was about 9 in toluene and 10 in cyclohexane, while the ratio of *trans* to *cis* configurations in linear polymer was 83:17. The exclusively entropically controlled backbiting process should, according to the authors, give the same *cis*/*trans* ratio in cyclics of all sizes. Therefore, these results for cyclic trimers, and the differences also observed for larger cyclics, indicate that some other factors, enthalpic in nature, such as exothermic formation of trimers, influence the ring–chain equilibria as well.[76]

4.04.7 Conclusions and Outlook

The ring–chain equilibration is a phenomenon frequently observed in ROP systems. Most often, it is treated as disadvantage disallowing a high-molar-mass polymerization product to be obtained. Knowledge of mechanism, kinetics, and thermodynamics of the ring–chain equilibria often allows the problems in obtaining a high-molar-mass products with negligible content of macrocycles to be overcome. However, for some systems, ring–chain equilibria can give access to low-molar-mass cyclics allowing the polymerization of them in a more controlled way than in direct polycondensation routes from initial substrates. Moreover, macrocycles, capable of being polymerized or used in other chemical processes, can often be produced from waste polymeric materials. Thus, ring–chain equilibria enable the recycling of such materials, which is becoming more and more important nowadays when environmental issues cannot be neglected.

Biographical Sketch

Ryszard Szymanski received his MS degree in organic synthesis from the Technical University at Lodz, Poland, in 1972. In the same year, he started his work at the Center of Molecular and Macromolecular Studies of the Polish Academy of Sciences (CMMS), Lodz, Poland, as research assistant. He worked in Professor Stanislaw Penczek's group and earned his PhD in 1980 in polymer chemistry. His PhD thesis was devoted to the reactions of alkoxymethylium cations with ethers and acetals as models of cyclic acetal polymerization. In 1981, he was a postdoc at Professor H.K. Hall's laboratory, in Tucson, Arizona, investigating polymerization of bicyclic orthoesters. After returning to Poland, he continued his work as an adjunct professor in the field of ROP in CMMS with Professor Penczek. His main interests are the mechanisms and kinetics of polymerization of cyclic monomers. In his work, he has developed computer simulation techniques. In 1994, he spent 6 months with Professor K. Matyjaszewski in Pittsburgh, Pennsylvania, where he studied the mechanism of cationic polymerization of styrene using computer simulation methods. After returning to CMMS, he received his DSc degree with the thesis on problems connected with equilibrium in copolymerization. He continues his work in CMMS as an associate professor in the Laboratory for Computer Simulations.

4.05 Equilibrium Copolymerization in Ring-Opening Polymerization

R Szymanski, Polish Academy of Sciences, Lodz, Poland

4.05.1 Phenomenon of the Equilibrium Copolymerization in Ring-Opening Polymerization

The general scheme of a ring-opening (RO) copolymerization contains, besides initiation and propagations (homo- and cross-propagations), additional processes. Among the many RO copolymerizations, the most important are processes that lead to depolymerization, usually homo- and cross-depropagations – the reverse reactions of the corresponding propagations. In many reversible RO copolymerizations, we have to also take into account reversible macrocyclizations, which can be regarded as depropagations and propagations of the composed monomers (built of two or more copolymer repeating units). All these reactions, together with another important reaction in many systems, namely, the segmental exchange leading to redistribution of copolymer repeating units, are shown in the simplified scheme of the reversible RO copolymerization (**Scheme 1**).

Depending on the relationships between the rates of reactions operating in the RO copolymerization shown in **Scheme 1**, we can have either a purely kinetically or thermodynamically controlled product or a copolymer that is neither of these when contributions of kinetic and thermodynamic control do not differ much or change during copolymerization. Similarly, when depropagations are slow but the segmental exchange (reshuffling) fast, a copolymer can resemble a thermodynamic product when the copolymer microstructure is analyzed, although its composition can correspond to the kinetic control.

The overall equilibrium in copolymerization requires attaining in the system the equilibrium composition and microstructure of a copolymer and the equilibrium concentrations of comonomers and all linear and cyclic oligomers and polymers. When the rate constants of all reactions operating in the system are known, the equilibrium conditions (concentrations of all reagents and the average parameters describing a copolymer such as contents of copolymer units and various sequences) can be predicted. As shown in Section 4.05.3, the equilibrium condition depends on the initial composition of the copolymerization system. However, kinetic restrictions can result in not reaching the overall equilibrium. Still, if the copolymer composition and microstructure are thermodynamically controlled, the process can be called an equilibrium copolymerization.

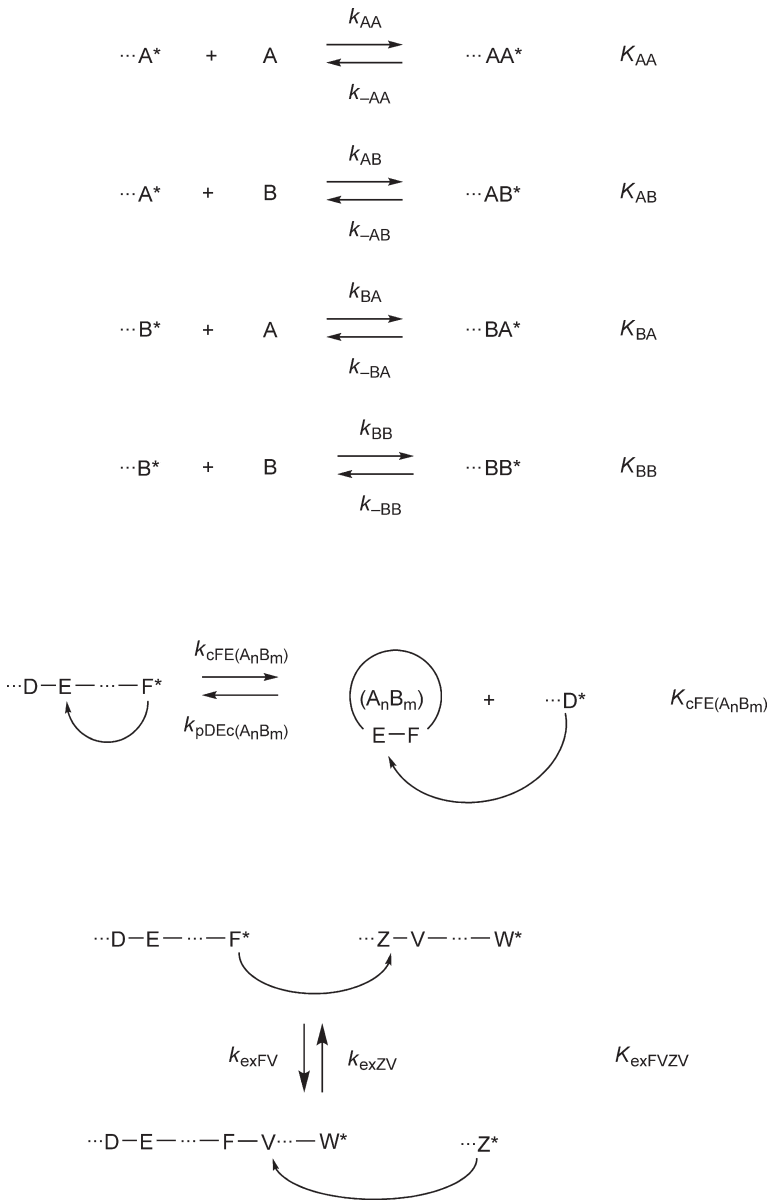
A specific case of the RO equilibrium copolymerization is one that is concerned with systems without a linear polymer, involving only (besides activators/catalysts) RO comonomers and cyclic oligomers and polymers, and in which equilibrium can be reached by ring expansion/contraction and/or ring fusion/fission reactions. Such systems are briefly discussed in one of the sections below.

4.05.2 The Concept of the Equilibrium Copolymerization

In literature the term 'equilibrium copolymerization' has two distinct meanings. The first meaning is copolymerization system at equilibrium, that is, the copolymerization system in the state when all propagation/depropagation reactions have reached their equilibrium (**Schemes 1** and **2**).

The equilibrium in all these reactions ensures that the equilibrium of the segmental exchange (cf. **Scheme 1**) is reached as well, independently of the rates of these reactions.

When the reaction routes leading to macrocyclization are available, the real equilibrium requires equilibration of the ring-chain interconversions (cf. **Scheme 1**) as well.



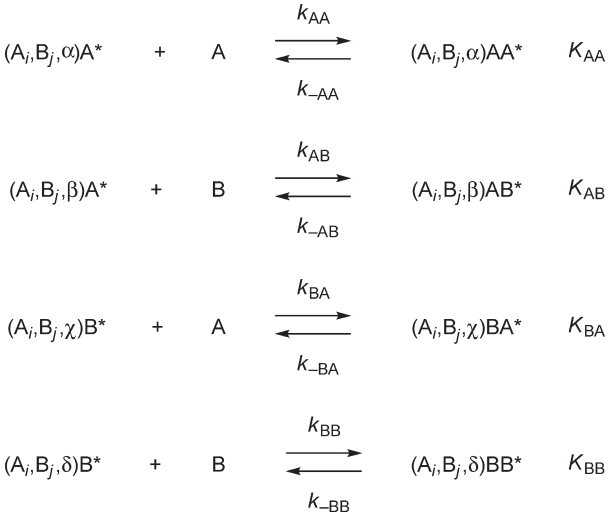
Scheme 1 A simplified scheme of an equilibrium binary RO copolymerization. Only the dyad model of propagation and depropagation reactions, reversible cyclizations, and segmental exchange reactions are shown. Equilibrium constants of the corresponding reactions (denoted with the capital letter *K* with subscripts) are equal to the ratios of the corresponding rate constants. D, E, F, V, W, and Z denote copolymer units A and/or B.

Unfortunately, the timescale of reaching the overall ring-chain equilibrium is usually much larger, and, therefore, most often, macrocyclization is not taken into account when the equilibrium copolymerization is analyzed.

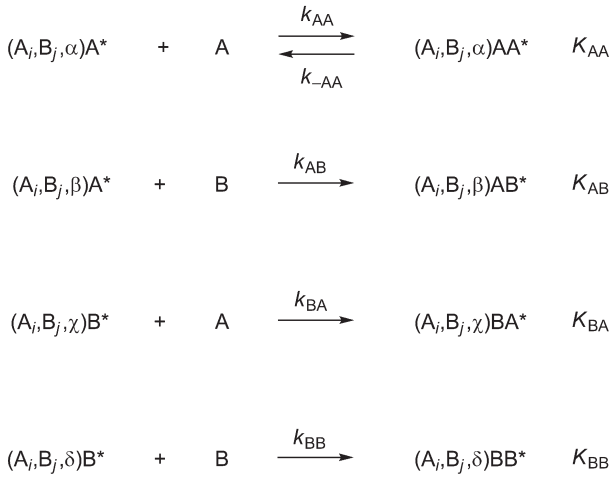
The second meaning of the 'equilibrium copolymerization' is a copolymerization process carried out in conditions when at least one of the reversible propagations is practically at equilibrium, that is, propagation (homo- or cross-propagation) is counterbalanced with the corresponding depropagation. Because other propagations are not at equilibrium, the conversion of all comonomers can proceed and be relatively high and contribution(s) of dyads (sequences) formed in the equilibrated propagation(s) can sometimes be significant. One of these types of the equilibrium copolymerization is shown schematically in **Scheme 3**.

Similarly, to this type of the equilibrium copolymerization belong systems with the equilibrated cross-propagation and systems where the equilibria are maintained for more than one propagation and/or in which all or some of the nonequilibrated propagations are reversible.

Some of the equilibrium copolymerizations of this type were kinetically analyzed by Lowry,[1] Hazell and Ivin,[2] Yamashita *et al.*,[3] and Wittmer,[4] who derived equations for the composition of a copolymer in systems with reversibility of some reactions in triad (or some in dyad) model copolymerizations. Although the analyzed systems are concerned with



Scheme 2 Equilibria of propagations in copolymerization hold for any chain length and copolymer sequences (i, j = 0, 1, 2, …; α, β, χ, and δ indicate symbolically all possible copolymer unit sequences).



Scheme 3 Equilibrium copolymerization with only one homopropagation being in equilibrium and other propagations being irreversible.

vinyl monomer copolymerizations, the derived equations can also be used for RO polymerization systems.

Because of the decreasing equilibrium concentrations of monomers, the equilibrium copolymerization often allows polymerization of RO monomers, which do not homopolymerize.

Some examples of such processes are shown in the following sections of the chapter.

4.05.3 Copolymerization Equilibrium

The term 'equilibrium copolymerization' was introduced by Alfrey and Tobolsky in 1959,[5] who stated that, mathematically, the equilibrium in copolymerization is identical with the Ising problem in ferromagnetism, which leads to the same solution. Consequently, the authors formulated the most important equation relating the composition of the equilibrium copolymer with the equilibrium constant, at that moment not yet related with chemical reactions:

$$\frac{(N_A - M_{AB})(N_B - M_{AB})}{M_{AB}^2} = K = \left(\frac{f_{AA}f_{BB}}{f_{AB}^2}\right)\exp\left(\frac{\Delta E_{AB}}{RT}\right) \quad [1]$$

where N_A and N_B are the numbers of monomeric units A and B, respectively, and M_{AB} is the number of dyads AB (equal to the number of dyads BA as the infinite chain length approximation was assumed). According to Alfrey and Tobolsky, K is an equilibrium constant expressed in terms of vibrational partition functions f_{AA}, f_{BB}, and f_{AB} and the energy change ΔE_{AB}. ΔE_{AB} is equal to the corresponding differences per mole of bonds AA, BB, and AB ($2E_{AB} - E_{AA} - E_{BB}$).

A few years later, Tobolsky and Owen[6] showed that the equilibrium copolymer composition is related to the propagation equilibrium constants in simple systems such as the copolymerization of sulfur with selenium (the terminal model of copolymerization without any effect of ultimate units, i.e., $K_{AA} = K_{BA}$, $K_{BB} = K_{AB}$; cf. propagation equations of Scheme 1).

It was Izu and O'Driscoll[7] who first formulated the equations describing the relationships between the equilibrium copolymer composition and microstructure, the equilibrium comonomer concentrations, and the equilibrium constants of the dyad model of copolymerization – the model most often used in the analysis of copolymerization processes. On analyzing the probabilities of finding copolymer units at various positions of copolymer chains, the authors obtained the following relationships:

$$[A]_e = \frac{\varepsilon}{K_{AA}} \qquad [B]_e = \frac{\eta}{K_{BB}} \quad [2]$$

$$K_{AB}K_{BA} = \left(\frac{1}{[A]_e} - K_{AA}\right)\left(\frac{1}{[B]_e} - K_{BB}\right) \quad [3]$$

$$\frac{K_{AB}K_{BA}}{K_{AA}K_{BB}} = \left(\frac{1-\varepsilon}{\varepsilon}\right)\left(\frac{1-\eta}{\eta}\right) \quad [4]$$

$$F_A = \frac{1-\eta}{2-\varepsilon-\eta} \qquad F_B = \frac{1-\varepsilon}{2-\varepsilon-\eta} \quad [5]$$

$$F_{AA} = \frac{\varepsilon(1-\eta)}{2-\varepsilon-\eta} \qquad F_{BB} = \frac{\eta(1-\varepsilon)}{2-\varepsilon-\eta} \quad [6]$$

$$F_{AB} = F_{AB} = \frac{(1-\varepsilon)(1-\eta)}{2-\varepsilon-\eta} \quad [7]$$

where F_A, F_B, F_{AA}, F_{BB}, F_{AB}, and F_{BA} are the mole fractions of the indicated copolymer units or dyads in the equilibrium copolymer; ε and η are the conditional probabilities of preceding the unit A and unit B, respectively, by a unit of the same kind.

On analyzing the above equations, which enable us, after adding the mass–balance relationships, to calculate the equilibrium conditions of binary copolymerization, we can easily find that the equilibrium constant K from Alfrey and Tobolsky's equation (eqn [1]) is equal to the ratio of products of cross- and homopropagation equilibrium constants, $(K_{AB}K_{BA})/(K_{AA}K_{BB})$.

In another paper, Howell with Izu and O'Driscoll[8] related the triad model of copolymerization equilibrium constants to the microstructure and composition of the equilibrium copolymer. Also, analysis of a multicomponent equilibrium copolymerization was presented.[9]

Most of the equations, derived by O'Driscoll and co-workers with the assumption of infinite chains, appeared to be valid also for the equilibrium systems with low X_n (number-average degree of polymerization), which was shown by Szymanski[10] in his analysis of equilibrium in copolymerization systems.

4.05.3.1 Comonomer Equilibrium Concentrations

Concentrations of comonomers at the copolymerization equilibrium are lower than those in homopolymerizations, provided no specific interactions/solvation play important roles in distinguishing these systems qualitatively or quantitatively. The decrease in the monomer equilibrium concentration in copolymerization stems from the decrease in the proportion of homosequences. For instance, for the dyad model of copolymerization, when we assume the same value for the equilibrium constant of homopropagation (no specific interactions) as in homopolymerization (cf. **Scheme 2**), the following equation for the equilibrium concentration of monomer A can be formulated, independently if homo- or copolymerization is considered:

$$[A]_{eq} = \frac{[-AA^*]}{[-A^*]K_{AA}} \quad [8]$$

where K_{AA} is the corresponding equilibrium constant of homopropagation; subscript eq refers to the equilibrium conditions (omitted from brackets denoting concentrations of active species); -AA* and –A* denote, respectively, the active chain ends terminated with the indicated dyad or unit; –A* includes the species with terminal dyads (–AA*), but besides them it contains linear unimers (XA*, where X denotes the fragment coming from the initiator) and in the case of copolymerization chains terminated with a heterodyad –BA* ($[-A^*] = [XA^*]+[-AA^*]+[-BA^*]$). Consequently,

$$\begin{aligned} \{[A]_{eq}\}_{homo} &= \frac{[-AA^*]}{[-A^*]K_{AA}} = \frac{[-A^*]-[XA^*]}{[-A^*]K_{AA}} \\ > \{[A]_{eq}\}_{co} &= \frac{[-AA^*]}{[-A^*]K_{AA}} \\ &= \frac{[-A^*]-[XA^*]-[-BA^*]}{[-A^*]K_{AA}} \end{aligned} \quad [9]$$

where subscripts homo and co correspond to homo- and copolymerization, respectively. The decrease in the equilibrium concentration in copolymerization is very large when the equilibrium copolymer resembles the alternating copolymer ($[-A^*] \approx [XA^*] + [-BA^*]$) and very small when the equilibrium copolymer microstructure can be characterized by large blocks, that is, low content of heterodyads and high average lengths of homosequences ($[-BA^*] \approx 0$).

This phenomenon of decreasing the equilibrium concentration of the monomer in copolymerization is essential to understanding why for some monomers it is not possible to obtain homopolymer but copolymers often can be obtained. Simply, the equilibrium constant of polymerization for a non (homo)polymerizing polymer (K_{AA}) is low (because of thermodynamic reasons), and its reciprocal corresponding to the equilibrium monomer concentration ($[A]_{eq(homo)} \approx 1/K_{AA}$) is higher than the concentration of the monomer in bulk. When an appropriate comonomer is found capable of forming effective heterodyads, the equilibrium concentration of a non-homopolymerizing monomer can drop below the bulk (or solution) concentration and the formation of a copolymer is thermodynamically possible. When the formation of heterodyads is strongly favored or the equilibrium constants of homopropagation are not too low (and moderate formation of heterodyads is sufficient), it is possible to form a copolymer from two (or a larger number of) the non-homopolymerizing monomers. The content of heterodyads in such a copolymer formed from non-homopolymerizing comonomers is higher than that in a random copolymer. If specific interactions operate in the system such that the apparent equilibrium constants are dependent on the system composition, then this restriction does not hold, as indicated in Section 4.05.4.1.

However, the dependence of the comonomer equilibrium concentrations on the equilibrium constants of homo- and cross-propagations and on the copolymerization feed is complex.

The aforementioned papers by O'Driscoll and co-workers[7–9] give access to the equilibrium concentrations of comonomers and copolymer sequences for systems when the infinite chain length approximation can be applied. In the next section, the relationships that enable us to compute all equilibrium features of copolymerization without any restrictions of the length of copolymer chains are presented. Quantities such as the equilibrium concentrations of comonomers and chains of any given sequence of copolymer units, X_n (number-average degree of the polymerization of copolymer chains), D_X (dispersity of copolymer chain lengths), and contributions of various sequences can be computed on the basis of the assumed model of copolymerization.

There is also a special case of the equilibrium copolymerization when no linear polymer is formed and the equilibrium is exclusively established between cyclic compounds: comonomers and cyclic homo- and copolymeric oligomers and polymers. Such an equilibrium can be observed only in those

systems in which no initiator of linear polymerization is added and only reactions of ring expansion/contraction and/or ring fusion/fission can operate, often catalyzed by the added catalyst or initiated with a cyclic initiator. A series of papers on the formation of cyclic RO polymers were published by Kricheldorf[11] (and see references listed therein), but there were none in which the equilibrium was quantitatively analyzed. The present author in another contributed chapter (see Chapter 4.30) discussed this problem, arriving at the conclusion that the concentrations of cyclic oligomers and polymers in systems without linear polymers are only slightly larger than those in which the ring-chain equilibrium was established. The reader can also look into that chapter to find the analysis of the ring-chain equilibrium in copolymerization.

4.05.3.2 General Treatment of Copolymerization Equilibrium

The general treatment of the copolymerization equilibrium without restrictions of the chain lengths was first presented by Szwarc and Perrin,[12] who delivered a mathematical solution for any number of comonomers but restricted to the dyad model of propagation. Applying equations derived by Szwarc and Perrin, we can compute the concentrations of chains of any length and the sequence of copolymer units and consequently can compute any statistical feature of the system, such as the equilibrium concentrations of any dyad, triad, or longer sequence of copolymer units. However, their solution cannot be applied to systems in which $K_{AA}K_{BB} = K_{AB}K_{BA}$, which results in singularity of matrixes used in computations.[13] This is an important drawback of the presented treatment, because many copolymerizations can be characterized as ideal, that is, those in which the difference between the Gibbs energies for the addition of any of the two comonomers to the same active center depends only on these comonomers. For such systems, $K_{AA}K_{BB} = K_{AB}K_{BA}$ and the equilibrium copolymer has a random microstructure. Then, a solution of this problem was suggested,[14] which would have, however, to be changed considering that generally $[^0A_1]/[^0B_1] \neq [^0A_2]/[^0B_2]$, where subscripts indicate the length of oligomers with the indicated comonomer unit at the starting position (hence superscripts 0).

Another general treatment of the copolymerization equilibrium was provided by Szymanski,[10] who used, while deriving his relationships, similarly as O'Driscoll and co-workers,[7–9] the 'reverse' conditional probabilities (of a copolymer unit to be preceded by the same or a different unit). This treatment looks simpler than the one proposed earlier by Szwarc and Perrin,[12] and similarly their equations can be applied to the systems of any number of comonomers and any average degree of polymerization. The proposed solution also applies to the systems of ideal copolymerization ($K_{AA}K_{BB} = K_{AB}K_{BA}$). Besides, the method can easily be extended to the triad model of copolymerization (corresponding equations are shown in the appendix of Reference 10).

When the dyad model of copolymerization equilibrium constants and initial conditions are known, the basic features of the equilibrium system (without cyclizations) can be found by solving a set of $4i$ equations, where i is the number of comonomers, denoted below as A, B, …, H:

$$\begin{bmatrix} (1-K_{AA}a) & -K_{AB}b & \dots & -K_{AH}h \\ -K_{BA}a & (1-K_{BB}b) & \dots & -K_{BH}h \\ \vdots & \vdots & \vdots & \vdots \\ -K_{HA}a & -K_{HB}b & \dots & (1-K_{HH}h) \end{bmatrix} \begin{bmatrix} Y_A \\ Y_B \\ \vdots \\ Y_H \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \\ \vdots \\ 1 \end{bmatrix} \quad [10]$$

$$\begin{matrix} A_0 = A_1^* Y_A \\ \vdots \\ H_0 = H_1^* Y_H \end{matrix} \quad [11]$$

$$\begin{matrix} (A) = A_0 + a_0 - a = A^* Y_A \\ \vdots \\ (H) = H_0 + h_0 - h = H^* Y_H \end{matrix} \quad [12]$$

$$\begin{bmatrix} (1-K_{AA}a) & -K_{BA}a & \dots & -K_{HA}a \\ -K_{AB}b & (1-K_{BB}b) & \dots & -K_{HB}b \\ \vdots & \vdots & \vdots & \vdots \\ -K_{AH}h & -K_{BH}h & \dots & (1-K_{HH}h) \end{bmatrix} \begin{bmatrix} A^* \\ B^* \\ \vdots \\ H^* \end{bmatrix} = \begin{bmatrix} A_1^* \\ B_1^* \\ \vdots \\ H_1^* \end{bmatrix} \quad [13]$$

where $a_0 \dots h_0$ and $a \dots h$ denote, respectively, the initial and equilibrium concentrations of comonomers ($[A]_0 \dots [H]_0$, $[A] \dots [H]$), while (P), P_0, P^*, and P_1^* (P = A…H) denote the total concentrations of copolymer units and the initial and equilibrium concentrations of active species and initiated monomers (living linear unimers) of the indicated type. $Y_A \dots Y_H$ denote the copolymer parameters equal to the ratios of copolymer units and active species of the given kind ($Y_A = (A)/A^*$; for homopolymerization, they are equal to X_n). K_{AA}, K_{AB}, …, K_{HH} are the dyad model of copolymerization equilibrium constants.

The solution of eqns [10]–[13] directly gives the equilibrium concentrations of comonomers ($a \dots h$) and the composition of the equilibrium copolymer ($(A) \dots (H)$). Besides, the equilibrium concentrations of living linear unimers and copolymerization parameters $Y_A \dots Y_H$ are found.

The copolymerization parameters Y_P allow computation of the average conditional probabilities of a copolymer unit of the given kind to be followed by a unit of the same (q_{PP}) or a different type (q_{PR}):

$$q_{PR} = K_{PR} r \left(\frac{Y_R}{Y_P} \right) \quad [14]$$

where P, R = A, B, … and $r = a, b, \dots$.

Consequently, the equilibrium concentrations of any copolymer sequence can be computed:

$$(PRS \dots TUV) = (P) q_{PR} q_{RS} \dots q_{TU} q_{UV} \quad [15]$$

where symbols in parentheses denote the equilibrium concentrations of copolymer sequences or copolymer units.

However, computation of the equilibrium concentrations of copolymer chains of a given sequence of copolymer units is more complex and can be found in the cited paper of Szymanski.[10] It stems from the fact that the probabilities of finding a unit of a given kind in a copolymer chain depends, in a general case, on X (degree of polymerization), considered position, and a type of active center. Only for an ideal equilibrium copolymerization ($K_{XX}K_{YY} = K_{XY}K_{YX}$), the probabilities of finding a copolymer unit at any chain position (but the first) are dependent only on the unit type and thus computation of all copolymer equilibrium concentrations is relatively simple.[10]

Another general solution describing relationships between the equilibrium constants of copolymerization and the features of the equilibrium systems, such as copolymer sequence distribution and comonomer equilibrium concentrations, computed for various initial conditions and various

relationships between the equilibrium constants was given by Cai and Yan.[15]

4.05.4 Thermodynamics of Copolymerization

The first comprehensive treatment of copolymerization thermodynamics was provided by Sawada,[16,17] who analyzed the relationships between the thermodynamic parameters of copolymerization and such features of the system as the equilibrium concentrations of comonomers and the sequence distribution. Generally, the (molar) Gibbs energy of copolymerization can be defined, similarly as for homopolymerization, as the difference between the Gibbs energies of 1 base-mole of a copolymer and comonomers (the average value):

$$\Delta_{xy}G = G_y - G_x = \frac{1}{n}G^{(n)}_{\mathrm{co}(y)} - f_{\mathrm{A}}G_{\mathrm{A}(x)} - f_{\mathrm{B}}G_{\mathrm{B}(x)} - \cdots \qquad [16]$$

where x and y describe the standard states of comonomers (A, B, …) and a copolymer, respectively. $G_y = G^{(n)}_{\mathrm{co}(y)}/n$ is the Gibbs energy of a copolymer with the degree of polymerization equal to n and specific composition and microstructure, while $G_x = f_{\mathrm{A}}G_{\mathrm{A}(x)} + f_{\mathrm{B}}G_{\mathrm{B}(x)} + \cdots$ is the average Gibbs energy of comonomers (where f_{A}, f_{B}, … are the molar fractions of different copolymer units and $G_{\mathrm{A}(x)}$, $G_{\mathrm{B}(x)}$, … are the standard Gibbs energies of comonomers). Usually the following notation of copolymer and comonomer states is adopted: c = condensed, c′ = crystalline, s = in solution, and so on. Note the use of, according to the IUPAC recommendation, the symbol delta with the subscript indicating the initial state of (co)monomers and of resulting (co)polymer in notations of the thermodynamic functions of (co)polymerization.

Equation [16] was formulated by assuming the following stoichiometric equation of copolymerization:

$$f_{\mathrm{A}}\mathrm{A} + f_{\mathrm{B}}\mathrm{B} + \cdots \longrightarrow \frac{1}{n}\{\mathrm{A}_{f_{\mathrm{A}}}\mathrm{B}_{f_{\mathrm{B}}}\ldots\}^{(\alpha)}_n \qquad [17]$$

where n denotes X_{n} of the copolymer ($n > 1$), { } contains copolymer composition, and (α) denotes the microstructure specific for the given copolymerization process.

The value of the Gibbs energy of copolymerization, $\Delta_{xy}G$, determines whether copolymerization can be a spontaneous process ($\Delta_{xy}G < 0$) or it can be the reverse reaction, depolymerization ($\Delta_{xy}G > 0$). When $\Delta_{xy}G = 0$, both processes are thermodynamically possible and copolymerization can be in equilibrium.

However, $\Delta_{xy}G = 0$ is not a sufficient condition for copolymerization to be at equilibrium, because $\Delta_{xy}G$ is an average thermodynamic function (averaged over the whole set of copolymer chains) and the equilibrium of copolymerization is reached only when all reactions describing the overall equilibrium are at equilibrium:

$$f_{\mathrm{A}}\mathrm{A} + f_{\mathrm{B}}\mathrm{B} + \cdots \underset{}{\overset{K_{f_{\mathrm{A}},f_{\mathrm{B}},\ldots,\beta,n}}{\rightleftharpoons}} \frac{1}{n}\{\mathrm{A}_{f_{\mathrm{A}}}\mathrm{B}_{f_{\mathrm{B}}}\ldots\}^{(\beta)}_n \qquad [18]$$

where n denotes X_{n} of the copolymer ($n = 1, 2, \ldots$) and (β) is the specific sequence of copolymer units. Here, all possible sequences have to be considered. The K on the arrow denotes the equilibrium constant, which is different for different values of n and (β) (other symbols have the same meaning as in eqn [17]).

Consequently, Gibbs energies for all component equilibrium reactions are (have to be) equal to zero for copolymerization being at equilibrium:

$$\begin{aligned}\Delta_{xy}G_{(f_{\mathrm{A}},f_{\mathrm{B}},\ldots,\beta,n)} &= G_{y\,(f_{\mathrm{A}},f_{\mathrm{B}},\ldots,\beta,n)} - G_{x(f_{\mathrm{A}},f_{\mathrm{B}},\ldots)} \\ &= \frac{1}{n}G^{(n)}_{\mathrm{co}(y,f_{\mathrm{A}},f_{\mathrm{B}},\ldots,\beta,n)} - f_{\mathrm{A}}G_{\mathrm{A}(x)} - f_{\mathrm{B}}G_{\mathrm{B}(x)} - \cdots = 0\end{aligned} \qquad [19]$$

Although there are an infinite number of equilibrium reactions to be considered, the reversibility-of-microstates rule allows us to decrease the number of considered equilibria to a relatively small number, depending on the assumed model of copolymerization (although if considered on the level of Gibbs energies, such models often do not take into account the distribution of chain lengths).

Analyzing thermodynamics of homopolymerization, the monomer polymerizability feature called the ceiling (or floor) temperature is often determined.

The Gibbs energy of polymerization can be expressed as a function of two other thermodynamic functions: enthalpy and entropy of polymerization. For equilibrium conditions, we have

$$\Delta_{xy}G = \Delta_{xy}H - T\Delta_{xy}S = 0 \qquad [20]$$

where $\Delta_{xy}H$ and $\Delta_{xy}S$ denote the enthalpy and entropy of polymerization for the process carried out in a way described by the subscripts, for example, ss denotes solution conditions of substrates and product and lc the liquid mixture of comonomers giving a condensed copolymer. The temperature T is given in absolute scale.

Rearranging this fundamental equation, we get the temperature at which the system is at equilibrium for the given values of enthalpy and entropy of polymerization:

$$T_{\mathrm{c}} = \frac{\Delta_{xy}H}{\Delta_{xy}S} \qquad [21]$$

where the subscript c refers to the ceiling temperature; the subscript f can be used when the equation is used to calculate the floor temperature.

Both terms describe the temperature at which a monomer and a polymer of a high molar mass and negligible quantity coexist at equilibrium and the difference between the ceiling and the floor temperature lies in what is below and above.

One has to keep in mind that the entropy of polymerization depends on the monomer concentration:

$$\Delta_{xy}S = \Delta_{xy}S^{\circ} + R\ln[\mathrm{M}] \qquad [22]$$

where $\Delta_{xy}S^{\circ}$ is the standard entropy of polymerization (where the standard state was assumed to be monomer at a concentration of 1 mol l^{-1}; alternatively, instead of monomer concentration, mole fraction can be used – in that case, the standard state corresponds to a pure monomer).

Because of the dependence of $\Delta_{xy}S$ on the monomer concentration, the ceiling and floor temperatures are dependent on the monomer concentration in feed.

This concept of ceiling/floor temperature formulated for homopolymerization can be applied to copolymerization as well. Similarly as for homopolymerization, the ceiling temperature can be found in these copolymerization systems in which, while increasing the temperature, we get positive $\Delta_{xy}G$ and consequently the depolymerization of a copolymer (provided the active species of the copolymerization are alive). On the other hand, when spontaneous depolymerization occurs

with the decreasing temperature, the equation describes the floor temperature and the subscript f should be used instead of c. The ceiling temperature is observed for exoenthalpic ($\Delta_{xy}H<0$) and exoentropic ($\Delta_{xy}S<0$) copolymerizations (most of RO homo- and copolymerizations), while the floor temperature is observed for endoenthalpic ($\Delta_{xy}H>0$) and endoentropic ($\Delta_{xy}S>0$) systems (e.g., polymerizations and copolymerization of sulfur and selenium). When $\Delta_{xy}H$ and $\Delta_{xy}S$ differ in their signs, no equilibrium is possible: for any temperature, $\Delta_{xy}G$ is either negative (exoenthalpic and endoentropic systems) and copolymers alone are thermodynamically stable or positive (endoenthalpic and exoentropic systems) and comonomers alone are thermodynamically stable.

This analysis is, however, a simplified one. Simplification stems from the fact that the average thermodynamic functions ($\Delta_{xy}G$, $\Delta_{xy}H$, $\Delta_{xy}S$) for copolymerization depend on the composition of the system. Consequently, for any copolymerization feed composition (including the content of solvent determining, besides the comonomer concentrations ratio, the comonomer concentrations), we can compute, using, for instance, the relationships describing equilibrium in copolymerization mentioned in Section 4.05.3, the equilibrium concentrations of comonomers. Consequently, we can determine whether a high-molar-mass copolymer is formed and what is its composition (which is usually different from that of the feed). When the thermodynamic parameters of all homo- and cross-propagations are known, which enables us to calculate the equilibrium constants for any temperature, we can repeat such computations for various temperatures and the copolymerization system compositions, thus finding the ceiling or floor temperatures. These temperatures correspond to conditions when negligibly low amount of a high-molar-mass copolymer is formed.

A simple mathematical analysis of relationships describing the copolymerization system allows us to predict (although not found yet experimentally) that there are possible copolymerization systems having for some compositions ceiling and for other floor temperatures.

For the sake of visualizing the dependence of the ceiling temperature on the composition of the copolymerization system, the author performed, especially for this chapter, some simulations and the computed ceiling temperatures for the copolymerization of 1,3-dioxolane (DXL) with 1,3-dioxane are presented in **Figure 3** (see Section 4.05.6.1.2).

4.05.4.1 Thermodynamics of Copolymerization in Systems with Intercomponent Interactions

Harvey and Leonard[18] were the first who analyzed the thermodynamics of copolymerization from the viewpoint of the Flory–Huggins theory of intercomponent interactions in polymer solutions. Unfortunately, in deriving their equations, Harvey and Leonard assumed the same composition of copolymer chain ends as that of the whole copolymer. Mita[19] provided an analogous solution without this assumption. He formulated the overall equilibrium as the equality of chemical potentials of comonomers and copolymer units ($\mu_x = (\partial G/\partial N_x)_{T,p,N_i(i\neq x)}$, where x, i are comonomer (A, B, …) or comonomer unit, N_i is the number of moles of the system component 'i', G is the Gibbs energy of the system; the partial derivative is determined for constant temperature, pressure, and numbers of moles of components, other than x, in the copolymerization system):

$$\mu_A = \mu_\alpha \qquad \mu_B = \mu_\beta \qquad [23]$$

where α and β refer to the corresponding copolymer units.

Taking into account the Gibbs energy of mixing and the entropy of the copolymer units distribution, he obtained the equations that enable us to predict for any initial conditions the composition of the copolymerization system at equilibrium (for the sake of simplicity, he assumed, while deriving the equations, that molar volumes of solvent, comonomers, and copolymer units are equal):

$$\exp\left(-\frac{\Gamma}{RT}\right) = [\exp(Z_A)-1][\exp(Z_B)-1] \qquad [24]$$

$$\frac{\Phi_{B0}-\Phi_B}{\Phi_{A0}-\Phi_A} = \frac{1-\exp(-Z_A)}{1-\exp(-Z_B)} \qquad [25]$$

$$\Phi_{A0}+\Phi_{B0} = \Phi_A+\Phi_B+\Phi_P = 1-\Phi_S \qquad [26]$$

where

$$\Gamma = \Delta G^\circ_{\alpha B}+\Delta G^\circ_{\beta A}-\Delta G^\circ_{\alpha A}-\Delta G^\circ_{\beta B} \qquad [27]$$

$$Z_A = \Delta G^\circ_{\alpha A}-\ln\Phi_A-1+\chi_{AP}(\Phi_A-\Phi_P)+(\chi_{BP}-\chi_{AB})\Phi_B + (\chi_{SP}-\chi_{AS})\Phi_S \qquad [28]$$

$$Z_B = \Delta G^\circ_{\beta B}-\ln\Phi_B-1+\chi_{BP}(\Phi_B-\Phi_P)+(\chi_{AP}-\chi_{AB})\Phi_A + (\chi_{SP}-\chi_{BS})\Phi_S \qquad [29]$$

and Φ_X (X = A, B, P, S) are volume fractions of comonomers, copolymer, and solvent, respectively and χ_{XY} (X, Y = A, B, P, S) denote the Flory–Huggins interaction parameters for the indicated copolymerization system components (in the above equations, $\chi_{XY}=\chi_{YX}$ because of the assumed equal molar volumes of all components).

The microstructure of the equilibrium copolymer can be predicted on the basis of the randomness parameter ψ, which is defined as the sum of the conditional probabilities of finding copolymer units followed by different units ($\psi = P_{\alpha\beta}+P_{\beta\alpha}$):

$$\psi = \frac{[1-\exp(-Z_A)]}{x_\beta} = \frac{[1-\exp(-Z_B)]}{x_\alpha} \qquad [30]$$

$$P_{\alpha\beta} = \psi x_\beta \qquad P_{\beta\alpha} = \psi x_\alpha \qquad [31]$$

$$P_{\alpha\alpha} = 1-P_{\alpha\beta} \qquad P_{\beta\beta} = 1-P_{\beta\alpha} \qquad [32]$$

where x_α is the molar fraction of copolymer unit A, equal to $(\Phi_{A0}-\Phi_A)/(\Phi_{A0}-\Phi_A+\Phi_{B0}-\Phi_B)$ because of the assumed equality of molar volumes of copolymerization system components; analogously, $x_\beta = 1-x_\alpha$.

Mita's treatment is useful in predicting the composition and microstructure of a copolymer as well as the equilibrium concentrations of comonomers on the basis of known thermodynamic functions characterizing the copolymerization system. When, however, these functions are not known, their determination from the analysis of the copolymerization experimental data is possible only by numerical fitting of the computed quantities to the experimentally determined ones (Φ_A, Φ_B, x_α, x_β, $P_{\alpha\alpha}$, $P_{\beta\beta}$, $P_{\alpha\beta}$, $P_{\beta\alpha}$).

However, the assumption introduced by Mita that the interaction parameters for all components of the copolymerization system are equal can be questioned. The present author[20] provided analogous analysis of the copolymerization equilibrium from the point of view of intercomponent interactions

distinguishing interactions between comonomers (χ_{ab}), giving a relatively simple solution for bulk copolymerization (without solvent) and equal molar volumes of comonomers and copolymer units (the interaction parameters involving copolymer units were assumed to be equal, and denoted as χ). This solution is a set of six equations with six unknowns (volume fractions of comonomers and dyads):

$$\Delta G^{\circ}_{AA} = RT\left[\ln\left(1+\frac{\Phi_{AB}}{\Phi_{AA}}\right)+\ln\Phi_a+\left(1-\frac{1}{DP}\right)-(2\Phi_a+2\Phi_b-1)\chi+\Phi_b\chi_{ab}\right] \quad [33]$$

$$\Delta G^{\circ}_{BB} = RT\left[\ln\left(1+\frac{\Phi_{BA}}{\Phi_{BB}}\right)+\ln\Phi_b+\left(1-\frac{1}{DP}\right)-(2\Phi_a+2\Phi_b-1)\chi+\Phi_a\chi_{ab}\right] \quad [34]$$

$$\Delta G^{\circ}_{AB}+\Delta G^{\circ}_{BA} = RT\left[\ln\left(1+\frac{\Phi_{AA}}{\Phi_{AB}}\right)+\ln\left(1+\frac{\Phi_{BB}}{\Phi_{BA}}\right)+\ln\Phi_a+\ln\Phi_b+2\left(1-\frac{1}{DP}\right)-2(2\Phi_a+2\Phi_b-1)\chi+(\Phi_a+\Phi_b)\chi_{ab}\right] \quad [35]$$

$$\Phi_{a0}=\Phi_a+\Phi_{AA}+\Phi_{AB}\quad \Phi_{b0}=\Phi_b+\Phi_{BB}+\Phi_{BA}\quad \Phi_{AB}=\Phi_{BA} \quad [36]$$

where DP is the average degree of the polymerization of a copolymer. Equations [36] are the mass–balance equations, with Φ_{a0}, Φ_{b0}, Φ_a, Φ_b, Φ_{AA}, Φ_{BB}, Φ_{AB}, and Φ_{BA} being the volume fractions of comonomers, initial and at equilibrium, and of copolymer dyads, respectively. The volume fractions of dyads are defined as

$$\Phi_{XY}=\frac{V_X n_{XY}}{V_a n_a+V_b n_b+V_A n_A+V_B n_B} \quad [37]$$

where V and n with the corresponding subscripts denote the molar volumes of comonomers and copolymer units and the numbers of moles of comonomers, copolymer units, and dyads, respectively.

The above-mentioned equations make it possible to predict the equilibrium conditions for any initial conditions, provided the standard free energies of comonomer additions are known. It is worth adding here that these thermodynamic functions are in fact $\Delta_{ss}G$ parameters referring to comonomers and a copolymer dissolved in the reaction mixture (however, some authors treat homogeneous bulk copolymerization as the lc process: liquid comonomers converted to an amorphous copolymer).

Choosing, however, as standard states for copolymer units the infinite dilution solutions in the corresponding comonomers, we can get an alternative set of equations for bulk copolymerization equilibria:

$$\overline{K}_{AA}=\frac{\Phi_{AA}}{\Phi_A\Phi_a}=K_{AA}\exp[\Phi_b\chi_{ab}+2(1-\Phi_a-\Phi_b)\chi] \quad [38]$$

$$\overline{K}_{BB}=\frac{\Phi_{BB}}{\Phi_B\Phi_b}=K_{BB}\exp[\Phi_a\chi_{ab}+2(1-\Phi_a-\Phi_b)\chi] \quad [39]$$

$$\overline{K}_{AB}\overline{K}_{BA}=\frac{\Phi_{AB}\Phi_{BA}}{\Phi_A\Phi_B\Phi_a\Phi_b}=K_{AB}K_{BA}\exp[(\Phi_a+\Phi_b)\chi_{ab}+4(1-\Phi_a-\Phi_b)\chi] \quad [40]$$

where K_{AA} and so on are the equilibrium constants. The ones with overbars are the apparent equilibrium constants, which are dependent on the system compositions, while the others can be treated as the absolute equilibrium constants, the thermodynamic functions depending only on the nature of comonomers and the temperature:

$$K_{XY}=\exp\left(-\frac{\Delta G^{*}_{XY}}{RT}\right) \quad [41]$$

where ΔG^{*}_{XY} is the $\Delta_{ss}G$-type standard molar Gibbs energy for the addition of the corresponding comonomer Y, leading to the dyad XY with comonomer Y as the solvent. It is worth noting that apparent equilibrium constants become equal to the absolute equilibrium constants when both χ and χ_{ab} are equal to zero. For such cases, eqns [38]–[40] become equivalent to the analogous equations derived for systems without intercomponent interactions (eqns [2]–[4]; however, note the difference in measurement units).

Equations [38]–[40] together with the mass–balance equations allow not only prediction of the equilibrium comonomer concentrations and the composition and microstructure of a copolymer but also relatively easy determination of the interaction parameters χ and χ_{ab} as well as the absolute equilibrium constants when they are not known.

Combining eqns [38]–[40], we can get relationships that allow the determination of χ_{ab} (and the ratio of the absolute equilibrium constants for homoaddition) from a simple linear regression of experimentally measured quantities (linear function of $\Phi_b-\Phi_a$):

$$\ln\frac{\Phi_{AA}\Phi_B\Phi_b}{\Phi_A\Phi_a\Phi_{BB}}=\ln\frac{K_{AA}}{K_{BB}}+(\Phi_b-\Phi_a)\chi_{ab} \quad [42]$$

Next, if χ_{ab} is known, the other interaction parameter (χ) and the absolute equilibrium constant of homoaddition can also be determined via linear regression (rearrangement of eqn [38]):

$$\ln\frac{\Phi_{AA}}{\Phi_A\Phi_a}-\Phi_b\chi_{ab}=\ln K_{AA}+2(1-\Phi_a-\Phi_b)\chi \quad [43]$$

Analogously, K_{BB} and $K_{AB}K_{BA}$ can be determined.

It is worth observing that the ratio of the products of volumes of hetero- and homodyads is equal to the simple functions of the absolute equilibrium constants, resembling (and in fact equal here, as equal molar volumes were assumed) the corresponding relationship derived for systems without intercomponent interactions (see the comment below eqn [7]):

$$\frac{\Phi_{AB}\Phi_{BA}}{\Phi_{AA}\Phi_{BB}}=\frac{\overline{K}_{AB}\overline{K}_{BA}}{\overline{K}_{AA}\overline{K}_{BB}}=\frac{K_{AB}K_{BA}}{K_{AA}K_{BB}} \quad [44]$$

Simulations presented in the original paper of Szymanski[20] have shown that although both interaction parameters χ_{ab} and χ are positive, they decrease the equilibrium comonomer concentrations, the latter being more important in influencing the copolymerization equilibrium. Besides, when comonomers do not homopolymerize (K_{AA}, $K_{BB}<1$; equilibrium constants defined by volume fractions), the copolymer in the system without intercomponent interactions (χ_{ab}, $\chi=0$) can be formed only for $K_{AB}K_{BA}>1$ (heterodyads prevail, a certain tendency of an alternating copolymer). When $K_{AB}K_{BA}>>K_{AA}K_{BB}$, the alternating copolymer is formed in equilibrium. When, however, both interaction parameters are positive, two non-homopolymerization comonomers – both having

absolute homopropagation equilibrium constants less than 1 – can be polymerized even when the absolute cross-propagation equilibrium constants are also less than 1 (cf. Figure 8 in the cited Reference 20, showing simulation for the system with $K_{AA} = 0.98$, $K_{BB} = 0.9$, $(K_{AB}K_{BA})^{0.5} = 0.94$, and $\chi_{ab} = \chi = 0.5$, resulting in the formation of a random copolymer). Without specific interactions, two such non-homopolymerizing comonomers can give a copolymer only when $K_{AB}K_{BA} > K_{AA}K_{BB}$, which results in the alternating tendency of dyad distribution.

4.05.5 Determination of the Equilibrium Constants on the Basis of the Analysis of the Copolymerization Equilibrium

The relationships between the comonomer and copolymer sequence equilibrium concentrations and the equilibrium constants, presented in the previous sections, allow prediction of the equilibrium conditions for any initial conditions, provided the equilibrium constants are known. Therefore, determination of these constants is crucial.

Rearranging eqns [10]–[13], we can get the following relationships,[10] making it possible to determine the equilibrium constants for the dyad model of copolymerization, on the basis of experimentally measurable quantities such as the equilibrium concentrations of comonomers and proportions of various sequences:

$$K_{XX} = \frac{(XX)}{(X)x} \quad [45]$$

$$K_{XY}K_{YX} = \frac{(XY)(YX)}{(X)(Y)xy} \quad [46]$$

$$K_{XY} = \frac{Y^*}{X^*}\frac{(XY)}{(Y)y} \quad [47]$$

where X and Y ($X \neq Y$) denote copolymer units (A, B, …), parentheses indicate the equilibrium concentrations of the corresponding units or dyads, and asterisks indicate the equilibrium concentrations of active species of the given kind. The lowercase x and y denote the equilibrium concentrations of comonomers.

Combining eqns [45] and [46], we can get the relationship that allows determination of the ratio of products of cross- and homopropagation equilibrium constants from experimentally determined contribution of various dyads (previously derived by O'Driscoll[7–9] for systems of infinitely large X_n):

$$\frac{K_{XY}K_{YX}}{K_{XX}K_{YY}} = \frac{(XY)(YX)}{(XX)(YY)} \quad [48]$$

It is more difficult to determine the equilibrium constants for the triad model of copolymerization. Only the equilibrium constants of triad homopropagation and some functions of the cross-propagation equilibrium constants can be determined directly on the basis of the experimentally found equilibrium concentrations of comonomers and proportions of copolymer sequences (notation similar to that in eqns [45]–[47])[21]:

$$K_{XXX} = \frac{(XXX)}{(XX)x} \quad [49]$$

$$K_X = \frac{K_{XXY}K_{YXX}}{K_{YXY}} = \frac{(XXY)(YXX)}{(XX)(YXY)x} \quad [50]$$

$$K_{XYX}K_{YXY} = \frac{(XYX)(YXY)}{(XY)(YX)xy} \quad [51]$$

Determination of other than K_{XXX} individual equilibrium constants is possible when proportions of all types of active species at equilibrium conditions are known:

$$K_{XYZ} = \frac{(XYZ)}{(XY)z}\frac{Y_{XY}}{Y_{YZ}} = \frac{(XYZ)YZ^*}{(YZ)zXY^*} \quad [52]$$

where Y_{XY} and so on are the ratios of concentrations of copolymer dyads and active species of the given kind, that is, the parameters analogous to Y_X obtained from eqns [10]–[13] for the dyad model of systems.

4.05.6 Selected Examples of the Equilibrium Copolymerization

4.05.6.1 Copolymerization of Cyclic Acetals

Cyclic acetals readily polymerize and copolymerize, provided enthalpic (mainly ring strain) or entropic factors make the Gibbs energy negative. From the technological point of view, the most important is the homo- and copolymerization of 1,3,5-trioxane (TXN). Unfortunately, little reliable data exist on the equilibrium conditions for the homogeneous copolymerization of TXN, mainly because products usually readily precipitate (at a higher content of TXN in feed) and the real homogeneous equilibrium is often not reached. One can, however, assume, on the basis of the estimated enthalpies of the homopolymerization of TXN in nitrobenzene (-0.3 ± 0.3 kcal mol^{-1} at 150–180 °C and -1.4 ± 0.1 kcal mol^{-1} at 25–180 °C),[22,23] that the Gibbs energy for homogeneous homoaddition of TXN is close to zero or even positive at higher temperatures and that the driving force for copolymerization is precipitation of the polymer from the solution and/or polymerization in solid state. Only very short active chains can exist in the solution in equilibrium with the dissolved monomer. Therefore, the copolymerization of TXN with other comonomers can often be treated as the equilibrium copolymerization understood as a copolymerization process carried out when some propagations are in equilibrium. The cationic copolymerization of TXN with 1,3-dioxepane (DXP) was investigated by Sharavanan *et al.*,[24] who observed the dependence of the precipitation time on the ratio of comonomer concentrations and no precipitation when the content of DXP was above 20%. Unfortunately, hardly any data on homogeneous systems were given. Copolymerization was carried out at 80 °C, that is, above the ceiling temperature of DXP, making it possible that the homopropagation of DXP (and maybe of TXN as well because of its low concentration) be considered to be at equilibrium (shifted to the monomer side). Consequently, the driving force for copolymerization in the homogeneous systems is the randomization of a copolymer (formation of heterodyads), either directly through cross-propagations or through the segmental exchange reactions.

There are also little data on the thermodynamics of the copolymerization of other acetals. In fact, the only reliable data on the equilibrium in homogeneous copolymerization systems of cyclic acetals are those reported by the present author and described in the following sections.

4.05.6.1.1 Equilibrium copolymerization of 1,3-dioxolane with 1,3-dioxepane

Equations [45]–[47] allow determination of the equilibrium constants on the basis of the experimentally found equilibrium concentrations of comonomers and ratios of contributions of copolymer sequences and concentrations of active species. The author of the paper on copolymerization of DXL with DXP[21] performed these determinations by using ^{1}H NMR (and ^{31}P NMR for the ion-trap determination of active species) analysis of the equilibrium in the copolymerization of DXL with DXP in dichloromethane solution. Examples of the NMR spectra are shown in Figures 1 and 2.

The determined equilibrium constants are listed in Table 1.

The thermodynamic parameters determined for homopropagations are similar to the corresponding parameters determined in homopolymerizations.[25–27] On the other hand, the sum of the thermodynamic parameters for heteroaddition is approximately equal to the sum of the corresponding parameters for homoadditions. This is equivalent to the approximately equal products of the equilibrium constants of homo- and cross-propagations, which results in the formation of a random copolymer. The individual equilibrium constants for cross-propagations were determined for active species only at one temperature, but the similarity of their values to the corresponding equilibrium constants for homopropagations of the same active species seems to indicate that the nature of active species is more important in comonomer additions than is the nature of comonomers.

4.05.6.1.2 Equilibrium copolymerization of 1,3-dioxolane with 1,3-dioxane

The equilibrium of the copolymerization of DXL with 1,3-dioxane (non-homopolymerizing comonomer) is

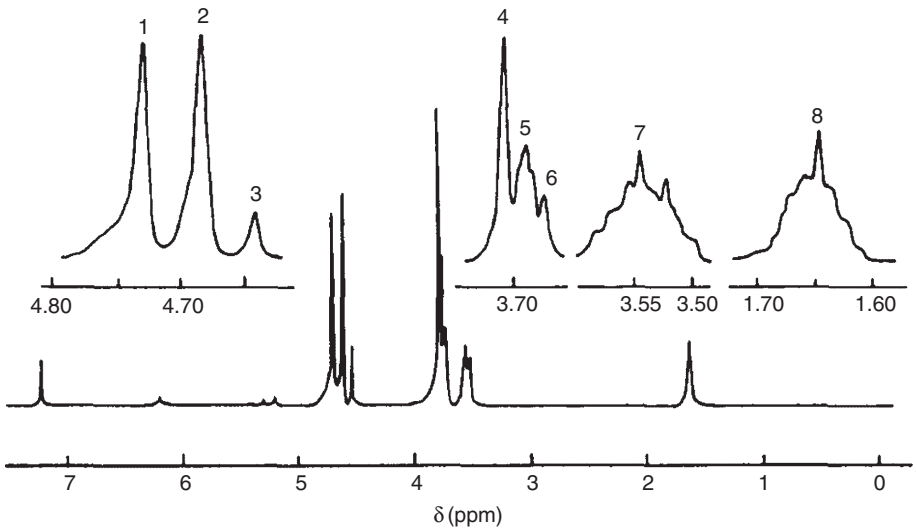


Figure 1 ^{1}H NMR spectrum of the equilibrium copolymerization of DXL (A) and DXP (B). Initial copolymerization conditions: $[A]_0 = 3.15\ mol\ l^{-1}$, $[B]_0 = 1.09\ mol\ l^{-1}$, $[(C_6H_5)_3C^+SbF_6^-]_0 = 5 \times 10^{-3}\ mol\ l^{-1}$ in CH_2Cl_2 at 0 °C. Assignment of signals: 1, 2, 3: $OC\underline{H}_2O$ in dyads AA, AB (and BA), and BB, respectively; 4, 5, 6: $OC\underline{H}_2C\underline{H}_2O$ in triads A$\underline{A}$A, A$\underline{A}$B (and B$\underline{A}$A), and B$\underline{A}$B, respectively; 7: $OC\underline{H}_2CH_2CH_2C\underline{H}_2O$; 8: $OCH_2C\underline{H}_2CH_2C\underline{H}_2O$. described in the same paper[21] that previously discussed the copolymerization of DXL with DXP. The observed dependence of the equilibrium concentrations of comonomers and of various dyads on the initial conditions could not be explained assuming the dyad model of copolymerization. The author explained the experimental results assuming the triad model of copolymerization. As an alternative, the analysis of the system from the point of view of the Flory–Huggins interaction parameters was also performed. Consequently, as for the system with DXP, some equilibrium constants and thermodynamic parameters could be determined. The quantities estimated assuming the triad model of copolymerization are listed in **Table 2**.[21]

The known thermodynamic parameters of copolymerization can be used to calculate the ceiling temperatures for the given system. The author made such calculations by using the apparent equilibrium constants for the dyad model reported in the original paper of Szymanski.[21] Assuming the linear dependence of the apparent thermodynamic parameters on the feed content of 1,3-dioxane, it was possible to calculate the apparent thermodynamic parameters for any temperature and any feed composition. As for the ceiling temperature, the content of a copolymer is negligible and consequently the feed concentrations are the equilibrium concentrations. It was sufficient to solve the set of four equations, with four unknowns – T, K_{AA}, K_{BB}, and $K_{AB}K_{BA}$ – to find the ceiling temperature ($T_c = T$) for any feed on the basis of the above-mentioned estimated linear correlations:

$$K_{AA} = \exp\left(\frac{-\Delta H_{AA} + T\Delta S_{AA}}{RT}\right) \quad [53]$$

$$K_{BB} = \exp\left(\frac{-\Delta H_{BB} + T\Delta S_{BB}}{RT}\right) \quad [54]$$

$$K_{AB}K_{BA} = \exp\left[\frac{-(\Delta H_{AB} + \Delta H_{BA}) + T(\Delta S_{AB} + \Delta S_{BA})}{RT}\right] \quad [55]$$

$$\frac{(1 - K_{AA}a)(1 - K_{BB}b)}{K_{AB}K_{BA}ab} = 1 \quad [56]$$

The last equation can be derived from eqns [45] and [46], remembering that for infinitely long copolymer chains the concentrations of units are equal to the sum of the corresponding homo- and heterodyads ($(X) = (XX) + (XY)$ and $(XY) = (YX)$).

Then, when the dependence of the ceiling temperature is computed for any feed the composition of the equilibrium copolymer (mole fraction of 1,3-dioxane units, fr(B)) can be calculated on the basis of the computed equilibrium constants of homopropagation (the equation easily derivable from relationships [45] and [46] assuming the infinite X_n):

$$\mathrm{fr(B)} = \frac{(1 - K_{AA}a)}{(1 - K_{AA}a) + (1 - K_{BB}b)} \quad [57]$$

The computed dependence of the ceiling temperature on the feed and copolymer composition for the bulk copolymerization of DXL with 1,3-dioxane is presented in **Figure 3**.

Table 2 The equilibrium constants and the corresponding thermodynamic parameters governing the bulk copolymerization of DXL (A) with 1,3-dioxane (B)

Temperature (K)	K_{AAA} (mol^{-1} l)	K_A[a] (mol^{-1} l)	K_{BBB} (mol^{-1} l)	K_B[a] (mol^{-1} l)	$(K_{ABA}K_{BAB})^{1/2}$ (mol^{-1} l)
273	1.203	1.642	0.0559	0.0417	0.226
294	0.653	0.969	0.0473	0.0430	0.152
313	0.391	0.715	0.0472	0.0441	0.120
ΔH_Z[b] (kJ mol^{-1})	−20 ± 2	−14.9 ± 0.8	−3 ± 1	1 ± 0.1	−11 ± 1
ΔS_Z[b] (J mol^{-1} K^{-1})	−71 ± 10	−50 ± 5	−36 ± 3	−22.8 ± 0.3	−54 ± 4

[a]$K_X = K_{XXY}K_{YXX}/K_{YXY}$ $(X \neq Y)$.
[b]Z denotes a type of thermodynamic parameter (AAA, A, …) that correspond to the listed equilibrium constants.

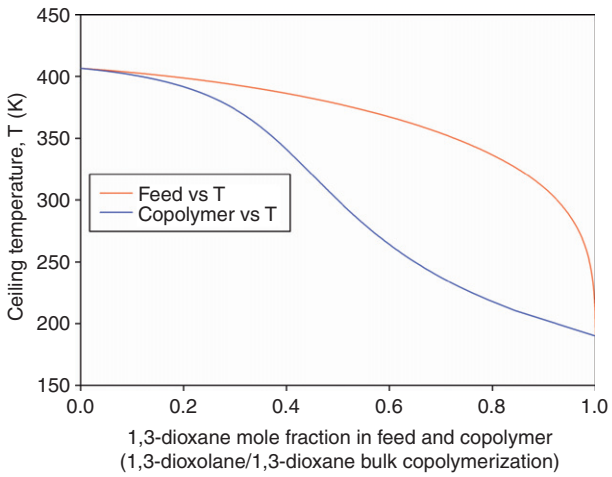

Figure 3 Dependence of the ceiling temperature on the feed and copolymer composition for the bulk copolymerization of DXL with 1,3-dioxane. Computations were performed by neglecting dependences of the comonomer densities on the temperature and melting point of 1,3-dioxane (11.8 °C).

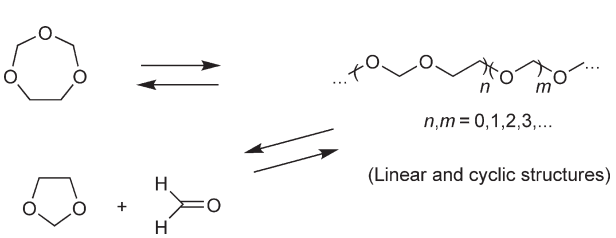
The plot shows a strong nonlinear dependence of the ceiling temperature on the feed composition and the discrepancy between the feed and copolymer compositions for ceiling temperature conditions. As expected, a copolymer is richer in DXL than feed for any ceiling temperature and, on the other hand, the ceiling temperature for any feed composition is higher than for a copolymer of the same composition. The highest difference between the compositions of the feed and the copolymer is observed for the ceiling temperature close to the average value for both comonomers and corresponding to the approximately equal contents of both comonomers in the feed. One would have to compute such dependences for various copolymerization systems in order to check whether these observations are general or only specific for the discussed system.

4.05.6.1.3 Equilibrium in 1,3,5-trioxepane polymerization regarded as an example of the equilibrium copolymerization

1,3,5-Trioxepane (TXP) is a seven-membered cyclic monomer formed from a DXL ring expanded by the insertion of a formaldehyde unit (F). Thus, it is a cyclic monomer containing two adjacent oxymethylene groups and four acetal bonds. Acetal bonds are very labile in cationic polymerization conditions, which results in the formation of a copolymer composed of statistically distributed DXL and F units (Scheme 4).[28]

During the polymerization of TXP formation of cyclic compounds, including DXL, oligomers of DXL and TXN, and other cyclic compounds containing all possible numbers of DXL and F units and characterized by all possible distributions of them



Scheme 4 Polymerization of TXP regarded as copolymerization of DXL with formaldehyde.

is observed. Besides, free formaldehyde is formed. Addition of these compounds to active species and the segmental exchange reaction operating in the system that cause all possible distributions of DXL and F units can also be found in a linear polymer.

The presence of two adjacent oxyethylene units (fragment of DXL unit) was not observed, probably because the nucleophilic attack of acetal oxygen atoms (weak base) on the ether carbon atom ($O\underline{C}H_2CH_2$ group) of oxonium cations (active species of copolymerization or of segmental exchange) is much slower than on the acetal carbon atom ($O\underline{C}H_2O$). Therefore, the equilibrium of the polymerization of TXN can also be regarded as the equilibrium of the copolymerization of DXL with F. Consequently, the method of analysis of a copolymer microstructure, making it possible to determine the thermodynamic parameters of homo- and heteroadditions, can be applied.

It was Szwarc and Perrin,[29] who first made this observation and calculated the correct equilibrium constants of homoaddition of TXN on the basis of the experimental data of Schulz *et al.*[28] and determined the thermodynamic parameters of its polymerization. The corresponding equation, the version modified by Szymanski,[30] that enables us to compute the equilibrium constant of homoaddition of TXN is shown in Chapter 4.30.

The thermodynamic parameters for the polymerization of TXN (to uniform polymer) as computed by Szwarc and Perrin[29] were $\Delta H_{TT} = -6.9\,kJ\,mol^{-1}$ and $\Delta S_{TT} = -31.5\,J\,mol^{-1}\,K^{-1}$ (which corresponds to the equilibrium concentration equal to $2.11\,mol\,l^{-1}$ at 0 °C and $3.66\,mol\,l^{-1}$ at 60 °C, while the observed concentrations by Schulz *et al.*[28] were much lower, equal to 0.23 and $1.36\,mol\,l^{-1}$, respectively, because of the copolymerization nature of the process).

4.05.6.2 Copolymerization of Sulfur with Norbornene Trisulfide

Penczek and Duda studied the copolymerization of sulfur with organic sulfides (cf. Reference 31 and references listed therein). These copolymerizations, when performed below the floor temperature of sulfur, can be regarded as the equilibrium copolymerization because homodepropagation of sulfur counterbalance the homopropagations, and the equilibrium is established determining the average length of blocks of sulfur atoms of the sulfur-terminated anionic active species of copolymerization. However, when alkylene monosulfides are copolymerized with sulfur, cyclic trisulfide is formed as the by-product and then it functions as a comonomer of copolymerization. Besides, homopolymerization of monosulfides is practically irreversible. Therefore, a simpler equilibrium copolymerization system is that when trisulfide is used instead of monosulfide in copolymerization with elemental sulfur.

Penczek and Duda investigated the copolymerization of norbornene trisulfide (NS_3) with sulfur (S_8) and managed to determine the equilibrium concentrations of both comonomers at 25 °C in the bulk. The results are listed in Table 3.[31]

Unfortunately, the authors did not discuss their results from the point of view of the copolymerization equilibrium. However, it is a bit striking that the equilibrium concentration of NS_3 is almost independent of the feed composition. This may indicate that either specific intercomponent interactions influence the values of the apparent equilibrium constants or

Table 3 Dependence of the equilibrium concentrations of norbornene trisulfide (NS_3) and sulfur (S_8) and of the average length of sulfur copolymer segments X_n on the feed composition

$\frac{8[S_8]_0}{8[S_8]_0+[NS_3]}$	$8[S_8]_0$ ($mol\,l^{-1}$)	$[NS_3]_0$ ($mol\,l^{-1}$)	$8[S_8]_{eq}$ ($mol\,l^{-1}$)	$[NS_3]_{eq}$ ($mol\,l^{-1}$)	X_n
0	0	7.0	0	3.70	3.0
0.50	6.3	6.3	1.7	3.17	4.5
0.67	11.5	5.7	3.6	3.30	6.2
0.75	15.8	5.3	6.8	3.15	7.2
0.80	19.6	4.8	11.4	3.20	8.0
0.83	22.4	4.5	15.5	3.20	8.4

the triad (or of higher order) model of copolymerization has to be taken into account, and consequently, while increasing the content of sulfur in the system the fraction of NS_3 dyads does not change significantly (in other words, the proportion of short S_3 segments almost does not change).

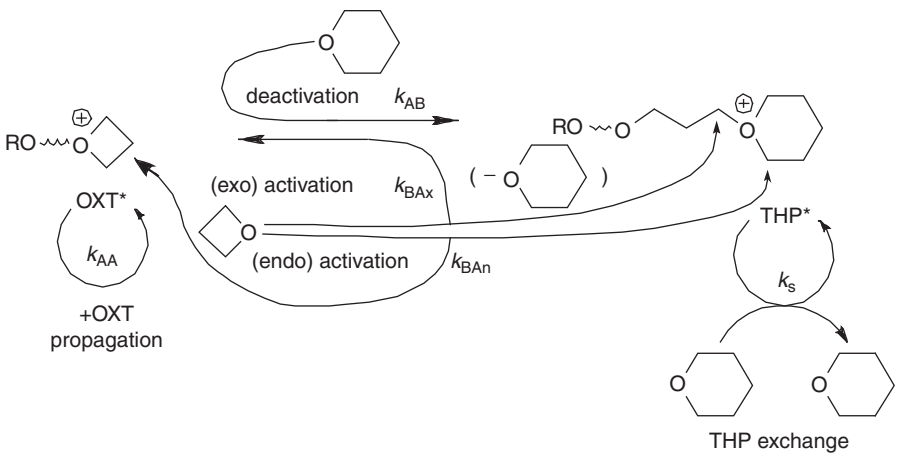
4.05.6.3 Equilibrium Copolymerization of γ-Butyrolactone with ε-Caprolactone

Five-membered cyclic ester γ-butyrolactone (BL) does not polymerize under normal conditions. It stems from low ring strain. Linear oligomers can, however, be obtained,[32] which indicates that the formal (apparent) homopolymerization equilibrium concentration of this monomer (equal to the reciprocal of the equilibrium constant of homopropagation) is not too high. Duda and Penczek[32] managed to copolymerize BL with ε-caprolactone (CL) and analyze the resulting copolymer. Unfortunately, because of the inability to determine quantitatively the contributions of various triads, the authors did not analyze their result from the point of view of the equilibrium copolymerization. Nevertheless, assuming the random microstructure of the copolymer for which the content of dyads can be computed on the basis of the Bernoulli statistics ($[-(BL)_2-]/[-BL-] = fr(BL)$, where fr(BL) is the molar fraction of BL units in the copolymer), the formal (apparent) equilibrium concentration of BL can be estimated to be for bulk conditions at 20 °C, equal to about 26 $mol\,l^{-1}$ ($[BL]_{eq(homo)} = [BL]_{eq(co)}/fr(BL)$). This value is close to the apparent monomer equilibrium concentration in the homopolymerization of 1,3-dioxane, discussed previously, and confirms relatively easy copolymerization of BL with CL and other lactones.

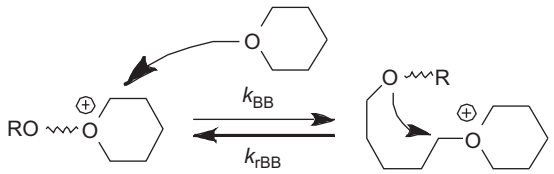
4.05.6.4 Equilibrium Copolymerization of Tetrahydropyran with Oxetane

Recently, Bouchékif *et al.*[33] published a paper claiming that they observed pseudoperiodic 'living' and/or controlled nature of cationic copolymerization of oxetane (OXT) with tetrahydropyran (THP). Their kinetic interpretation of the results of the copolymerization is, however, not correct. The authors considered the formation of a copolymer as a pseudoperiodic living and/or controlled cationic RO copolymerization of OXT with THP, as described by Scheme 5.

The kinetic analysis presented in this chapter is incorrect, assuming that the THP exchange reaction (rate constant k_s in Scheme 5) is crucial, which, according to the authors, determines the kinetics of copolymerization. This incorrect assumption (the THP exchange reaction does not influence copolymerization) resulted in an erroneous interpretation of results. The



Scheme 5 Copolymerization of OXT with THP as a living process with 1-alkyl-tetrahydropyranium cations regarded as dormant species.



Scheme 6 Equilibrium of homoaddition of THP in copolymerization of OXT with THP.

copolymerization system under consideration can, however, be regarded as the equilibrium copolymerization, understood as a process in which the homoaddition of THP (non-homopolymerizing comonomer) is at equilibrium shifted strongly to the monomer side. The homopropagation of THP is counterbalanced by depropagation, which results in very short THP copolymer segments, the average length being close to unity (Scheme 6).

The authors claimed that only monads are incorporated in a copolymer, simplifying the system description or overlooking formations of dyads (and because of the statistical nature of propagations, also longer sequences, existing in much lower quantities). The ^{13}C NMR spectrum of the carbon atoms of the THP copolymer units, adjacent to the oxygen atoms, clearly indicates the presence of about 17% of the THP dyads (about one sixth of THP carbon atoms in the corresponding magnetic environment) in the total content of the THP segments (Figure 4).

This information is sufficient to estimate the equilibrium constant of the homopropagation of THP and the formal equilibrium concentration of THP for homopolymerization (the reciprocal equilibrium constant) (cf. eqn [45]):

$$K_{BB} = \frac{[-BB-]}{[-B-][THP]_{e(co)}} \approx \frac{1}{6 \times 20} = 8.3 \times 10^{-3}\ \text{mol}^{-1}\ \text{l}$$

$$[THP]_{e(homo)} = K_{BB}^{-1} \approx 120\ \text{mol l}^{-1}$$

The estimated equilibrium constant of the homopolymerization of THP is much lower than the estimated equilibrium constant for another six-membered cyclic monomer 1,3-dioxane (4.73×10^{-2} mol^{-1} l at 294 K); the copolymerization of 1,3-dioxane with DXL was discussed in Section 4.05.6.1.1. Consequently, the formal equilibrium concentration in the homopolymerization of THP (120 mol l^{-1}) is much higher than for 1,3-dioxane (21.1 mol l^{-1}). This can be

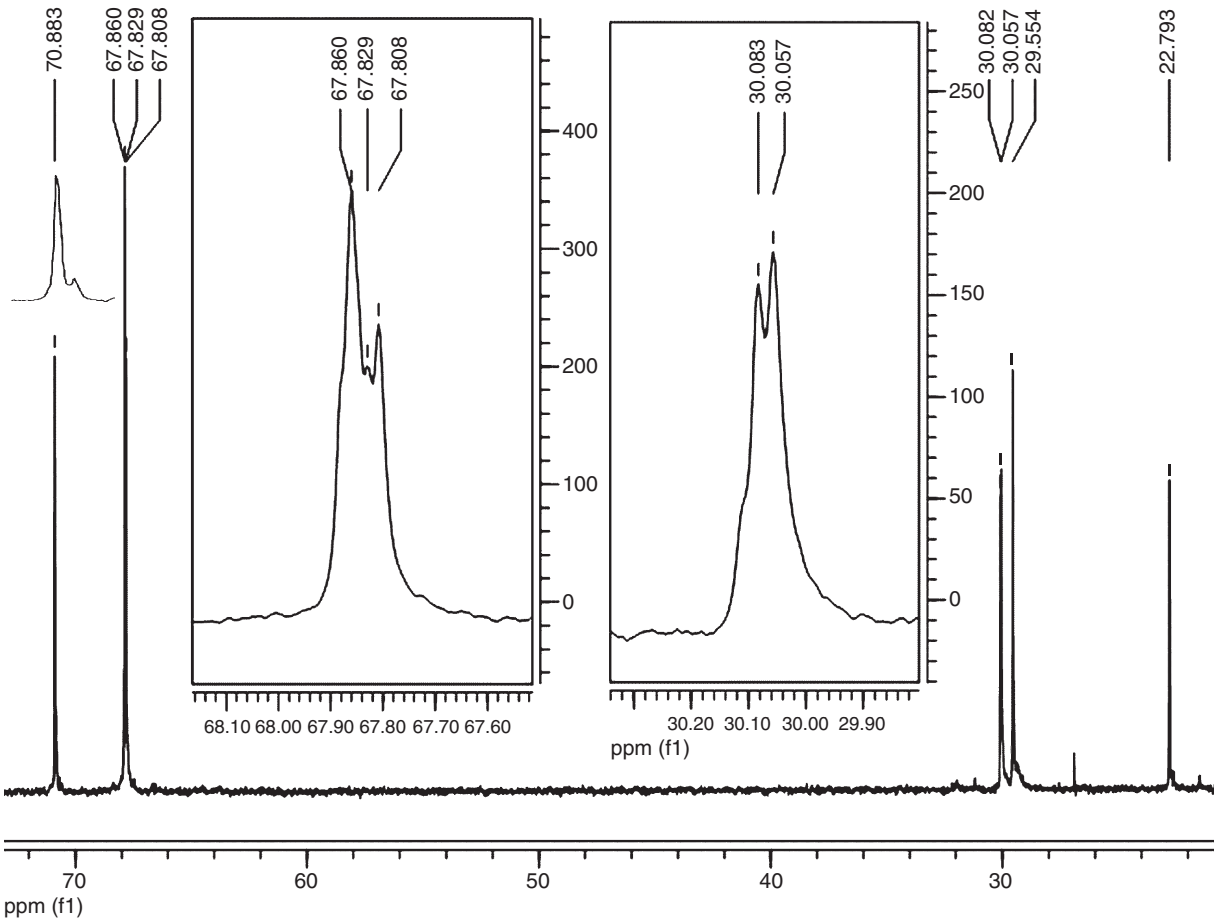


Figure 4 ^{13}C {^1H} NMR spectrum of the copolymerization of THP with OXT, showing expanded fragments of copolymer signals. Note the presence of signals of $O(CH_2)_4\underline{C}H_2OX$ dyads at about 71 ppm and X = OXT (larger peak) and THP (smaller peak). Experimental conditions: $[OXT]_0 = 0.25$ mol l^{-1}, $[THP]_0 = 20$ mol l^{-1}, room temperature, OXT conversion = 4%, THP content in copolymer = 29.2%, $M_{n(SEC)} = 7300$, $Đ_n = 1.6$. Reproduced with permission from the supporting information of Bouchékif, H.; Philbin, M. I.; Colclough, E.; Amass, A. J. *Macromolecules* **2010**, *43*, 845.[33]

explained by the nonexistence of THP monomer interactions that are important in 1,3-dioxane, mainly between oxygen atoms; this increases for 1,3-dioxane the Gibbs energy of the formation of a cyclic compound in comparison to linear one (polymer segment).

4.05.6.5 Equilibrium Copolymerization of Tetrahydrofuran Above Its Ceiling Temperature with Oxetanes

Kubisa and Penczek[34] reported the copolymerization of tetrahydrofuran (THF) above its ceiling temperature (bulk systems at 100 °C, while the ceiling temperature is about 80 °C; $Al(i\text{-}Bu)_3$ used as the catalyst) with a few 3,3-bis-substituted oxetanes. Applying some simplifications, the authors derived equations that enable them to determine the reactivity ratios and the apparent equilibrium constant of the homopropagation of THF in the studied systems. The maximum content of THF in a copolymer was found to be about 50% for copolymers with 3,3-dimethyloxetane and with 3,3-bis(fluoromethyl)oxetane but about 66% for bis(chloromethyl)oxetane (BCMO). This may suggest that the penultimate unit effect can be important for the bulkiest comonomer, causing depropagation of the THF–THF dyad-terminated active species to be slower than the homopolymerization of THF, and consequently the corresponding propagation equilibrium constant is larger. In fact, the apparent equilibrium constant of homopropagation of THF was found to be $K_{AA} = 0.8\ mol^{-1}\ l$ by using the aforementioned equations, which would correspond to the equilibrium concentration of THF being equal to $1.25\ mol\ l^{-1}$ if the dyad model of copolymerization was true for this system. The determined reactivity ratios for this system were $r_{BCMO} = 0.35$ and $r_{THF} = 9$, which corresponds to the product of these values equal to about 3, indicating a certain tendency to block formation. The THF–BCMO system was also studied by Yamashita *et al.*,[3] who had similar observations but studied the system at several temperatures and also observed the dependence of the reactivity ratios and composition of a copolymer on the catalyst used. It may indicate the importance of the nature of active species on their relative reactivities toward different comonomers. For the THF–BCMO system catalyzed with $Et_3O^+BF_4^-$, the determined reactivity ratios were $r_{BCMO} = 0.3$ and $r_{THF} = 1.2$, indicating the tendency to form alternating copolymers contrary to the previously mentioned tendency to block formation.

4.05.7 Conclusions and Outlook

Reversibility of propagation is often observed in RO polymerization systems, including copolymerization. Although attaining equilibrium is rather infrequently the aim of copolymerization, it can be used as a tool not only for obtaining copolymers of thermodynamically defined properties but also for other purposes. The term 'equilibrium copolymerization' means not only the equilibrium in copolymerization but also copolymerization in which one or more of homo- or cross-propagations are counterbalanced by depropagations. Consequently, although the equilibrium is often not reached, equilibrium copolymerization frequently allows us to obtain products containing substantial content of units coming from non-homopolymerizing comonomers. When the real equilibrium is reached, the analysis of copolymer composition and microstructure, combined with determination of the equilibrium concentrations of comonomers, gives access to the equilibrium constants of homopropagation. In this way, equilibrium constants of homoadditions of non-homopolymerizing monomers can be determined as well, and consequently the thermodynamic parameters of the polymerization of such monomers are often not accessible by other methods. When the equilibrium concentrations of active species can be measured, the equilibrium constants and the corresponding thermodynamic parameters of cross-propagations can be additionally determined.

Biographical Sketch

Ryszard Szymanski received his MS degree in organic synthesis from Technical University at Lodz, Poland, in 1972. In the same year he started his work in the Center of Molecular and Macromolecular Studies of the Polish Academy of Sciences (CMMS), Lodz, Poland, as a research assistant. He worked in Professor Stanislaw Penczek's group and received his PhD in 1980 in polymer chemistry. His PhD thesis was on the reactions of alkoxymethylium cations with ethers and acetals as models of cyclic acetal polymerization. He worked as a postdoc at Professor H.K. Hall's Laboratory in Tucson, AZ, in 1981, and investigated the polymerization of bicyclic orthoesters. After returning to Poland, he continued his work as an adjunct professor in the field of ring-opening polymerization in CMMS with Professor S. Penczek. In 1994 he spent 6 months with Professor K. Matyjaszewski in Pittsburgh, PA, where he studied the mechanism of the cationic polymerization of styrene by using computer simulation methods. After returning to CMMS, he received his DSc degree, with the thesis on problems connected with equilibrium in copolymerization. He continues his work in CMMS as an associate professor in the Laboratory for Computer Simulations. His main research interests are mechanisms and kinetics of the polymerization of cyclic monomers. In his work he develops computer simulation techniques.

4.06 Organocatalyzed Ring-Opening Polymerizations

M Fèvre, J Vignolle, Y Gnanou, and D Taton, Université de Bordeaux, Pessac, France

4.06.1 Introduction

Polymer chemistry has been dominated, in the twentieth century, on the one hand, by radical processes, and, on the other hand, by metal-based catalysis. Besides polymers obtained by radical polymerization, which account for about 50% of polymeric materials produced industrially, most of the other synthetic polymers require metallic species to catalyze, activate, or initiate elementary reactions that bring about their synthesis.[1,2] In most cases, the metallic catalyst (typically, organometallic complexes based on transition metals or metal-based ionic species) represents minute amounts and remains in the final polymer.

A representative example of a metal-based catalysis is the Ziegler–Natta process, which has been gradually improved to such an extent that the monomer-to-catalyst ratio is typically in the range 10^6–10^8.[3] As a matter of fact, removal of the metallic catalyst is not needed and commodity polymers obtained in this way (polyolefins) are directly processed without any purification step. In contrast, the synthesis of specialty polymers used in niche applications requires larger amounts of metallic catalysts (the monomer-to-catalyst ratios being 10^3–10^4). To prevent hazards due to the presence of toxic metallic species that can freely migrate out of the polymeric material when in service, a purification process is sometimes required which adds to the cost of the polymer produced. In sensitive domains such as biomedical, packaging, and microelectronics, metal-based catalysts are prohibited.

Organic and enzymatic catalyses appear today as reliable alternatives to metal-mediated catalysis for polymer synthesis.[4–7] Organocatalysis, in its general sense, is a part of the general concept of catalysis and is categorized as green chemistry. Organocatalysis has been known for a while, since Justus Liebig[8] reported as early as 1859 the synthesis of oxamide employing acetaldehyde as organic catalyst. A few decades later, Emil Fischer[9–11] developed the glycosidation processes using acids as catalysts. Some significant examples of organocatalytic approaches were reported in the 1970s.[12–14] However, not less than a century had passed before organocatalysis could be finally recognized as the third pillar of catalysis,[5] besides metallic catalysis and enzymatic catalysis. The twentieth century has indeed witnessed the dramatic development of transition metal-based catalysts; meanwhile, concepts of organocatalysis have been clearly neglected. While in the last decade, tremendous efforts have been made in molecular chemistry to develop powerful organocatalysts for a variety of transformations, most of the work has been focused on enantioselective processes, using chiral organocatalysts and taking inspiration from the *modus operandi* of enzymes to catalyze reactions in a biomimetic fashion. In this regard,

organocatalysts can be viewed as 'minimal enzymes' possessing advantages of enzymes such as selectivity and mild reaction conditions, without the drawbacks of biocatalysts such as the complexity of their structure/conformation, their lack of availability, and their lack of robustness due to possible deactivation/denaturation.[15] In molecular chemistry, most of the organocatalyzed enantioselective transformations can be classified as follows:

1. asymmetric C–C bond and C–X (X = O, N, H, etc.) forming reactions (e.g., Michael additions, Mannich reactions, aldol additions, vinylogous aldol additions, allylation reactions, α-alkylation of amino acids, α-halogenation or α-amination of carbonyl compounds, protonation, etc.);
2. enantioselective oxidation–reduction processes (epoxidations, sulfoxidations of thioethers, enantioselective reduction processes, and α-hydroxylation of carbonyl compounds).

Several reviews have already reported on the general topic of organocatalysis in molecular chemistry.[16–20] It is not yet viewed as a mature field and it is far from being applied in the chemical industry. A representative example is the synthesis of the Wieland–Miescher ketone developed in 1970 on an industrial scale, via an enantioselective organocatalytic aldol process.[21]

In the last decade, organocatalysis has also been applied to a few polymerization reactions, in an attempt to replace classical catalysts and to enhance the rate of polymerization through activation of monomers and/or polymer chain ends.[5,6]

Use of organocatalysts as promoters of polymerization reactions has actually been known for a while. For instance, the polyurethane synthesis by step-growth polymerization of multihydroxy compounds with multiisocyanates can be catalyzed with tertiary amines such as 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) or triethylamine. The group transfer polymerization (GTP) of methacrylic monomers can be also categorized, to some extent, as organocatalyzed polymerization when a metal-free nucleophilic catalyst (Lewis base) is employed.[22] One can also mention pioneering works by the group of Penczek[23] in the late 1980s regarding the cationic ROP of cyclic ethers by acids such as BF_3 or HPF_6, which have provided the first metal-free approach for precision polymer synthesis.

However, the (re)emergence of the field of organocatalyzed polymerization dates back to 2001 with the first reports by Hedrick (IBM), Waymouth (Stanford), and co-workers who employed dialkylaminopyridines for the ring-opening polymerization (ROP) of lactones and lactide.[24,25]

This chapter covers past and recent achievements related to ROP reactions employing organic catalysts. This field – including chain and step-growth polymerizations – was reviewed in 2007 and at the beginning of 2010 by Kamber *et al.*[5] and Kiesewetter *et al.*[6] Roughly a hundred papers have been published in peer-reviewed journals in the past 20 years. The introduction of the chapter will present general consideration on the meaning of 'organocatalyzed polymerization', all of the employed catalysts (classified according to the nature of the active center of the catalyst, i.e., its functional group), monomers which have been polymerized, and general polymerization mechanisms encountered. The discussion will then put a special emphasis on the scope and limitations of each family of catalysts as well as on related mechanisms (monomer activation and/or chain end activation), though the latter aspect has not been systematically discussed in the original reports.

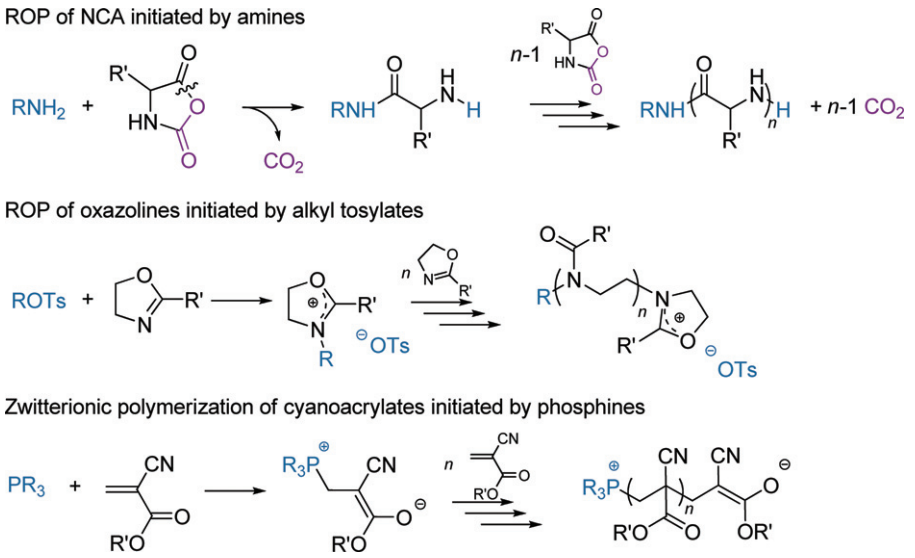
4.06.2 Metal-Free Initiated versus Metal-Free Organocatalyzed Polymerizations

Beyond radical processes, the use of organic promoters for the purpose of metal-free polymerization reactions is well documented.[6] A distinction should be made, however, between metal-free polymerizations triggered by organic reagents actually playing the role of initiators and truly organocatalyzed polymerizations, where an organic promoter is used in the presence of a chain length regulator as the other component. For instance, the ROP of *N*-carboxyanhydrides (NCAs) can be readily initiated with amines, as reported in the early 1970s.[26] The ROP of β-lactones can be triggered with amines, phosphines, or tetraalkyl ammonium caboxylates, as organic initiators.[27,28] The same is true for the ROP of epoxides in the presence of organic amino-containing initiators.[27] The cationic ROP of 2-alkyl oxazolines generally employs organic benzyl halides or alkyl tosylates.[29] Initiation of the zwitterionic chain-growth polymerization of cyanoacrylates can be achieved with phosphines,[30] and so on. In all cases, however, the organic initiator is part of the polymer being formed (**Scheme 1**). In contrast, an organic catalyst is supposed to be regenerated on the completion of the polymerization process and, ideally, it is employed in substoichiometric amounts relatively to the initiator. Only studies fulfilling at least the first criterion will be discussed in the following section.

4.06.3 Organocatalytic Platforms, Monomer Candidates, and Related Mechanisms

4.06.3.1 The Different Organic Catalysts

Organic catalysts can be classified according to the nature of the reactive center (its functional group) involved in the activation of monomers and/or chain end (**Figure 1**). Only organocatalysts employed in polymerization reactions will be considered in this chapter. These include Bronsted acids, from weak carboxylic derivatives (e.g., CF_3COOH, lactic acid, and alanine) to stronger acids (e.g., CF_3SO_3H and CH_3SO_3H) and superstrong acids (e.g., $(CF_3SO_2)_2NH$ and $(C_4F_9SO_2)_2NH$), Bronsted bases (e.g., phosphazenes such as *t*-BuP_4, pyridine derivatives, and carbenes), and Lewis bases (mostly phosphines, 4-(dimethylamino) pyridine (DMAP), guanidines, and carbenes). Combination of two amphiphilic catalysts, within the same molecule or not, leads to bifunctional systems, but the strength of each antagonistic reactive center has to be moderate enough so as to not quench the system (e.g., a strong Bronsted acid combined with a strong Bronsted base will react together preventing any monomer activation). Most of the systems reported involved a basic-nucleophilic-type function, associated with a weak acid-electrophile. Note that thiourea (TU) derivatives can be considered as weak electrophiles due to their H-bonding donor ability.[31] Such organic catalytic systems lead to cooperative activation of the monomer and initiator (see Section 4.06.3.3.4). In this respect, bifunctional organocatalysts find analogies with multicentered enzymatic catalysis, which allows synergistic



Scheme 1 Examples of metal-free initiated polymerizations.

interactions with the different reaction partners with high selectivities. A typical example of a dual activation by hydrogen bonding is provided by the bicyclic guanidine 1,5,7-triazabicyclo[4.4.0]dec-5-ene (TBD) (Section 4.06.5) or by combination of a TU moiety with an amino group (Section 4.06.6) in a mono- or a bicomponent catalytic system.

Many of the aforementioned organic catalysts provide high rates and selectivities, tolerance to functional groups, easy handling, and environmental friendliness and sometimes offer opportunities for new synthetic strategies.[5,6]

4.06.3.1.1 4-(Dialkylamino)pyridines

4-(Dialkylamino)pyridines (**Figure 1**) behave either as weak bases or as nucleophiles via the sp^2-hybridized nitrogen atom. DMAP and 4-pyrrolidinopyridine (PPY), which are commercially available, are prototypes of such 4-aminopyridine derivatives. In molecular chemistry, these compounds have proven efficient in acylation transesterification reactions.[32,33] Section 4.06.4 will discuss their use for the organocatalyzed ROP of carbonyl-containing heterocycles.

4.06.3.1.2 Guanidines and amidines

The guanidine moiety is present in many natural products where its catalytic activity has been established.[34] Representative examples of these organocatalysts are shown in **Figure 1**. They include 7-methyl-1,5,7-triazabicyclo[4.4.0]dec-5-ene (MTBD), DBU, and the aforementioned TBD. In terms of basicity, TBD is more basic than MTBD and DBU: $pK_a(MTBDH^+) = 25.5$, $pK_a(DBUH^+) = 24.3$, and $pK_a(TBDH^+) = 26.0$, as determined in acetonitrile and where pK_a is given with regard to the cationized conjugated acid of each base. For the sake of comparison, the pK_a value of (−)-sparteine, a base often employed in combination with TU in organocatalysis, is equal to 17.3. TBD is commercially available. The synthesis of specific acyclic guanidines can be performed by reaction of carbodiimides with secondary amines.[35]

Literature in molecular chemistry has shown that TBD can be employed as a strong base for a variety of reactions, including Michael additions,[36] Wittig reactions,[37] enantioselective Strecker synthesis of R-aminonitriles and R-amino acids,[38] or transesterification reactions.[39] Section 4.06.5 will highlight the higher catalytic efficacy of TBD over MTB and DBU for various organocatalyzed polymerizations.

2-Amino-oxazoline and 2-aminothiazoline (**Figure 1**) are organocatalysts whose structure exhibits similarities with that of TBD.[40] Indeed, both 2-aminothiazoline and 2-amino-oxazolines have a three-centered –N=C–NH– moiety, like TBD. These catalysts were shown to provide a dual activation in the organocatalyzed ROP of lactide.

4.06.3.1.3 TU-amino derivatives

Ureas and TUs are hydrogen-donating compounds that can easily activate carbonyl-, sulfoxide-, or nitro-containing substrates[19,35] and can be viewed as weak electrophile.[31] In molecular synthesis, a variety of chiral urea- and TU-based catalysts have been employed for stereoselective C–C bond forming reactions, including the Strecker, Mannich, Pictet–Spengler reactions, and aza-Henry and Michael reactions.[41–53] As mentioned above, bifunctional TU-amino derivatives allow for an activation of carbonyl substrate in a dual manner, when the TU moiety is combined with an amino-functionality in a mono- or a bicomponent catalytic system.[45,46,54,55] The strength of hydrogen bonding can be finely tuned through a proper selection of substituents both on the TU and on the amine.

4.06.3.1.4 Phosphorus-based catalysts: Phosphines and phosphazenes

Tertiary phosphines are known to behave as Lewis bases in acylation reactions that proceed through a nucleophilic activation mechanism (see Section 4.06.7 for possible mechanisms operating in organocatalyzed polymerization).[56,57] Their use as nucleophilic catalysts in enantioselective processes, which include the addition of alcohols to ketenes, the rearrangement of O-acylated azlactones, and the kinetic resolution of alcohols, is also well documented.[58–63]

Surprisingly, and to the best of our knowledge, while phosphines have been used to directly initiate several metal-free

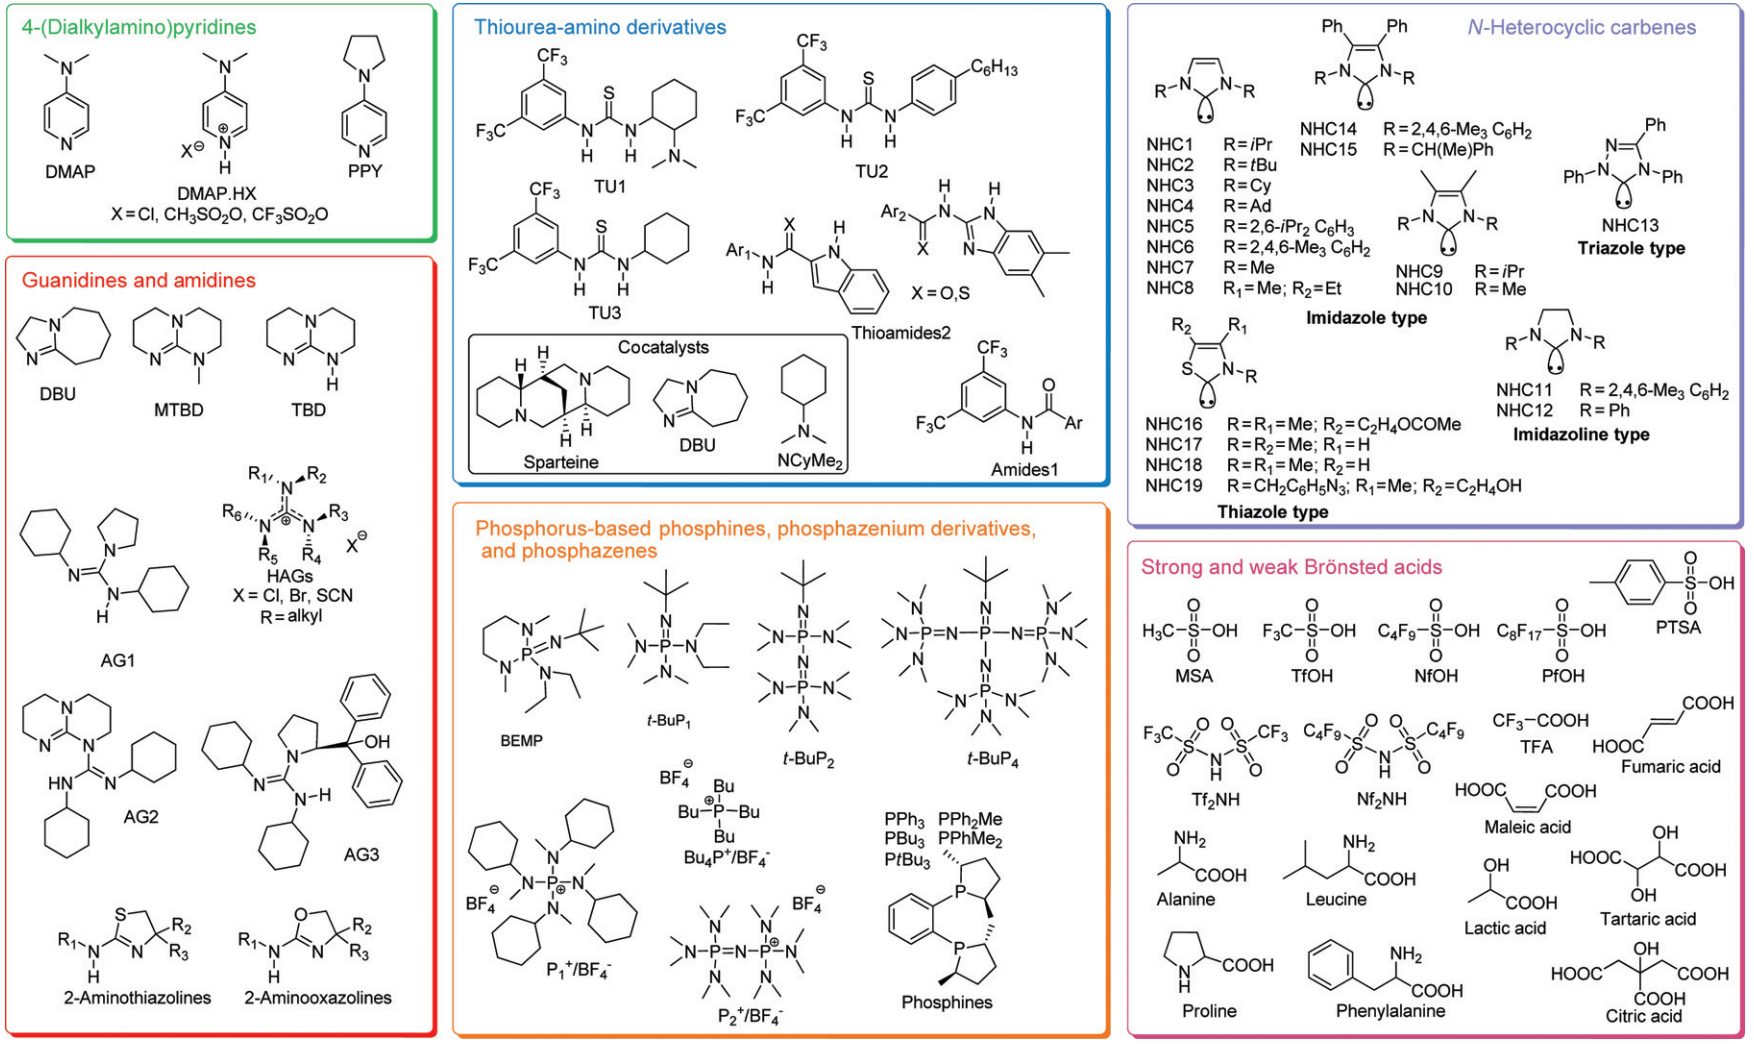


Figure 1 Organic catalysts used for polymerization reactions.

(noncatalyzed) polymerizations (see Section 4.06.2), there is only one report about their use as true organic catalysts (and not as initiators).[64] In these circumstances trialkyl- and triarylphosphines such as PBu_3, PPh_3, $PPheMe_2$, and PPh_2Me have been employed (Section 4.06.7).

Phosphazenes such as (*tert*-butylimino)-tris(dimethylamino)phosphorane (*t*-BuP_1), {[(*tert*-butylimino)bis(dimethylamino)phosphoranyl]imino}tris(dimethylamino)phosphorane (*t*-BuP_2), (*tert*-butylimino)tris{[tris(dimethylamino)phosphoranylidene]amino}phosphorane (*t*-BuP_4), and 2-(*tert*-butylimino)-2-(diethylamino)-1,3-dimethylperhydro-1,3,2-diazaphosphorinane (BEMP) were developed by Schwesinger and Schlemper.[65] They are generally considered as strong, nonnucleophilic, neutral Bronsted bases, high pK_a value characterizing their conjugated acid (pK_a = 27.6, 30.2, and 27.6 for the conjugate acid of *t*-BuP_1, *t*-BuP_4, and BEMP, respectively, as measured in acetonitrile and dimethyl sulfoxide).[66] Generally speaking, phosphazenes are thus more basic by approximately 2–3 pK_a units than guanidines such as DBU and MTBD (pK_a around 24.3–25.5 for the corresponding acids). For this reason, phosphazenes have exclusively served as strongly basic deprotonating agents of acidic OH-, SH-, or CH-containing initiators in metal-free polymerizations (see Section 4.06.7).

4.06.3.1.5 N-heterocyclic carbenes

N-heterocyclic carbenes (NHCs) are a specific subgroup of carbenes, which are neutral divalent species of carbon, possessing six peripheral electrons in their valence shell. Four of them are involved in two σ-bonds while the two nonbonding electrons remain at the central carbon. When the carbene center is not properly substituted, these species are highly reactive with lifetime typically under 1 s (0.1–1 ns).[67] The first isolated stable carbene was a non-NHC acyclic (phosphinosilyl)carbene, synthesized by Igau *et al.* in 1988.[68] A few years later, Arduengo *et al.*[69] succeeded in isolating the first NHC, 1,3-diadamantylimidazol-2-ylidene. Variation of R_1–R_4 substituents of NHCs offers opportunities to tune both the electronic and steric properties, hence modulating their reactivity/nucleophilicity. Since these pioneering works on stable carbenes, these species have received considerable attention in molecular synthesis[70–72] and, more recently, in macromolecular chemistry as well.[5,6] Thanks to their peculiar electronic properties, stable singlet carbenes, and in particular NHCs, have become not only versatile ligands for transition metals[73–77] but also powerful organocatalysts for a variety of organic transformations. Many of these NHC-catalyzed reactions are based on the activation of the carbonyl group (e.g., benzoin condensation, Stetter reaction, and transesterification),[70,72] though other electrophilic groups such as trimethylsilyl can be activated (e.g.,cyanosilylation or (trifluoromethyl)silylation reactions).[78]

NHCs are generally obtained by deprotonation of their conjugate acids, namely imidazoli(ni)um salts, with a strong base. Excellent reviews can be found on the synthesis of carbenes, their electronic properties, their reactivity, and means to manipulate these catalysts.[70,75,79,80]

The pK_a values of some carbenes were determined both experimentally and theoretically and they range between 15 and 30 (pK_a values of corresponding azolium salts in water at 25 °C: NHC2 ~ 25, NHC5 and NHC6 ~ 21, see **Figure 1**).[81]

4.06.3.1.6 Bronsted acids

Besides strong Bronsted acids, such as trifluoromethanesulfonic acid (CF_3SO_3H also denoted TfOH), recent years have witnessed the development of so-called superstrong Bronsted acids as powerful catalysts in organic synthesis. Of particular interest are sulfonimide-type acids, whose prototype bis(trifluoromethanesulfonyl)imide $(CF_3SO_2)_2NH$ (Tf_2NH) allowed significant achievements in molecular chemistry for a variety of C–C bond forming reactions.[82–84] Penczek pioneered the use of Bronsted acids to trigger the ROP of cyclic ethers in the late 1980s (see Section 4.06.9). Among acid-containing catalysts, strong and superstrong acids such as methanesulfonic acid (CH_3SO_3H), CF_3SO_3H, or $(CF_3SO_2)_2NH$ have been the most studied. Nevertheless, not only weak acids such as carboxylic acids (e.g., CF_3CO_2H) but also naturally occurring α-hydroxyacids and α-amino acids can serve as organocatalysts of polymerization (**Figure 1**).

4.06.3.2 Monomer Candidates

Figure 2 shows the different families of monomers that were subjected to an organocatalyzed polymerization pathway, with their name and abbreviation as will be used hereafter. In their vast majority, monomers amenable to organocatalyzed polymerizations are heterocyclics, which are the main focus of this chapter. In particular, carbonyl-containing heterocyclics were subjected to ROP by almost all categories of the aforementioned organic catalysts. Carbonyl heterocycles thus include lactide (both in its racemic and enantiopure versions, *rac*-LA and DD- or LL-LA, respectively), lactones, cyclic carbonates, NCAs, and 1,3-dioxolane-2,4-diones, referred to as *O*-carboxyanhydrides (OCAs). In the two latter cases, the driving force of the polymerization is the evolution of a CO_2 molecule in each propagation step. For instance, the ROP of L-Lac-OCA proved a competitive synthetic route to poly(LA) (=PLA) compared with the ROP of LA.[85] Due to space limitation, the synthesis of specific monomers that were thus polymerized by an organocatalyzed pathway cannot be detailed. Related information can be found in the original reports.

Many of these heterocycles are commercially available. They arise from petroleum as source, except LA. Methyl-substituted seven-membered ring carbonates (7CCs), namely 4-methyl- and 5-methyl-1,3-dioxepan-2-one (R-Me7CC and β-Me7CC), have been synthesized by cyclization of the corresponding α,ω-diols drawn from green renewable acids.[86]

Specific monomers incorporating functional groups in a protected form, for example, protected functional cyclic carbonates or L-Glu-OCA or (3*S*)-3-{2-[(benzyloxy)carbonyl]ethyl}-1,4-dioxane-2,5-dione (BED), were purposely designed, sometimes via multistep synthetic methods.[87–89] Introduction of pendant functional groups in the resulting polymers was aimed at bestowing better degradation properties and greater hydrophilicity of these materials.

Less polar cyclic monomers, such as ethylene oxide (EO), propylene oxide (PO), cyclosiloxanes and cyclocarbosiloxanes, have also been reported to undergo a metal-free ROP, in particular using NHCs as organocatalysts.

Besides, a few examples of polymers grown (or depolymerized) by GTP of (meth)acrylics and step-growth (de)polymerizations, employing NHCs (and more recently TBD), were also described.

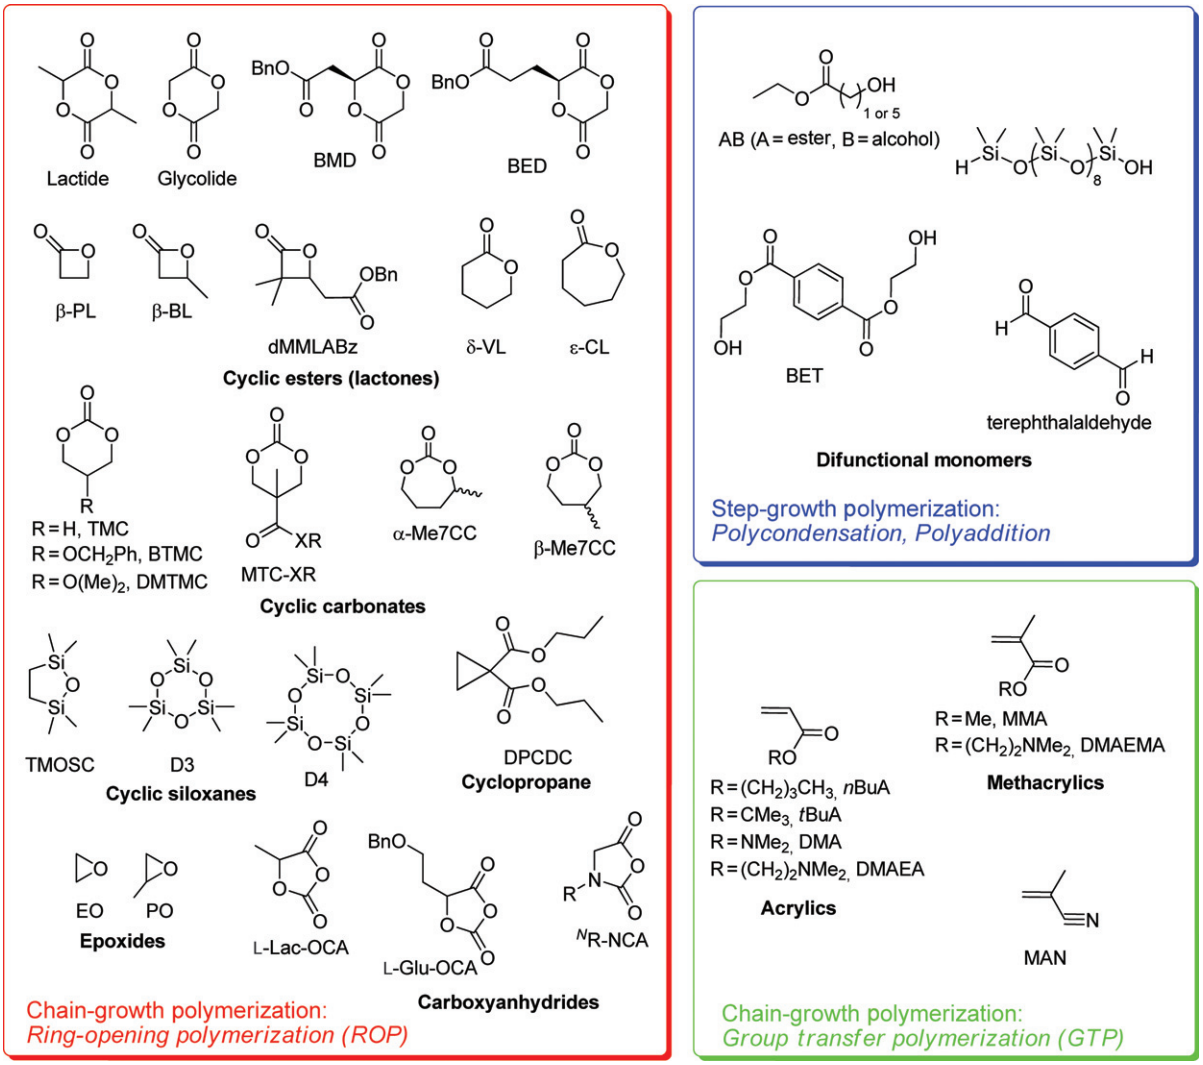

Figure 2 Monomers polymerized via an organocatalytic pathway.

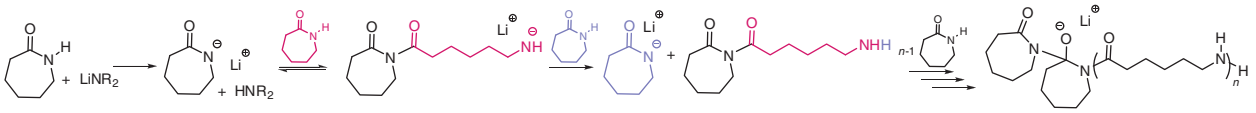
4.06.3.3 General Polymerization Mechanisms

Since organic catalysts may operate differently as compared with metal-based ones, they may offer a diversity of mechanistic pathways to control the polymerization. In the particular case of the ROP of heterocycles, four distinct mechanisms can be singled out, depending upon the nature of the active center of the organocatalyst (acid vs. base and/or electrophilic vs. nucleophilic) used.[6] In the presence of a purposely added 'chain regulator', that is, an initiator controlling the resulting polymer chain length (typically an alcohol in the following examples), the organocatalyst can activate either the latter initiator and then the polymer chain ends after repetitive propagation steps or the monomer substrate or both via a cooperative dual activation.

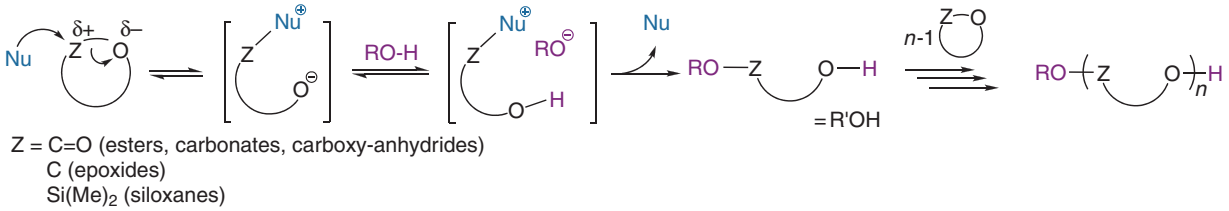
Polymerization proceeding by activation of the monomer is referred to as the 'activated monomer mechanism' (AMM) – both nucleophilic and electrophilic – whereas polymerization by activation of the initiator/polymer chain ends is referred to as the 'active chain end mechanism' (ACEM). Note that, in the context of true organocatalysis, only basic catalysts are able to promote ACEM. Although out of the main focus of this chapter, the so-called dissociative versus associative polymerization mechanism operating in the GTP of (meth)acrylic monomers mediated by organic catalysts (e.g., ammonium fluoride, strong acids, or NHCs) is another example of initiator/polymer chain end activation. In some cases, it is unclear whether polymerization occurs solely by monomer activation, initiator activation, or both. Sometimes, one mechanism is exclusive (as in the case of bulky nonnucleophilic phosphazenes, which operate as strong bases to activate the initiator), but in general, different mechanisms may be operative concomitantly.

4.06.3.3.1 Nucleophilic AMM

AMM has been suggested in the early 1970s for several polymerizations involving organometallic species. A typical example is the ROP of ε-caprolactam by lithium amides, as illustrated in Scheme 2.[90] With the recently developed nucleophilic organic catalysts, the nucleophilic AMM proceeds by a direct attack of the cyclic monomer by the catalyst Nu (Scheme 3). This ring opening generates a zwitterionic intermediate, typically an alkoxide featuring a bulky and soft countercation, for example,



Scheme 2 ROP of ε-caprolactam by lithium amides (nucleophilic activated monomer).[90]



Scheme 3 AMM via nucleophilic monomer activation.

pyridinium and imidazolinium when DMAP or a NHC is used. Protonation of this zwitterionic 'activated monomer' by the alcohol initiator (ROH), and subsequent displacement of the bound catalyst by the alkoxide arising from the initiator (RO^-), generates a ring-opened alcohol monoadduct, with concomitant release of the organic catalyst. The next propagation step proceeds in the same way, that is, by activation of the monomer, except that this is the alcohol monoadduct which reacts with the activated monomer. This nucleophilic AMM mechanism has been proposed for miscellaneous nucleophilic organocatalysts, including DMAP, PPY, trialkyl- and triarylphosphines, and NHCs (Scheme 3).

4.06.3.3.2 Electrophilic AMM

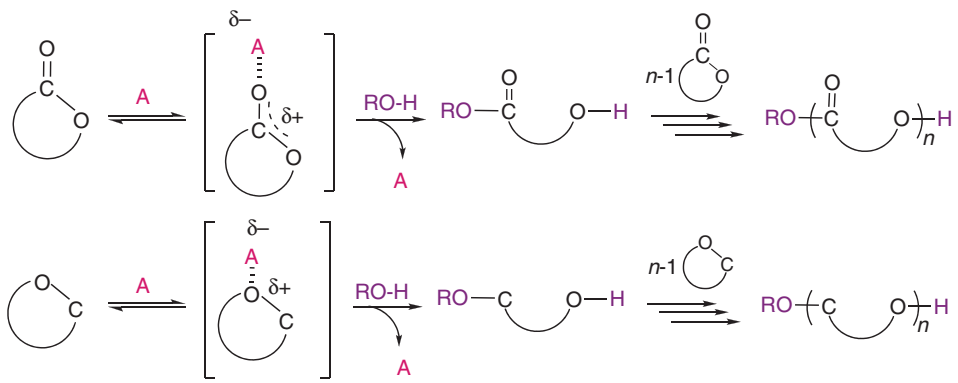
As already mentioned, the AMM induced by Lewis or Bronsted acids has been established, in particular by the group of Penczek *et al.*,[91,92] for the ROP of cyclic ethers. In this case, the electrophilic (acidic) catalyst activates the cyclic monomer through protonation of the heteroatom (e.g., the oxygen of the carbonyl group for cyclic esters or the oxygen atom of cyclic ethers, Scheme 4). The resulting activated monomer undergoes ring opening by nucleophilic attack of the oxygen of the alcohol initiator (or polymer chain end), leading to the formation of the monoadduct alcohol, while the acidic catalyst is regenerated. Strong and weak acids have been reported to induce such an electrophilic AMM in the case of the ROP of epoxides, LA, lactones, or cyclic carbonates (Scheme 4, see also Section 4.06.9).

4.06.3.3.3 Active chain end mechanism

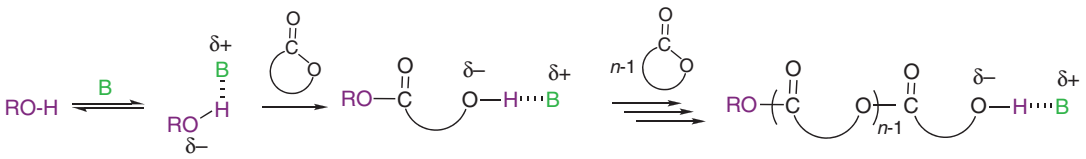
ACEM occurs in the anionic or ionic coordinated ROP of many heterocycles mediated by organometallic species. Propagation occurs by the direct attack of the active chain end (an alkoxide, a carboxylate, a silanolate, and a thiolate, depending on the cyclic monomer involved) on the cyclic monomer. With metal-free organic catalysts, a similar mechanism can operate but under milder conditions, where the basic catalyst typically activates the initiator (or the polymer chain end), most often by hydrogen bonding thereby increasing its nucleophilicity, which favors the attack on the cyclic monomer (Scheme 5). Note that depending on the pK_a difference between the initiating alcohol and the Bronsted base, the RO–H proton can be completely transferred to the basic site, thus generating an alkoxide. In fact, the extent of proton transfer will greatly vary with the nature of the alcohol and the basicity of the catalyst.

4.06.3.3.4 Dual activation of monomer and initiator/chain end

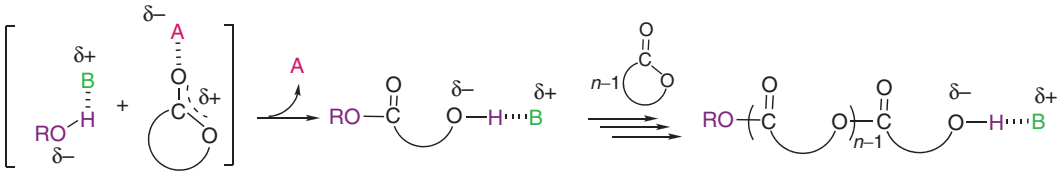
Cooperative dual activation of both the monomer and the initiator/polymer chain ends can be operative with specific catalysts (e.g., TU-amino derivatives, TBD, or even DMAP) as a means to trigger the ROP of cyclic esters. Here also, analogies can be found with some metal-based catalysts which have been suggested to behave by such a dual activation (Scheme 6).[27] Using true organic catalysts for ROP implies that an electrophilic moiety (typically proton) activates the heteroatom of the



Scheme 4 AMM via acid (A) monomer activation.



Scheme 5 Basic active initiator/chain end mechanism (ACEM).



Scheme 6 Acid-basic bifunctional activation.

cyclic monomer, while a base interacts with the proton of the alcohol initiator, increasing its nucleophilicity.

4.06.4 Polymerizations Catalyzed by 4-(Dialkylamino) pyridines

An overview of the main monomers polymerized from these organocatalysts and related formed polymers is shown in Figure 3. Table 1 summarizes the different works employing DMAP or PPY for the ROP of a few heterocycles, including trimethylene carbonate (TMC), LA, ε-CL, and OCAs, in the presence of hydroxy- or amino-containing initiators.

Kricheldorf *et al.*[97] have reported that pyridines can be directly used as organic nucleophilic initiators for the metal-free – but noncatalyzed – zwitterionic ring-opening polymerization (ZROP) of pivalolactone (Scheme 7). Linear zwitterionic aliphatic polyesters, with a pyridinium and a carboxylate group, in α- and ω-position respectively, are formed in this way.

In polymer synthesis, DMAP is among the first employed organocatalyst. In 2001, Nederberg *et al.*[24] indeed reported the 'first organocatalytic living polymerization' of LA mediated either by DMAP or PPY, in the presence of ethanol, isopropanol, or benzyl alcohol as initiator (Table 1, entry 1). PLAs with a predictable degree of polymerization (from 5 to 120) and a dispersity below 1.2 could be achieved under relatively mild

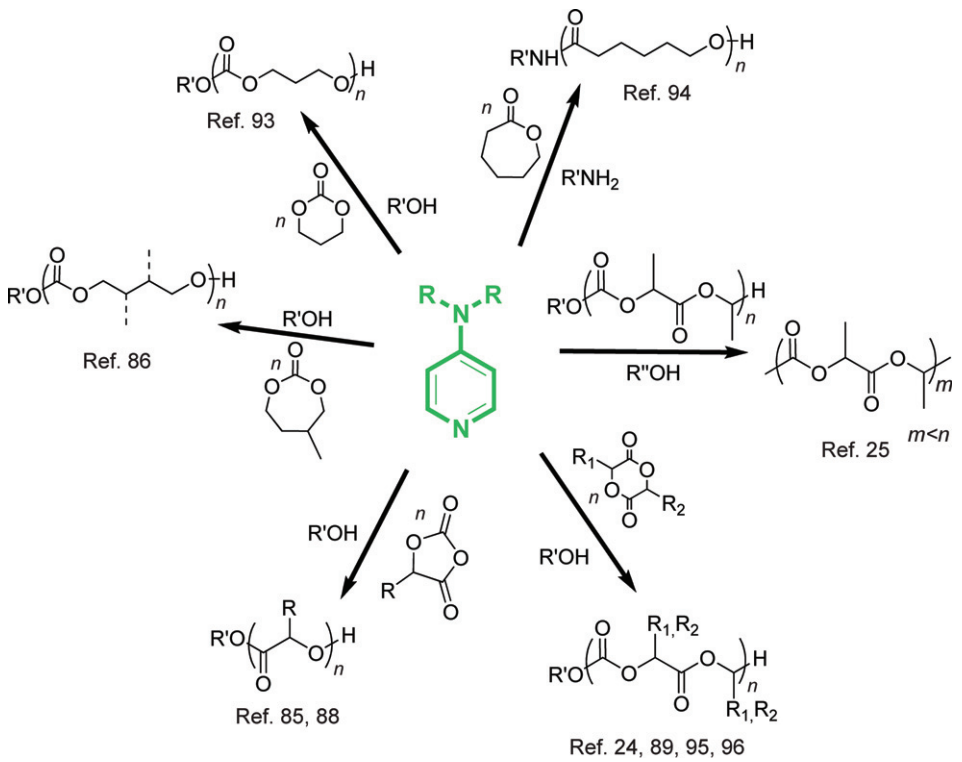


Figure 3 Overview of main polymers obtained from 4-(dialkylamino)pyridines as catalysts.

conditions (bulk at 135 °C or in CH_2Cl_2 at 35 °C), though 0.1–4 equiv. of amine relative to the initiating alcohol was employed. It was also possible to immobilize DMAP onto cross-linked polystyrene particles and thus perform the ROP of LA from such polymer-supported organocatalysts, allowing its easy recovery by simple filtration.

A significant advantage of DMAP is its high selectivity of propagation in the ring opening of cyclic esters and resistance to adverse intra and/or intermolecular transesterifications (chain reshuffling).

DMAP was also found compatible with a metal-centered tris-hydroxylated initiator, namely $[Ru(bpyPLA_2)_3](PF_6)_2$, so as to produce three-arm PLA stars with luminescent tris(2,2′-bipyridine)ruthenium centers (**Table 1**, entry 2).[95]

In 2006, Feng and Dong[94] applied the DMAP-induced ROP to prepare a series of biodegradable graft copolymers consisting of a naturally occurring chitosan backbone and poly(ε-caprolactone) (PCL) grafts (entry 3). They employed 2 equiv. of DMAP relative to the amino groups carried by chitosan and water as swelling agent. The grafting density could be finely tuned through the [ε-CL]/[chitosan] molar feed ratio. It was shown that initiation took place from the primary amino-functions of chitosan rather than from the hydroxyl groups, in agreement with the higher nucleophilicity of

amino versus alcohol functions. However, the extent of amino groups participating in the initiation was found to decrease, as the [ε-CL]/[chitosan] ratio increased, which was ascribed to the progressive heterogeneity of the aqueous reaction mixture.

Relatively slow reaction times characterize the DMAP-catalyzed ROP of cyclic esters, in spite of a catalyst concentration in the order of that of initiator (**Table 1**). LA could be polymerized by both DMAP and PPY as organic catalysts, either in solution or in the melt.[24,25]

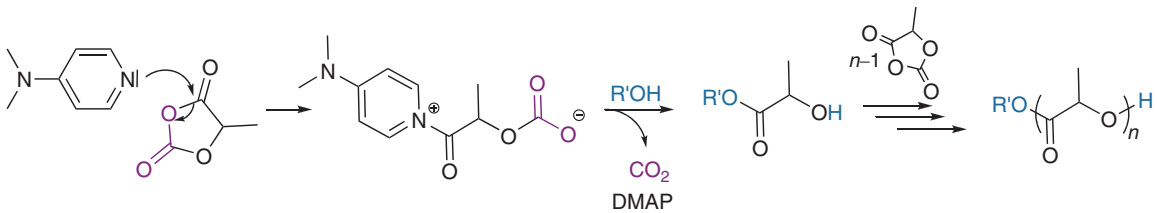
In contrast, the lactide equivalent *O*-carboxyanhydride (L-Lac-OCA) was polymerized much more rapidly than LA, in the presence of DMAP and an equivalent of either primary or secondary alcohols as initiators (**Table 1**, entry 4) typically within a few minutes at room temperature (vs. a few days at 35 °C for LA) for the [L-Lac-OCA]/[*n*-pentanol]/[DMAP] ratio equal to 20/1/1.[85]

The attack of DMAP at the more electrophilic carbonyl group of the monomer was postulated, followed by an exchange of proton with the hydroxyl-containing initiator or polymer chain end and decarboxylation (**Scheme 8**), the polymerization thus occurring through an AMM. The same group also reported the DMAP-mediated ROP of OCA derived from glutamic acid (L-Glu-OCA, **Figure 2**).[88] This functional monomer was found to exhibit a much higher reactivity compared with its 1,4-dioxane-2,5-dione homolog. Here also, 1 equiv. of DMAP relative to the initiator was employed (entry 5). Metal-free aliphatic (co)polyesters featuring pendant protected carboxylic acid groups in the form of benzyl esters could thus be obtained. Such polymers were prepared with degree of polymerization (DP) up to 100 in dichloromethane at room temperature, using *n*- or 2,2-bis(hydroxymethyl)propane-1,3-diol (*neo*-pentanol) as initiator, with a good polymer chain end fidelity. Complete deprotection of the pendant COOH groups could be readily achieved by hydrogenolysis. Synthesis of both random and block copolymerization of L-Glu-OCA and L-Lac-OCA was also investigated. Block copolymers were synthesized by the DMAP-catalyzed sequential ROP of both monomers, whereas access to various statistical copolymers was possible by varying the L-Glu-OCA to L-Lac-OCA ratios from 1:10 to 1:1. The random character of these copolymers was supported by analysis using ^{13}C NMR spectroscopy. A comparative study finally showed that the functionalized monomer, L-Glu-OCA, was slightly more reactive than L-Lac-OCA.

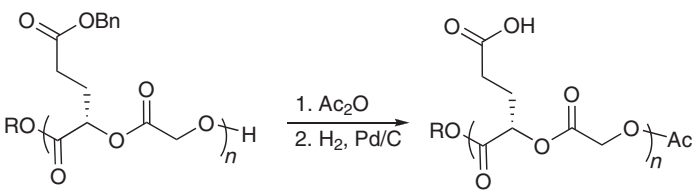
DMAP-induced ROP of (3*S*)-3-{2-[(benzyloxy)carbonyl] ethyl}-1,4-dioxane-2,5-dione (BED, **Figure 2**) was also recently investigated by du Boullay *et al.*[89] Well-defined polymers of molar masses up to 36 000 g mol^{-1} were obtained at 30 °C in dichloromethane ([BED]$_0$ = 1 mol l^{-1}) and *n*-pentanol as initiator (entry 6). Complete conversion was achieved in a few hours. Under these conditions, BED showed a slightly higher reactivity compared with LA. Deprotection of the pendant carboxylic groups was achieved by hydrogenolysis (**Scheme 9**). However, a bicomponent catalytic system based on TU and (−)-sparteine was found significantly more active than DMAP (see Section 4.06.6).

Two recent studies by Brignou *et al.*[86] and Helou *et al.*[93] showed that substoichiometric amounts of DMAP relative to the alcoholic initiator could be employed to polymerize six-membered cyclic carbonates (entry 7). Polymerizations were performed in bulk (solvent-free conditions) in a range of temperatures between 60 and 150 °C. The ROP of the seven-membered cyclic carbonates (entry 8) was conducted with equimolar amounts of DMAP relative to the OH-containing initiator which also required higher temperature (110 °C) compared with organometallic complexes used as catalysts.

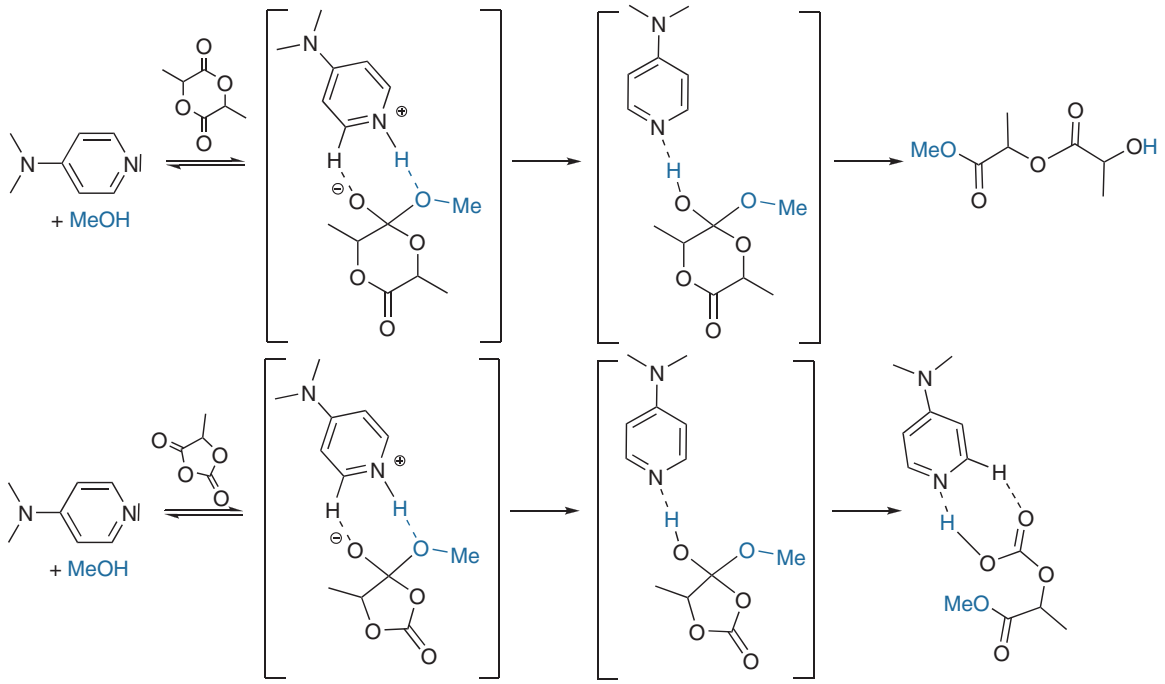
An AMM was originally put forward to account for the ROP of LA, via a direct nucleophilic attack of DMAP onto the carbonyl function of the cyclic ester (see **Scheme 1**).[24,85] However, on the basis of computational investigations of model reactions in the case of DMAP-catalyzed ROP of LA and Lac-OCA, Bonduelle *et al.*[98] suggested that an ACEM, where DMAP activates the alcohol through hydrogen bonding, was energetically more favorable (**Scheme 10**). The ACEM provided, indeed, the lower energy profile compared with the AMM involving *N*-acylpyridinium intermediates.[98] The authors demonstrated the key role of multiple hydrogen bonding, as well as the possibility of DMAP to act not only as a base but also as a



Scheme 8 Polymerization of L-Lac-OCA initiated by ROH and catalyzed by DMAP (AMM).[85]



Scheme 9 Deprotection of PBED pendant carboxylic groups by hydrogenolysis.[89]



Scheme 10 Mechanism proposed for DMAP-catalyzed ROP of LA and L-lac-OCA on the basis of computational studies by Bonduelle *et al.*[98]

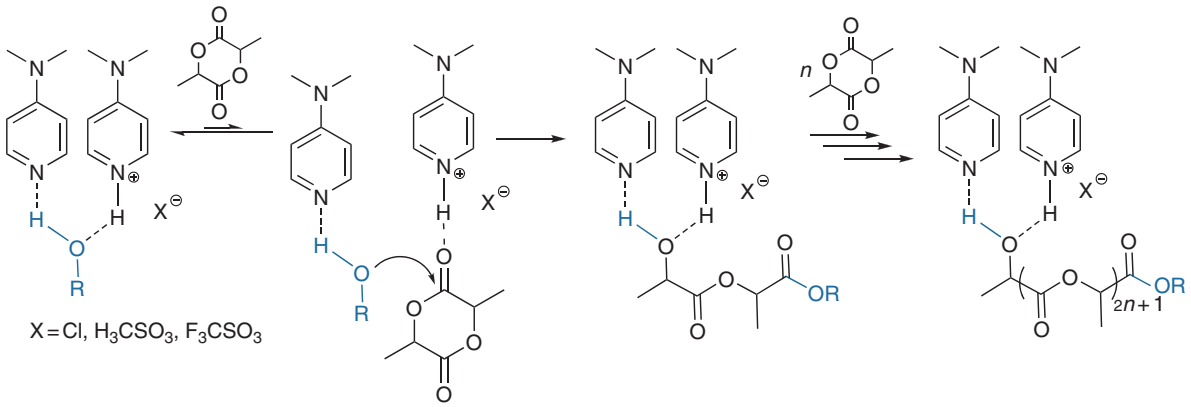
bifunctional catalyst, through its basic nitrogen center and an acid ortho-hydrogen atom.

In 2010, Kadota *et al.*[96] employed DMAP coexisting with equimolar amounts of its conjugate acid, that is, in its protonated form (DMAP/HX), to trigger the organocatalyzed ROP of LA in the presence of various alcohols as initiators. Such a combination provided cooperative activation by H-bondings of both the PLA chain end and the monomer (Scheme 11). Such bicomponent catalytic systems should thus be also categorized as dual catalysts (see Section 4.06.3.3.4). These organocatalytic systems, where the counteranion X^- could be varied, were found significantly more active than DMAP alone, with a rate enhancement in the order $X = CF_3SO_3 > CH_3SO_3 > Cl$. Control of molar masses up to 13 000 g mol^{-1} and PLA with relatively narrow dispersities were obtained at room temperature after 24–48 h (entry 9).

4.06.5 Polymerizations Catalyzed by Amidines

Representative examples of amidines are shown in Figure 1; see also Table 2 and Figure 4 for a summary of potentials offered by these organocatalysts. First attempts to polymerize ε-CL, LA, and glycolide using hexaalkylguanidinium salts (HAGs) as direct initiators – not catalysts – were reported by Li *et al.*[102] These metal-free polymerizations were performed in bulk at 120 °C. However, a relatively poor control over molar masses and dispersities was obtained (Table 2, entry 1).

Both MTBD and DBU efficiently catalyze the ROP of LA, leading to well-defined PLAs with a DP up to 500, a dispersity lower than 1.1 in less than 1 h, and a turnover frequency (TOF) ~0.05 s^{-1} (entry 2).[103] However, broadening of molar mass distribution due to transesterification was observed at high conversions. Attempts to catalyze the ROP of other heterocyclic



Scheme 11 Cooperative activation by H-bondings proposed for the ROP of LA catalyzed by DMAP+DMAP/HX.[96]

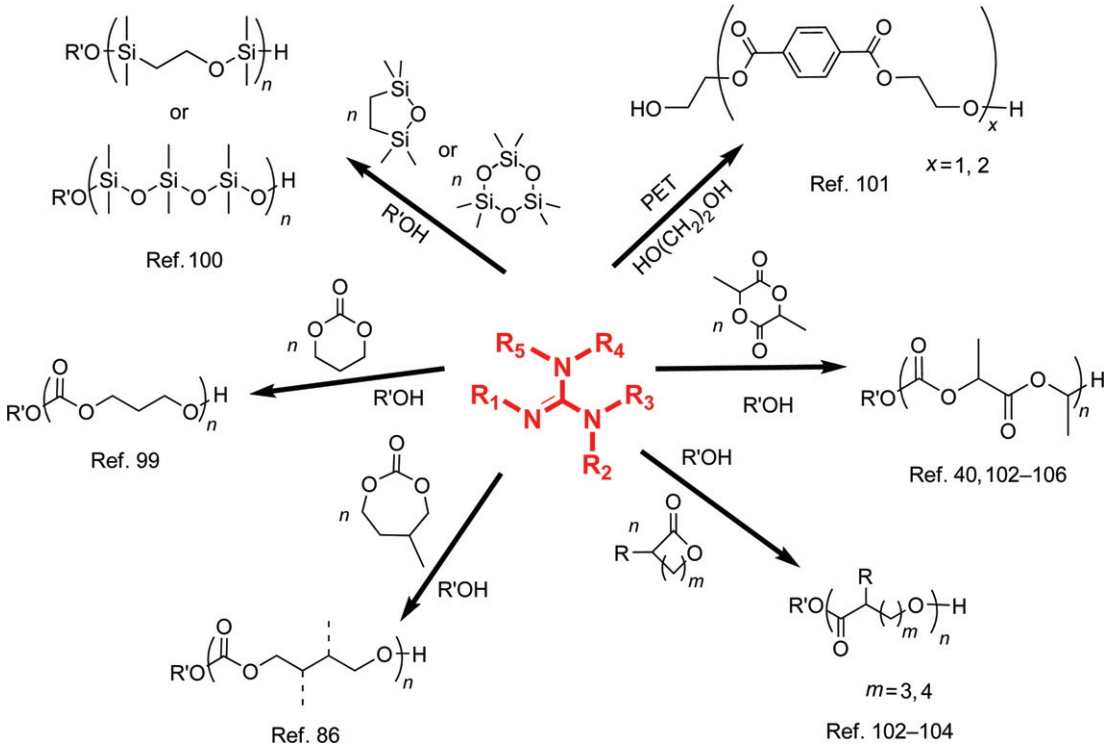


Figure 4 Overview of polymers obtained from amidines as catalysts.

substrates including ethylene oxide (EO), β-butyrolactone (βb-BL), δ-valerolactone (δ-VL), or ε-caprolactone (ε-CL) or carbosiloxanes by MTBD and/or DBU met with very limited success.[100,103] Improvements were observed when employing these organocatalysts in combination with TU (see next section).

In contrast, TBD proved highly active in the ROP of LA, δ-VL, ε-CL, methylcarboxytrimethylene carbonate (MTC), TMC, and even noncarbonyl monomers such as carbosiloxanes with exceptionally high rates, rivaling the carbene organocatalysts (Section 4.06.8) in TOF.[99,104,107] TBD exhibited a much higher reactivity toward the ROP of LA and TMC than its substituted analog, MTBD (TOF = 81 vs. 0.002 s^{-1} and TOF = 0.1 s^{-1} vs. 0.1 h^{-1} for the ROP of LA and TMC, respectively). For instance, polymerization of LA in CH_2Cl_2 using 0.1% catalyst relative to monomer and 1% of 4-pyrenebutanol (PBuOH) gave a well-defined PLA in seconds at room temperature (entries 2 and 3, **Table 2**). At the completion of these polymerizations, however, TBD also catalyzed transesterification reactions of the resulting aliphatic polyester, as indicated by the broadening of the molar mass distribution. As a matter of fact, poor reliability of the presence of end groups was noted. Yet, TBD could be quenched, before it catalyzed transesterification of PLA chains, simply by adding benzoic acid.

Note that ROP of β-BL cannot be performed at room temperature by TBD due to the formation of a stable hydrogen-bonded intermediate with the catalyst (**Scheme 12**).[106] In contrast, TBD-catalyzed ROP of δ-VL was carried out in benzene solution and was found more slowly than that of LA, leading to poly(δ-valerolactone) (PVL) with a molar mass of 14 500 g mol^{-1} and a dispersity of 1.09. A significant increase in dispersity was noted for PCL prepared by ROP of ε-CL catalyzed by TBD.[103]

Use of monohydroxy-functionalized polymers as macroinitiators (e.g., poly(ethylene oxide), PEO; poly(styrene), PS; and poly(*N*,*N*-dimethylacrylamide), PDMA) allowed the synthesis of block copolymers with PLA, P(δ-VL), and P(ε-CL) as second block. Interestingly, sequential ROP of cyclic esters of different reactivity employing TBD could be achieved at room temperature. Aliphatic block copolyesters could thus be obtained, by polymerizing first the slower propagating monomer to high conversion and subsequently adding the second monomer.[103]

No transetherification was noted at full conversion in the case of the TBD-catalyzed ROP of carbosiloxanes (entry 6), in contrast to the situation prevailing for NHCs (see Section 4.06.8).[100] Bulk polymerization at 65 °C or solution polymerization (2.0 M in CH_2Cl_2) at room temperature of TMC was also efficiently accomplished in the presence of MTBD, TBD, and DBU organocatalysts, providing good control over molar mass and dispersity (entries 4 and 5, **Table 2**).[99] Polycarbonates with M_n up to 40 000 g mol^{-1} and dispersity below 1.08 were obtained in this way. Random copoly(ester-*co*-carbonate)s were also prepared by copolymerizing TMC and δ-VL in bulk. Synthesis of block copolymers featuring biodegradable PTMC blocks could also be achieved by combining distinct polymerization techniques, for example, nitroxide-mediated polymerization (NMP) or reversible addition fragmentation chain transfer (RAFT) polymerization with TBD-catalyzed ROP of TMC.

Whereas DBU and MTBD seem to only activate the alcohol initiator by ACEM (**Scheme 13**),[99,103] the unique activity of TBD catalyst was explained by its bifunctionality during ROP of LA, involving a H-bonding mechanism (**Scheme 14**). This was supported by computational studies which provided the lower

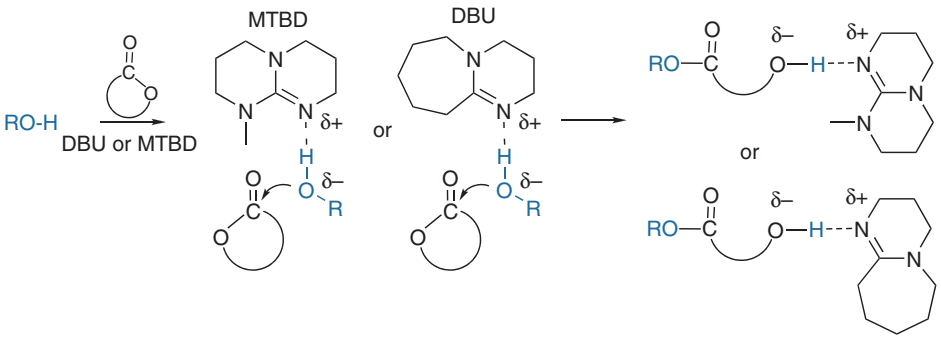
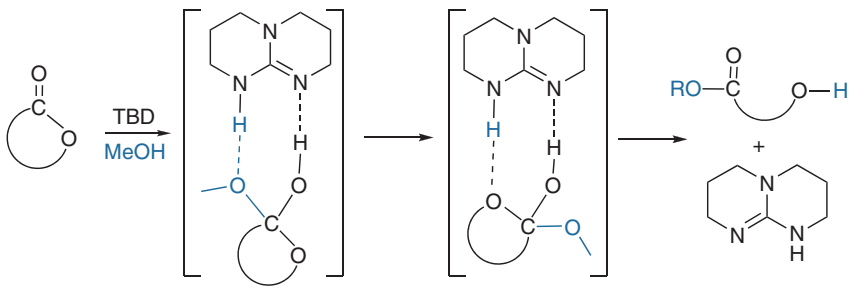
energy profile in the case of such a dual activation, relatively to a nucleophilic AMM involving an acyl–TBD intermediate.[106,108] TBD would thus simultaneously activate both the alcohol and the carbonyl group of the cyclic ester by H-bonding. In molecular chemistry, bicyclic guanidine catalysts were also found to provide such hydrogen bonding for the enantioselective Strecker reaction of R-aminonitriles and R-amino acids.[35]

The acyclic guanidines synthesized by reaction of carbodiimides with secondary amines were also shown to catalyze the



Scheme 13 Proposed mechanism (ACEM) for the ROP of cyclic esters catalyzed by MTBD or DBU.[99,103]



Scheme 14 Proposed mechanism (bifunctional activation) for the ROP of cyclic esters catalyzed by TBD (computational study).[106,108]

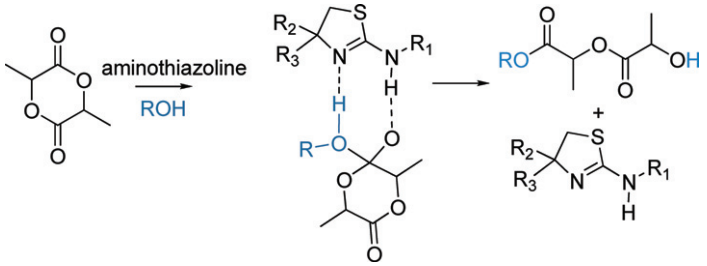
ROP of LA (Table 2, entry 7), though providing lower rates of reactions as compared with TBD under the same conditions.[107] Polymerizations were performed in CH_2Cl_2 (2 M) with equimolar amounts of catalyst relative to initiator (4-pyrenebutanol), corresponding to 1 mol.% relative to monomer. PLAs were obtained in approximately 40 min in nearly quantitative yield and high end-group fidelity was demonstrated. The molar masses were varied from 17 600 to 37 000 g mol^{-1} with a dispersity lower than 1.1. Though less basic than TBD, these guanidines were also found to be hydrogen donors and, similarly to TBD, could catalyze the reaction by activation of the alcohol initiator through hydrogen bonding.

TBD-catalyzed ROP of LA was recently applied by Theryo *et al.* to the synthesis of graft copolymers consisting of a rubbery backbone ($T_g \approx -80$ °C) and PLA grafts.[105] A statistical copolymer was first synthesized by ring-opening metathesis copolymerization (ROMP) of 1,5-cyclooctadiene and 5-norbornene-2-methanol in the presence of the second-generation Grubbs' catalyst. The PLA grafts were then grown from the statistically distributed pendant primary hydroxyl groups by TBD-catalyzed ROP of LA, following a grafting from approach (entry 8). A chain transfer agent, namely (*Z*)-1,4-diacetoxybut-2-ene, was used to control the chain length of the ROMP-derived rubbery copolymer. Despite a large compositional asymmetry, these graft copolymers exhibited a microphase-separated morphology and an improved tensile ductility compared with neat PLA homopolymer.

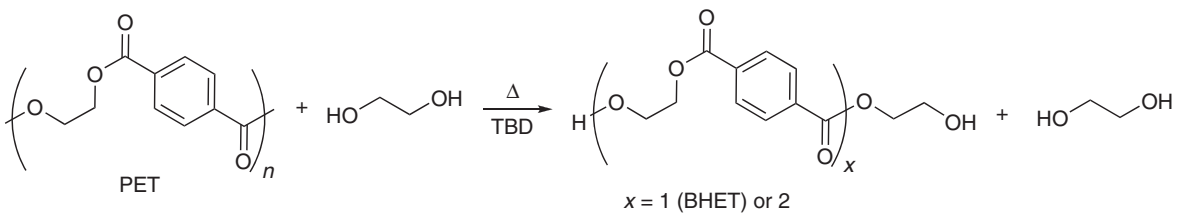
Works by Brignou *et al.*[86] and Helou *et al.*[93] showed that very low amounts (as low as 10 ppm) of TBD could efficiently catalyze the ROP of six- and seven-membered cyclic carbonates (TMC, 3,3-dimethoxytrimethylene carbonate (DMTMC), 3-benzyloxytrimethylene carbonate (BTMC), or methyltetramethylene carbonate (Me7CC) in Figure 2) in bulk, in the presence of benzyl alcohol, though relatively high temperatures (60–150 °C) were required to counterbalance the low catalyst loading (entries 9 and 10, Table 2). At 110 °C, for instance, 500 equiv. of monomer was converted within 5 min (vs. 30 min at 60 °C). Interestingly, 10 000 equiv. of the technical-grade unpurified TMC monomer could be almost quantitatively polymerized in the presence of 200 equiv. of alcohol, in contrast to organometallic catalytic systems. The highest activity was obtained for TBD-catalyzed ROP of purified TMC at 150 °C: TOF = 49 200–55 800 h^{-1}. The molar mass distribution of polycarbonates prepared in bulk was slightly larger than that observed for solution polymerization, owing to the higher probability of side reactions such as transesterification and/or transcarbonation reactions.

As mentioned above, 2-amino-oxazoline and 2-aminothiazoline show structural analogies with TBD (see Figure 1). The ROP of LA at room temperature in CH_2Cl_2 mediated by these organocatalysts (7 mol.% loading relative to monomer), in the presence of *neo*-pentanol (2,2-dimethylpropan-1-ol) as initiator, was found to be well controlled (entry 11), as described by Becker *et al.*[40] The more active catalysts were the more electron-rich derivatives, in particular that featuring a 2-cyclohexylamino substitution on the thiazoline ring. The polymerization kinetics was found to be first order with respect to monomer, initiator, and catalyst. Significant interactions between the three components were also noted, suggesting that these catalysts, like TBD, provide a dual activation of both the monomer substrate and initiator by hydrogen bonding (Scheme 15). Upon increasing the reaction time, however, transesterification side reactions were observed.

As reported by Fukushima *et al.*,[101] TBD was used as catalyst to depolymerize polyethylene terephthalate (PET) leading to bis(2-hydroxyethyl)terephthalate (BHET) (Scheme 16). The



Scheme 15 Dual activation proposed for the ROP of LA catalyzed by aminothiazolines.[40]



Scheme 16 Depolymerization of PET catalyzed by TBD.[101]

high efficiency of this catalyst was highlighted since 0.5 mol.% is sufficient to achieve complete glycolysis at 190 °C. These results are comparable with the one obtained for commonly used metal catalysts. With a large excess of ethylene glycol to decrease the content of final BHET dimers, TBD (10 mol.%) allowed complete depolymerization of PET within 150 min even after nine consecutive catalyst cycles.

4.06.6 Polymerizations Catalyzed by TUs and TU-Amino Derivatives

As mentioned above, TU derivatives easily activate carbonyl-containing substrates by hydrogen bonding. Such organocatalysts have thus logically served to trigger the ROP of various cyclic esters, as illustrated in **Figure 5** (see also **Table 3** for the most representative results). For instance, mono- and bicomponent TU-amino catalysts (**Figure 1**) allowed good control of the ROP of LA in solution in CH_2Cl_2 (1 M) at 25 °C in the presence of 4-pyrenebutanol as initiator (entries 1 and 2 in **Table 3**).[103,111] In the former case, a PLA with $M_n = 23\,000\,g\,mol^{-1}$ and a dispersion of 1.05 was obtained for 97% monomer conversion, which required, however, long reaction times (48 h). These organocatalysts exhibited a high selectivity toward polymerization of LA relative to transesterification of in-chain esters, as indicated by the invariance of molar mass distribution even after prolonged reaction times (several days). Analysis by ^{13}C NMR of PLAs thus obtained showed that racemization did not occur.

Use of a monohydroxy PDMA macroinitiator to initiate the TU-amino-catalyzed ROP of LA allowed the authors to prepare PDMA-*b*-PLA diblock copolymers (**Scheme 17**). Double-headed initiators were also used for the purpose of block copolymer synthesis, by combining controlled radical polymerization (RAFT or NMP) and organocatalysis by TUs.[112]

Catalytic systems based on the combination of MTBD or DBU with TU3 were found to control the ROP of δ-VL, yielding PVL with DP up to 200 and TOF around $5\,h^{-1}$ (entry 3). When applied to the ROP of ε-CL, however, several days were required to reach 80% conversion.[103]

The high selectivity of TU organocatalysts toward ring opening of cyclic esters relative to side transesterification reactions can be explained by the higher H-binding capacity of TU with the more basic cyclic esters (**Scheme 18**). The strength of the hydrogen bonding can be manipulated through the proper design of the catalyst, which allows a shortening of the reaction times and a better control of the polymerization.[112] For instance, TUs bearing the most electron-withdrawing substituents (arising from the starting isothiocyanate) exhibited the highest activity, due to its enhanced acidity toward activation of the lactide. A proper selection of the amine Bronsted base is also crucial, however, for an efficient polymerization. Thus, pyridine and *N*,*N*-dimethylaniline were ineffective, likely because of their too weak basic character, to activate the alcohol initiator. In contrast, combination of TU with DMAP or (cyclohexyl)dimethyl amine, triethylamine, 1,4-diazabicyclo[2.2.2]octane (DABCO), and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) in a bicomponent catalytic system led to complete conversion of LA. The chiral (−)-sparteine was found to be the most effective amine, 95% conversion being achieved in only 2 h, with an excellent control over molar mass and dispersity of the resulting PLAs. This base also allowed some stereocontrol of the ROP of *rac*-LA. Characterization by NMR indicated that isotactic enrichment in such organocatalyzed ROP occurred by a chain end control.

The mechanism of TU-amino-mediated ROP thus occurs by a dual activation via a hydrogen bonding between the TU group and the carbonyl group of the monomer and, in the meantime, activation of the initiating/propagating alcohol by the basic amino-functionality group of the catalytic system (**Scheme 19**). Hence, the presence at the same time of both the TU and the amino-functions is necessary for an efficient catalysis of polymerization, as demonstrated in control experiments. The implication of hydrogen bonding in the activation process was supported by studying the polymerization in various solvents. While nonhydrogen bonding solvents, such as

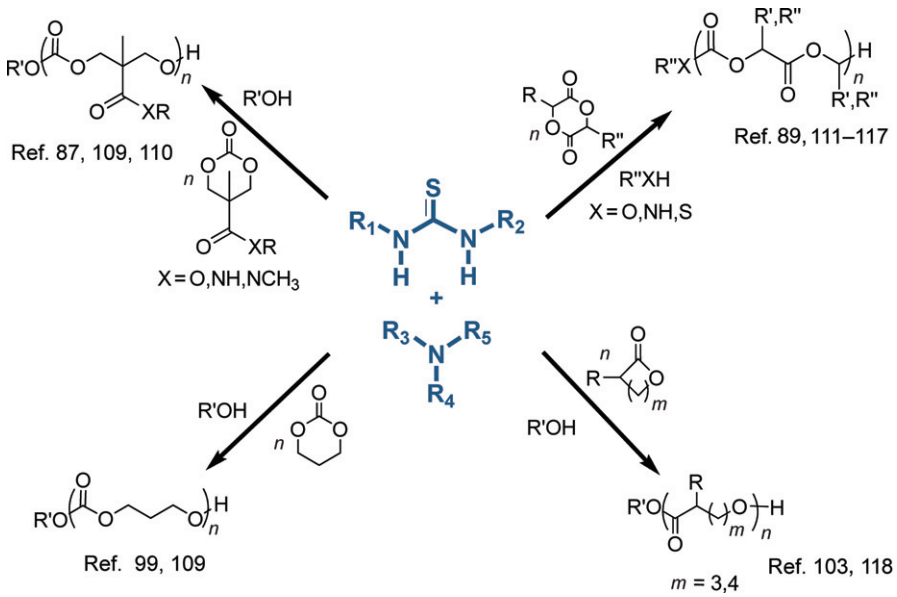


Figure 5 Overview of polymers obtained from TU-amino derivatives as catalysts.

$CHCl_3$, CH_2Cl_2, and toluene led to well-defined PLAs, no polymerization was observed in tetrahydrofuran (THF) and dimethylformamide (DMF), owing to a competitive hydrogen bonding of these solvents by the TU moiety.[112]

Middleton *et al.*[113] recently employed astaxanthin as bifunctional hydroxy-containing initiator for the ROP mediated by the monocomponent bifunctional TU/tertiary amine catalyst (**Table 3**, entry 4). Astaxanthin is a conjugated pink-colored carotenoid that is present in plants, phytoplankton, or algae. It can serve as an antioxidant. It aids in light absorption during photosynthesis. For these reasons, carotenoids in general possess antiinflammatory properties that can be exploited in the treatment of cardiovascular diseases. PLAs with a central astaxanthin moiety were synthesized with molar masses up to 30 000 g mol^{-1}. In this case, prolonged time periods of polymerization of LA (up to 36 days) revealed the occurrence of transesterification, compared with polymerizations utilizing 4-pyren-1-ylbutan-1-ol as initiator.

Combining TU with MTBD and DBU favored an efficient polymerization of various heterocycles, including δ-VL, ε-CL, TMC, and MTC, whereas, as highlighted in previous sections, MTBD alone or TU combined with other amines can only activate the ROP of LA.[87,99,103] For instance, the DBU/TU combination used for the ROP of the cyclic carbonates MTC bearing an -OR functional group (MTC-OR) gave a higher TOF (19 h^{-1}) than for TMC.[109] This catalytic system also allowed random copolymerizations of these MTC-OR cyclic carbonates with TMC. The MTC-OR monomers were more rapidly incorporated in the copolymer than TMC, suggesting the formation of gradient copolymers, in accordance with their higher reactivities in homopolymerization (entries 5–7).[99,109] Block copolymer synthesis by sequential ROP of six-membered cyclic carbonates was also possible. The functionalized cyclic carbonates were polymerized using the organocatalyst combination TU/DBU.[87] Miscellaneous polycarbonates with predictable molar masses and dispersities close to unity could thus be obtained.

In order to introduce pendant functionalities in aliphatic polyesters, Pounder and Dove[114] took advantage of the selectivity of the TU/DBU catalytic system for the ROP of six-membered cyclic carbonates, namely (3*S*)-3-{[(benzyloxy) carbonyl]methyl}-1,4-dioxane-2,5-dione (BMD) and (3S,6*S*)-3,6-bis{[di(benzyloxy)carbonyl]methyl}-1,4-dioxane-2,5-dione (malide) both derived from malic acid (**Figure 2**). The resulting polymers thus consisted of glycolic acid and benzyl L-(alkylamino)malate units. The TU/(−)-sparteine-mediated ROP of BMD, in the presence of benzylamine or primary or secondary alcohol initiators, led to structurally well-defined polyesters (entry 8). OH-containing initiators included monohydroxy poly(ethylene oxide) (PEO) and L-PLA used for the preparation of block copolymers. In contrast, the ROP of malide with the same catalytic system was ineffective. The poly(glycolic acid-*co*-malic acid)s (PGMAs) generated by deprotection of the benzyl groups of poly(BMD)s by hydrogenation were found to undergo autocatalytic degradation in dilute H_2O, with complete degradation within 6 days.

In addition to DMAP (see Section 4.06.4), du Boullay *et al.*[89] employed the bicomponent TUCy/(−)-sparteine organocatalyst to trigger the ROP of (3*S*)-3-{2-[(benzyloxy) carbonyl]ethyl}-1,4-dioxane-2,5-dione (BED, **Figure 2**) in CH_2Cl_2 solution at 30 °C (**Table 3**, entry 9). Neither interference of the pendant functional group nor transesterification reactions in the polymerization were noted. Ring opening of BED was shown to occur indifferently on either of the endocyclic ester groups. As a matter of fact, the resulting poly(BED)s exhibited a random distribution of glycolic and *O*-{2-[(benzyloxy)carbonyl]ethyl}glycolic units. Deprotection by hydrogenolysis led to well-defined poly(*R*-hydroxyacids).

Fukushima *et al.*[110] applied TU-mediated organocatalyzed polymerization to macromolecular engineering. For instance, they reported the synthesis of 'comb-shaped block copolymers' made of PEO as the hydrophilic component and a statistical copolycarbonate as hydrophobic backbone carrying

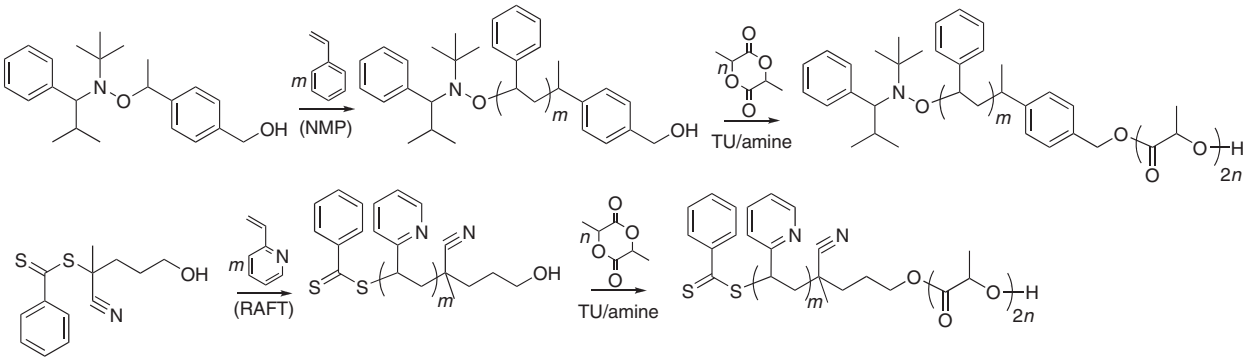
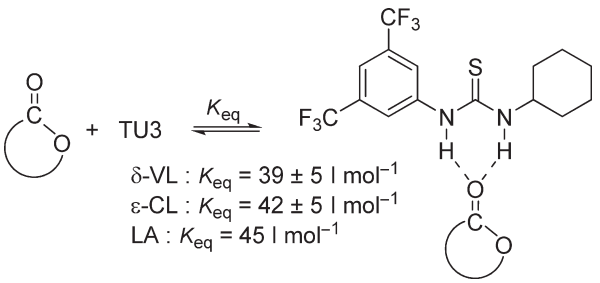
stereoregular L-PLA or D-PLA grafts (Scheme 20).[110] The latter backbone was prepared by copolymerizing two different cyclic carbonates, as discussed above, including a latent (tetrahydropyranyl)oxy-initiating group. After formation of the amphiphilic backbone, followed by deprotection under acidic conditions and ROP of LA in the presence of TU organocatalyst, relatively well-defined copolymers were obtained, with up to eight PLA grafts. Mixtures of the enantiomerically pure copolymers of L-LA and D-LA showed that stereocomplexation occurred, as evidenced by a significant increase in the melting point. The stereocomplexes were found to form micelle-like structures at very low concentrations.



Scheme 17 Block copolymer synthesis: first block PS (by NMP) or PDMA (by RAFT), second block: PLA (by organocatalyzed ROP).[112]



Scheme 18 Binding constants of TU3 with some cyclic esters.[103]

The same group reported a synthetic strategy utilizing a carboxylic acid-containing cyclic carbonate derived from 2,2′-bis(hydroxymethyl)propanoic acid and the TU-mediated organocatalysis to prepare ABC-type miktoarm copolymers.[115] The functional carbonate was first coupled onto a monohydroxy PEO. Subsequent ring opening of the cyclic carbonate using a functional amine (RNH_2) generated a carbamate group carrying a functional moiety in the R group, namely an alkoxyamine or a protected hydroxyl group aimed at triggering NMP or ROP, respectively, together with a primary hydroxyl group (**Scheme 21**). The two additional polymer arms of the ABC-type miktoarm stars were then grown by tandem polymerization. The amphiphilic miktoarm star copolymers featuring poly(D- and L-LA) were found to form stereocomplexes in the bulk. Micelle-like structures with narrow size distribution were observed in aqueous solution from the stereocomplex mixture of Y-shaped miktoarm stars, PEO-poly(D-LA)-poly(D-LA) and PEO-poly(L-LA)-poly(L-LA), or the stereoblock miktoarm PEO-poly(D-LA)-poly(L-LA). The critical micelle concentrations of these micelles were significantly lower than the values generally obtained from traditional stereoregular linear or branched (Y-shaped) amphiphiles. Such polymer micelles exhibited a high loading capacity of the anticancer drug paclitaxel, leading to a near-zero ordered release of the drug, without a significant initial burst.

In 2009, Misaka *et al.*[118] reported the synthesis of macrocyclic PVLs (**Scheme 22**) by ring closure of an α-azido, ω-alkynyl-PVL by the Huisgen 1,3 dipolar cycloaddition (referred to as 'click chemistry'). The heterodifunctionalized PVL precursors (M_n from 2600 to 9900 g mol^{-1}) were first obtained by ROP of δ-VL in toluene at 25 °C, using the bicomponent TU/DBU catalytic system in the presence of 6-azidohexan-1-ol (**Table 3**, entry 12), followed by post-functionalization of the thus formed ω-end of α-N_3,ω-OH PVL with hex-5-ynoyl chloride. The 'click cyclization' was achieved in 60–80% yield in DMF, under highly diluted conditions, in the presence of the Cu(I)Br/2,2′-bipyridine catalytic system.

(Thio)amidoindoles and (thio)amidobenzimidazoles show structural similarities with TU-amino derivatives (**Figure 1**). These bifunctional organocatalysts were employed by Koeller *et al.*[116] to polymerize LA. These authors first showed that amidoindole combined with (−)-sparteine could efficiently catalyze the ROP of LA (entry 13), yielding PLAs of controlled dispersity and molar mass.[116] It was first shown that both NH groups of the amide and the indole moieties provided activation of the LA substrate by hydrogen bonding, as supported by the X-ray structure of the hydrogen-bonded 1:1 complex between the catalyst and LA. Complete conversion

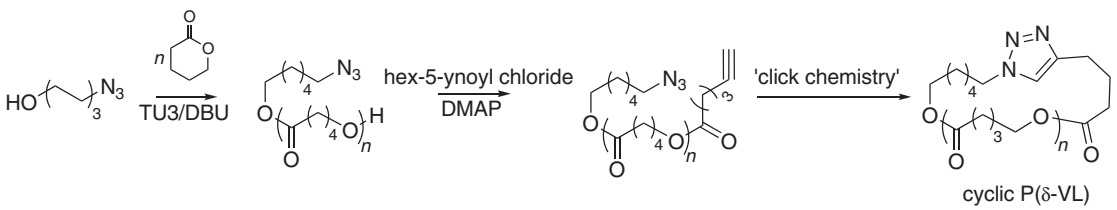
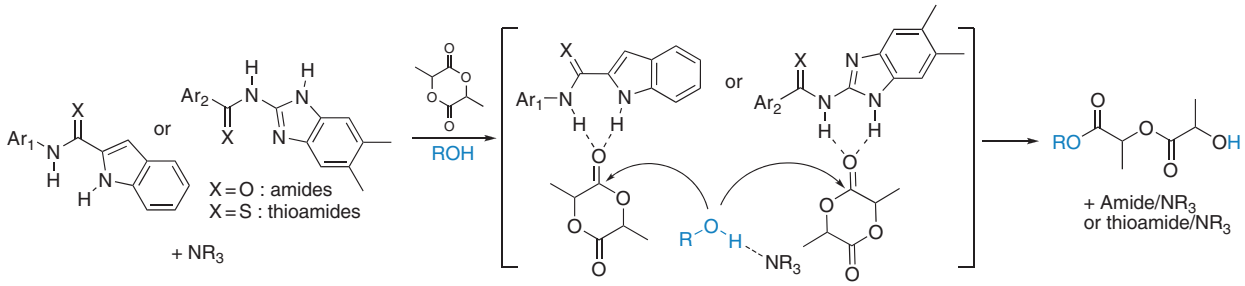


Scheme 22 Synthesis of macrocyclic PVLs via organocatalyzed ROP and click chemistry.[118]

was achieved within 2 h at 20 °C in 0.7 M CH_2Cl_2 solution. In a subsequent contribution, the same group investigated more systematically the catalytic activity of amides and related thioamides carrying either an indole or a benzimidazole moiety, toward the ROP of LA when used in the presence of a tertiary amine as cocatalyst (entry 14).[117] These molecules tended to form dimeric species by self-assembling, making the NH group less available for monomer activation. Therefore, the proper selection of the two partners in such bicomponent catalytic systems proved crucial for the outcome and the control of the



Scheme 23 Proposed mechanism for ROP of LA catalyzed by amides and thioamides.[117]

polymerization. For instance, catalytic activity could be enhanced by introducing electron-withdrawing groups in the aromatic ring and using an amide rather than a thioamide moiety. In the latter case, indeed, the catalytic activity of (thio) amides was inhibited owing to the development of hydrogen bondings between the two partner catalyst (Scheme 23).

4.06.7 Polymerizations using Phosphorus-Based Catalysts: Phosphines and Phosphazenes

As already mentioned, although the use of commercially available phosphines as acylation nucleophiles is well documented, their potential for organocatalyzed polymerizations has been certainly underexploited so far. There is only one report in 2002, by Myers *et al.*[64] where phosphines, such as PBu_3, $PPhMe_2$, PPh_2Me, and PPh_3, were employed as true catalysts for the ROP of LA in the presence of an alcohol initiator.[64] The catalytic efficacy was found to depend on the substitution pattern of the phosphine: for instance, trialkylphosphines proved more active (being more basic and more nucleophilic) than the triaryl phosphines. Polymerizations could be carried in bulk at 135 °C, yielding well-defined PLAs with a TOF of 0.01 s^{-1} (Table 4, entry 1).

In the context of ROP of heterocycles, phosphazenes were reported to operate mainly as deprotonating agents of alcohols or thiols, or even of CH-acid compounds serving as initiators. The main polymers obtained in this way are shown in Figure 6, and the main results are summarized in Table 4. Upon protonation, the resulting phosphazenium cation is soft and bulky enough to induce controlled/living polymerization of several monomers, including EO, cyclosiloxanes, ε-CL, δ-VL, LA, and cyclic carbonates. In addition, when associated with enolate precursors, the 'controlled/living' metal-free anionic polymerization of (meth)acrylates was also reported.[128,129]

Using phosphazenes in the context of polymerization was pioneered by the group of Molenberg and Möller[119] who first demonstrated their utility for the metal-free anionic ROP of octamethylcyclotetrasiloxane in bulk or in toluene, in the presence of methanol as initiator (Table 4, entry 2). The base *t*-BuP_4 allowed shortening reaction times and gave rise to homogeneous reaction mixtures, compared with metal-based alkoxide initiators. However, quite a broad molar mass distribution was observed. The same group reported the metal-free anionic ROP of EO with $[t\text{-}BuP_4H]^+$ as countercation, performed at 80 °C in a glass autoclave or at room temperature in solution in THF or in toluene.[120] Methanol or octan-1-ol served as initiators, leading to well-defined PEOs with M_n values ranging from 4400 to 6600 g mol^{-1} and a dispersity < 1.13 (Table 4, entry 3). In addition, pentaerythritol and poly[ethylene-*co*-(vinyl alcohol)] as tetrafunctional initiator and multifunctional polymer, respectively, were successfully employed to access tetra-arm star PEOs and poly{[ethylene-*co*-(vinyl alcohol)]-*graft*-PEO} graft copolymers. The soft cation $[t\text{-}BuP_4H]^+$ associated was found to improve the solubility of the multifunctional alkoxide-type initiators, in comparison to metal-based alkali alkoxides. Initiation of ROP of EO from pentaerythritol occurred from a heterogeneous dispersion in THF, owing to the poor solubility of the initiator. After 30% monomer conversion, however, a homogeneous solution was obtained, and the resulting star polymer proved relatively well defined. As for the poly[ethylene-*co*-(vinyl alcohol)] precursor used for synthesis of the graft copolymers, it also gave a heterogeneous reaction mixture at room temperature, but homogeneous conditions were achieved in xylene at 80 °C. Complete solubilization at room temperature occurred in the former case after 25% conversion (2–3 h).

The contribution by Schlaad *et al.*[121] in 2001 described the synthesis of heterobifunctional PEOs using a similar strategy. In this case, either (R)-(α-methylbenzyl) cyanide or *p*-cresol was employed as CH- and OH-initiating precursors to be deprotonated by equimolar amounts of *t*-BuP_4 (Scheme 24). Anionic ROP of EO was conducted in THF at 45 °C for 20 h, leading to well-defined PEOs (M_n < 3000 g mol^{-1}; D < 1.1). Postfunctionalization of α-PEO chain ends of each of the PEO products allowed the authors to access α-amino-ω-hydroxy and α-bromo-ω-hydroxy-PEOs.

Rexin and Mülhaupt[122] investigated the effect of the bulky tetrakis[cyclohexyl(methyl)amino]-phosphonium (P_1^+), where the positive charge is delocalized over five atoms in the phosphazenium countercations, during the ROP of PO. The challenge with this monomer is to avoid side reactions, in particular, the transfer reaction to monomer, restricting the molar mass and forming allyl end groups. P_1^+ was thus compared with cations K^+, $P_2{}^+$, Bu_4P^+, and *t*-BuP_4H^+ (Scheme 25). Furthermore, the polymerization with Bu_4P^+ whose positive charge is not delocalized was investigated. A series of alkoxides derived from dipropylene glycol (DPG) serving as initiators with different organic countercations ($P_1{}^+$, $P_2{}^+$, Bu_4P^+, *t*-BuP_4H^+) were first prepared by reacting phosphonium or phosphazenium methoxide with DPG. An extent of

[a] 5% of I is actually deprotonated.
[b] Terminated with alkyl halides.

deprotonation of only 5% was chosen, owing to the fast exchange occurring between propagating (secondary) alkoxides of poly(propylene oxide) (PPO) and dormant hydroxylated PPO chains. ROP of PO was performed at 100 °C at atmospheric pressure (Table 4, entry 5). It was found that propagation rates increased in the following order: Bu$_4$P$^+$ < K$^+$ < P$_1^+$ < P$_2^+$ < *t*-BuP$_4$H$^+$. The DP of the resulting poly (PPO)s was in the range of 20–64 and dispersities were between 1.03 and 1.09. Unsaturations at polymer chain ends were observed, however, in a range 13–60 mmol kg^{-1}, with larger contents by increasing polymerization rates.

Phosphazenes such as *t*-BuP$_1$ and BEMP were also successfully employed as basic catalysts for the ROP of lactones and LA in the presence of alcohol initiators, BEMP being the most effective.[123] The BEMP-mediated ROP of L-LA was studied in dry toluene at room temperature, in the presence of 4-pyren-1-ylbutan-1-ol as initiator (entry 6). The higher activity of BEMP came at the expense of the control of the polymerization, since transesterification of the polymer backbone was noted at high conversion. As for ε-CL, it was polymerized very slowly since only 14% of monomer conversion was obtained after 10 days.

An ACEM involving the sole activation of the alcohol by hydrogen bonding (and subsequently the activation of the hydroxyl polymer chain end) and favoring a nucleophilic attack on the monomer substrate by the active initiator was proposed (Scheme 26).[123] The resulting aliphatic polyesters exhibited high reliability of the presence of end groups, narrow dispersities, and a linear relationship between conversion and molar mass.

The same group reported that the ROP of *rac*-LA catalyzed by the dimeric phosphazene *t*-BuP$_2$ exhibited a high

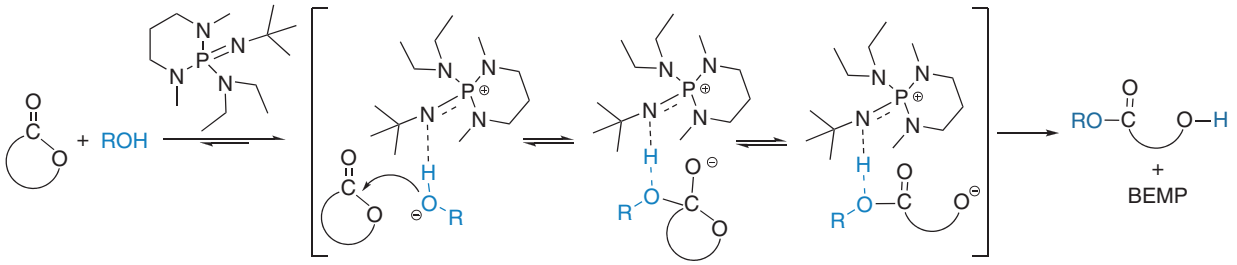
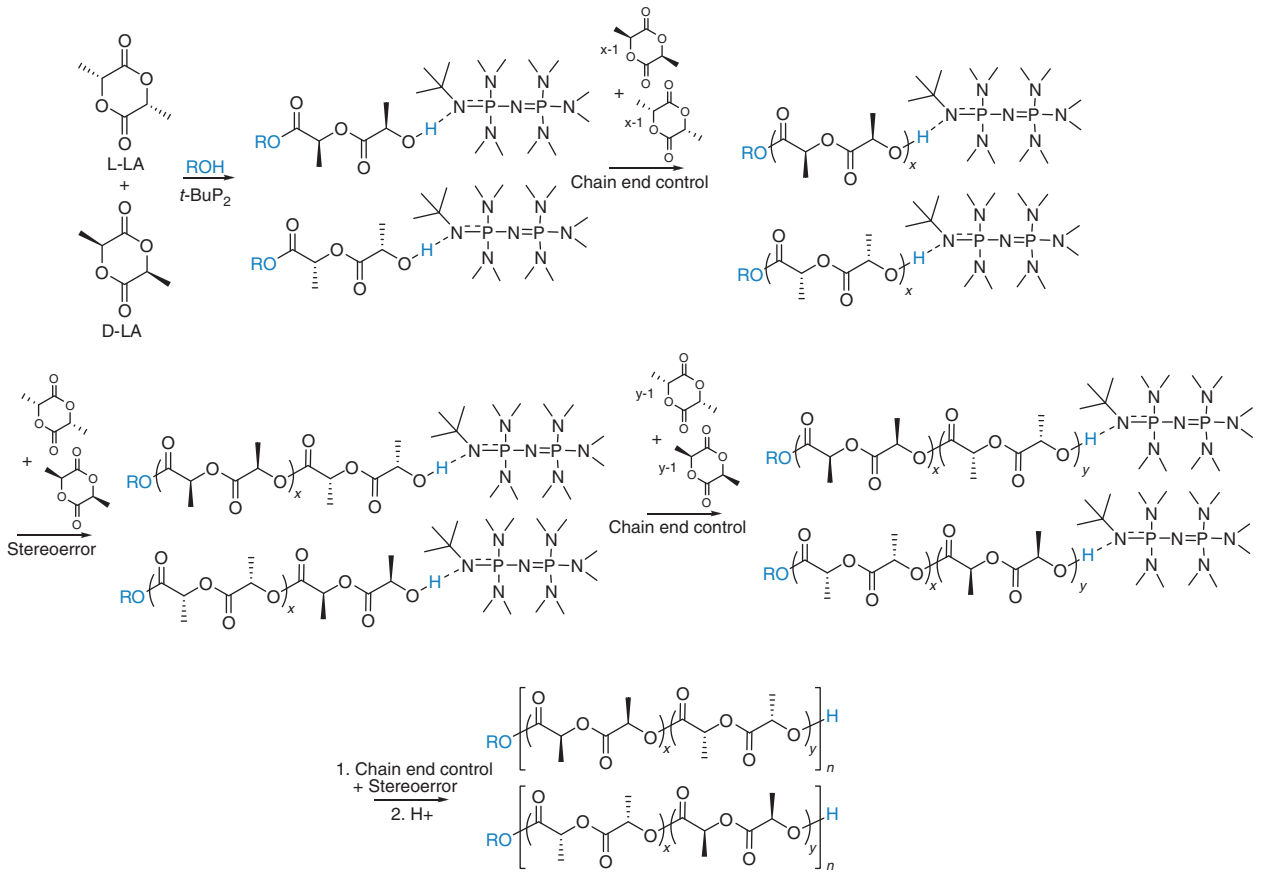


Scheme 26 Putative mechanism (ACEM) for the ROP of cyclic esters with BEMP.[123]

stereoselectivity at low temperature.[124] Catalysis of polymerization by *t*-BuP$_2$ was first studied in toluene at room temperature with enantiomerically pure L-LA, in the presence of 4-pyren-1-ylbutan-1-ol as initiator. Complete monomer conversion was achieved within 10 s using a monomer-to-initiator-to-catalyst molar ratio of 100:1:1 (entry 7). The ROP of *rac*-LA was accomplished at room temperature under dilute conditions (0.08 M) or at lower temperature, which yielded 99% conversion after 3 h. A *rac*-PLA was also prepared at –75 °C for comparison purpose and was found to be a crystalline polymer with a melting peak at 201 °C, which was much higher than that of L-PLA (163 °C). No transesterification was observed at such a low temperature. Analysis by NMR of the microstructure of the different PLAs formed, combined with DSC data, established the formation of a stereocomplex morphology of the *rac*-PLA at –75 °C, with long isotactic poly(*S*) segments and poly(*R*) segments. Cocrystallization of L-PLA and D-PLA blocks could explain the high melting peak of the thus-formed *rac*-PLA. In contrast, the *rac*-PLA obtained at room temperature was an amorphous polymer. The stereoselectivity of the *t*-BuP$_2$-catalyzed polymerization was explained by a chain end control mechanism whereby the terminal alkoxide of the last inserted monomer in the growing chain selectively attacked the monomer of the same configuration, leading to isotactic enchainment (**Scheme 27**). The bulky *t*-BuP$_2$ catalyst presumably influences the steric hindrance around the catalytic site, enhancing the stereoselectivity, in particular at low temperature.

(*RS*)-4-[(benzyloxy)carbonyl]-3,3-dimethyloxetan-2-one (dMMLABz, **Figure 2**) was subjected to ROP in THF at room temperature catalyzed by *t*-BuP$_1$, *t*-BuP$_2$, and *t*-BuP$_4$, as reported by De Winter *et al.*[125] Such a substituted



Scheme 27 Stereoselectivity of PLA during the ROP of *rac*-LA with *t*-BuP$_2$.[124]

four-membered β-lactone was also polymerized using these phosphazenes in the presence of ω-COOH-containing precursors, namely cinnamic acid or a purposely designed ω-carboxylic acid PEO used as a macroinitiator. Good control over the molar masses, dispersities, and reliability of the end-group presence in the resulting polyesters was achieved with all catalysts, the catalytic activity increasing in the order *t*-BuP$_1$ < *t*-BuP$_2$ < *t*-BuP$_4$. In the latter case, the poly(dMMLABz) of molar mass as high as 1.5×10^6 g mol^{-1} could be prepared (Table 4, entry 8). As indicated by the molecular characteristics of the obtained polyesters, the mechanism of this polymerization involved deprotonation of the COOH-functionality and ring opening of the β-lactone via an *O*-alkyl scission forming phosphazenium carboxylate active species.

In two recent reports, the group of Carpentier and Guillaume showed that six- and seven-membered cyclic carbonates such as TMC, DMTMC, BTMC,[93] as well as R-Me7CC and β-Me7CC[86] could undergo a 'controlled/living' ROP under relatively mild conditions (bulk, 60–150 °C), in the presence of BEMP as organocatalyst and a mono- or a multifunctional hydroxylated initiator (entries 9 and 10, Table 4). For instance, 100 000 equiv. of TMC was fully converted using only 10 ppm of BEMP, providing PTMCs of high molar mass. Very high activities (e.g., 55 800 h^{-1} in the case of the ROP of TMC) thus characterize these polymerizations. Well-defined α-hydroxy-ω-alkoxy, α,ω-dihydroxytelechelic linear, or three-arm star polycarbonates of controlled molar masses were obtained in this way, using benzyl alcohol, propane-1,3-diol, or glycerol as initiator, respectively. PTMCs with a molar mass as high as 45 800 g mol^{-1} could be obtained from a technical-grade, unpurified TMC, with a BEMP loading as low as 10 ppm (i.e., 2 mg of BEMP used to polymerize, quantitatively, 74.4 g of TMC). In comparison with other organocatalysts employed by the authors, BEMP could be ranked as follows regarding the ROP of TMC in bulk within 30 min at 60 °C: TOF: TBD (990 h^{-1}) > BEMP (800 h^{-1}) > DMAP (500 h^{-1}) and within 5 min at 110 °C: TOF: TBD (5940 h^{-1}) > DMAP (5220 h^{-1}) > BEMP (4800 h^{-1}). Both BTMC and DMTMC were also subjected to ROP initiated with a [BEMP]$_0$/[alcohol]$_0$ ratio of 1:5 at 60 or 90 °C. For instance, 500 equiv. of monomer was readily converted into the polycarbonates within 240 min.

In 2009, Illy *et al.*[126] reported that *t*-BuP$_4$ could successfully deprotonate mono- or difunctional thiol precursors such as benzenethiol and bis(2-sulfanylethyl)ether for the subsequent ROP of dipropyl cyclopropane-1,1-dicarboxylate, via malonate carbanions featuring phosphazenium as active species. Stoichiometric amounts of *t*-BuP$_4$ were employed (Table 4, entry 11), affording polymers with a narrow dispersity (< 1.08) under milder conditions (THF at 60 °C), in comparison with conventional processes utilizing alkali metal benzenethiolates as initiators. Upon quenching the living polymeric malonates with allyl bromide, the authors could introduce functional allylic groups in ω-position of the polymer formed. The scope of this metal-free polymerization of cyclopropane-1,1-dicarboxylates was further extended to a range of OH-, SH-, NH-, and CH-containing initiating precursors, including aromatic and aliphatic thiols, a phenol, a carbazole, and a malonate precursor.[127] Polymerizations could be performed in a nonpolar solvent such as toluene as a substitute to THF, which allowed the authors to control the polymerization at 100 °C.

4.06.8 Polymerizations Catalyzed by NHCs

Among organocatalysts, carbenes were the most investigated in the last decade for the purpose of polymerization (Figure 7). As already mentioned, both the electronic and steric properties of carbenes, hence their reactivity/nucleophilicity, can be finely tuned through variation of their substituents R_1–R_4 pattern. In particular, NHCs have served to catalyze different polymerization reactions, including step-growth and chain-growth polymerizations. Interestingly, not only carbonyl-containing monomer substrates but also epoxides as well as silicon-containing initiators or monomers could be activated.

It is worth mentioning that the first attempt to synthesize polymers via a NHC organocatalysis was reported by Jones *et al.* in the late 1990s.[158,159] These authors applied the principle of the so-called Stetter reaction to diformylarenes and bis-Mannich bases used as bifunctional monomers (Scheme 28) in the presence of a thiazolylidene catalyst. Polymeric 1,4-diketones were synthesized in this way. Subsequent ring closure of these polymer precursors by the Paal–Knorr reactions led to conjugated alternating copolymers bearing pyrroles, furan, or thiophene moieties.

In the course of their investigations into NHC-catalyzed transesterification reactions occurring in the corresponding ROP, Nyce *et al.*[137] reported the synthesis of PET. This could be achieved using a two-step procedure with NHCs as single catalytic components for the preparation of BHET, followed by its self-condensation (Scheme 29). The reaction proved reversible in the presence of methanol. Interestingly, the same NHCs were also effective for chemical degradation of PET under mild conditions (typically at 80 °C or even less), representing the first example of a depolymerization reaction utilizing organocatalysis.[136,138] The same group described the synthesis of PCL and poly(glycolide) by self-condensations of ethyl 6-hydroxyhexanoate and ethyl glycolate.[136] The reactions were performed in bulk at 60 °C under vacuum for 24 h, leading to aliphatic polyesters with molar masses M_n ranging from 8000 to 20 000 g mol^{-1}. In addition, a copolymer was also obtained from the condensation of the two monomer types.

By taking inspiration of the mechanism of benzoin condensation, which consists in reacting two aldehyde functions through a resonance-stabilized enaminol-type intermediate called the Breslow intermediate, Pinaud *et al.*[134] employed a commercially available bis-aldehyde, namely terephthaldehyde. The latter monomer was polymerized by a NHC-catalyzed step-growth polymerization (Scheme 30), leading to the formation of poly(1,4-phenylene-1-oxo-2-hydroxyethylene)s referred to as polybenzoins under relatively mild conditions (THF or dimethylsulfoxide (DMSO) at 40 °C). Out of the four organocatalysts employed in this study, 1,3,4-triphenyl-1,2,4-triazol-5-ylidene was the most active. Formation of cyclic polymers during the polymerization was also noticed, and the cyclic content was found to vary depending on the reaction media used and the monomer conversion reached.

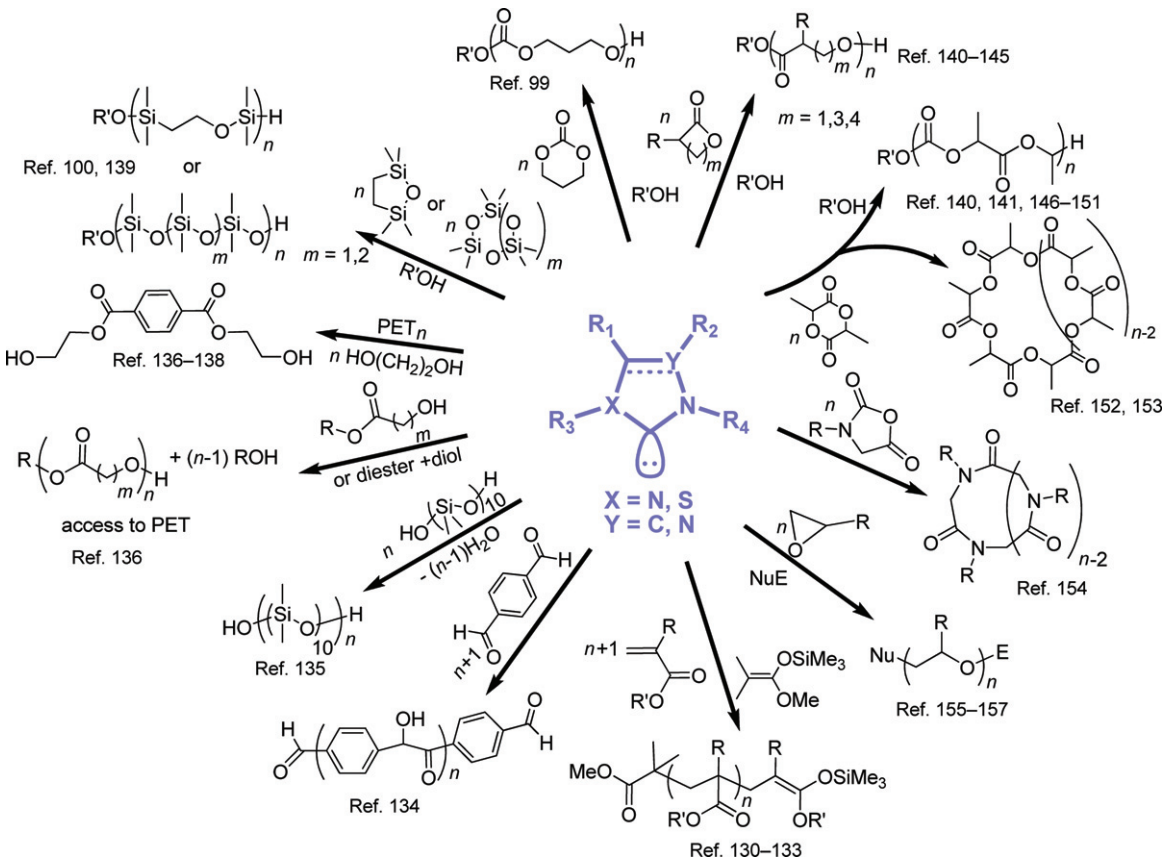


Figure 7 Overview of polymers obtained from NHCs.

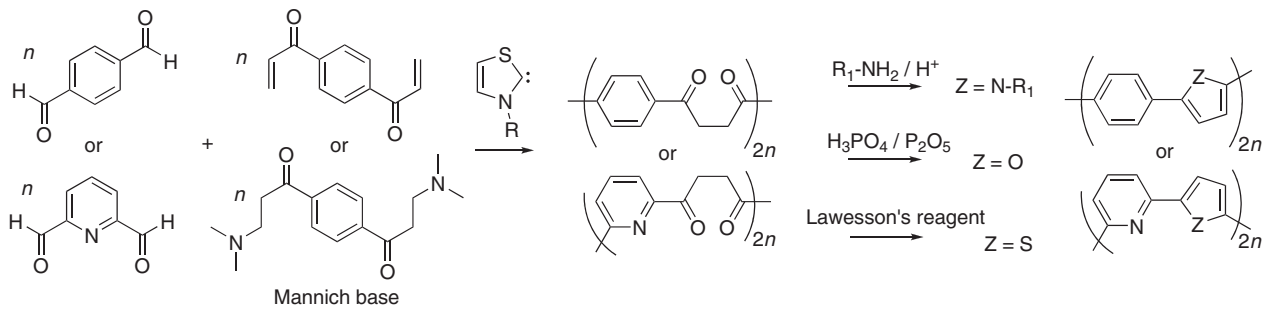
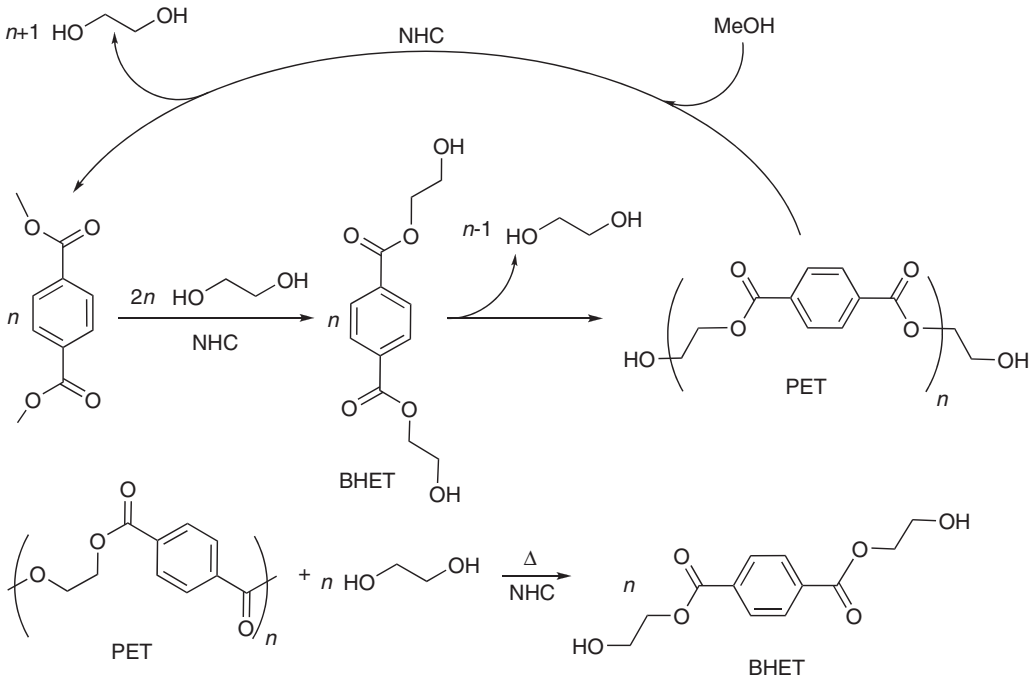


Scheme 28 Synthesis of polymeric 1,4-diketones by thiazolylidene-catalyzed step-growth polymerization and subsequent ring closure.[128,129]

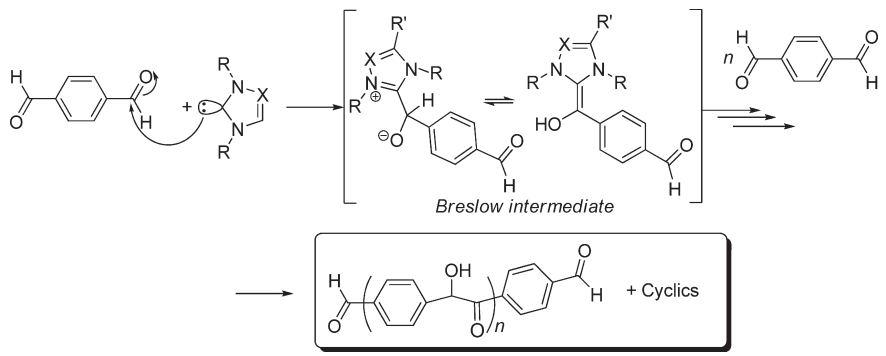
Another example of a NHC-catalyzed step-growth polymerization was reported by Marrot *et al.*[135], concerning the polycondensation of α,ω-dihydroxy disilanol oligomers, forming polydimethylsiloxane (PDMS). What was unexpected here was the dehydration of the disilanol precursors by NHCs, in spite of their moisture sensitivity. This was explained by the fact that the as-formed H_2O was not miscible with PDMS. HO $[(SiMe_2)O]_{10}$-H was heated at 80 °C for 16 h, in the presence of 2500 ppm of NHCs, causing an increase in viscosity of the reaction mixture and a modification of the signals in the ^{1}H NMR spectrum of the recovered PDMS.

Besides their use to trigger step-growth polymerization reactions, NHCs were mainly used as organic catalysts in chain-growth ROP of cyclic esters to produce linear as well as cyclic aliphatic polyesters, as summarized in **Table 5**.[5,6]

The first report dates back to 2002 and exploited the ability of NHC6 (IMes) to catalyze transesterification reactions. PLA, PCL, poly(β-butyrolactone) (PBL), and PVL with controlled molar masses, high chain end fidelity, and a dispersity close to unity were synthesized by the ROP of corresponding cyclic esters in THF solution (1–2 M) at 25 °C, in the presence of benzyl alcohol or 4-(pyren-1-yl)butan-1-ol playing the role of initiator (chain regulator controlling the molar mass of the polyesters) (**Table 5**, entry 1).[140] A chain extension experiment employing a PLA precursor yielded a PLA of molar mass of 39 500 g mol^{-1} and a dispersity of 1.17. A well-defined star PCL was even synthesized from six-arm poly(propylene glycol), PPG (M_n = 3000 g mol^{-1}), as macromolecular hexafunctional initiator. Compared with DMAP, the ROP of LA catalyzed by IMes proved much faster (TOF ~ 18 s^{-1}).



Scheme 29 Synthesis of PET by step-growth polymerization and depolymerization of PET via transesterification with a NHC.[136–138]



Scheme 30 NHC-catalyzed benzoin condensation in step-growth polymerization.[136]

Since this first report, several other NHCs, in their naked or under their masked form, were tested for the ROP of cyclic esters. In most cases, OH-containing precursors were employed as initiators which control the chain length of the final polymer.[5,6]

In a more systematic study, Nyce *et al.*[141] reported that NHCs derived from imidazolium- and thiazolium ionic liquid salts (precatalysts) could be generated *in situ* using a strong Bronsted base. This allowed screening different precatalysts and thus correlating the catalytic activity of NHCs toward the polymerization rate and the quality of control of these polymerizations with their structure. LA, β-PL, δ-VL, and ε-CL were investigated (**Table 5**, entry 2). For instance, imidazole-based NHC catalysts (e.g., NHC6) exhibited a higher reactivity than thiazole-based catalysts. Imidazol-2-ylidene and imidazolin-2-ylidene catalysts showed similar catalytic activity. IMes was found the most active for the ROP of LA. This particular NHC proved quite active even with low catalyst loading (0.5 mol.%), and molar masses could be targeted by varying the monomer to initiator ratio (DP = [M]/[I]) without changes in dispersity ($D < 1.2$).

In the same report, the authors developed an attractive interfacial polymerization process where the ionic liquid precatalyst served as reservoir forming a two-phase reaction mixture with THF solution containing both the monomer and the initiator. Subsequent *in situ* activation of the ionic liquid allowed generating the NHC that was able to migrate to the THF phase so as to trigger repetitive ROPs. Treatment under acid conditions on the completion of the reaction allowed regeneration and ready recovery of the ionic liquid precatalyst. The use of cross-linked polymer-supported precatalysts was also developed to trigger the ROP of cyclic esters. The versatility of this approach was demonstrated through the synthesis of well-defined homopolyesters, macromonomers, as well as block and graft copolymers.

As described in the literature on molecular chemistry,[160] alternatives to *in situ* generation of NHCs imply the thermolysis of NHC monoadducts, serving as masked NHCs. Upon

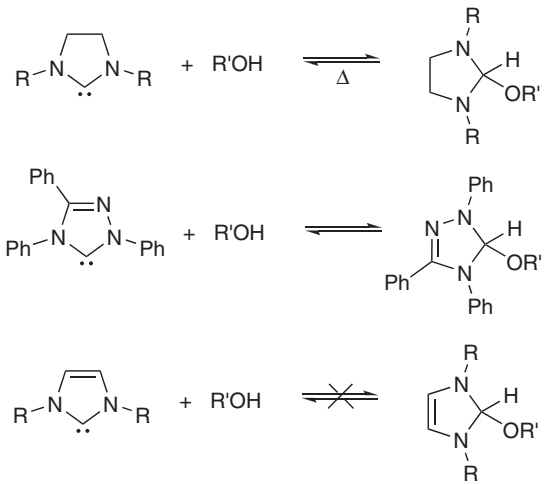
[a] *In situ* generated with *t*-BuOK (triethylamine for thiazole-based carbenes).
[b] Adducts with $R(OH)_x$ ($R(OH)_x$ is further used as the initiator) (equilibrium between NHC and adduct at RT).
[c] Forms adducts with alcohols and amines (stable at RT).
[d] *t*-BuOH used to decrease the NHC activity (by adduct formation).
[e] dMMLABz + β-BL both incorporated at the beginning of the polymerization.
[f] Adducts with $CHCl_3$ or $C_6H_xF_{(6-x)}$ ($x > 1$) (stable at RT).
[g] *rac*-Lactide leading predominantly to isotactic polymers (*RRR* or *SSS*); *meso*-L-lactide leading predominantly to heterotactic polymers (*RRSSRRSS*).
[h] Terminated with CS_2, leading to cyclics.
[i] Terminated with Dithranol, leading to cyclics.
[j] Terminated with NuE, leading to α,ω difunctionalized PEO.
NM, not mentioned.



Scheme 31 Reaction of alcohol with free NHCs.[131,146]

heating, such precursors undergo an α-elimination reaction, affording NHCs without the need for a strong base. This method was used by Enders *et al.*[161] to obtain the first commercially available NHC in the late 1990s.

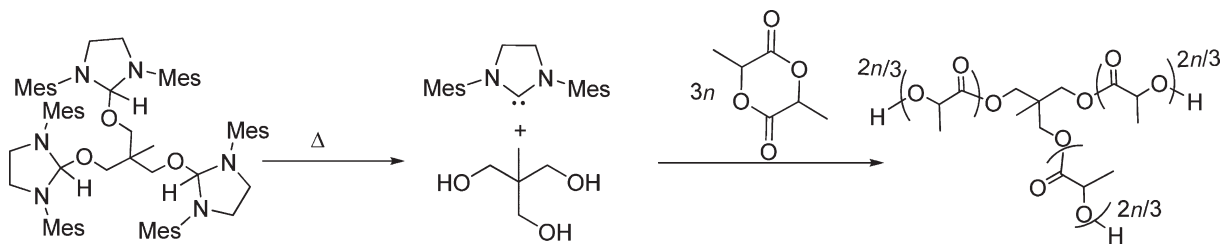
For instance, upon heating the NHC13-alcohol monoadduct at 80 °C under vacuum (0.1 mbar) methanol is released, forming the corresponding 1,2,4-triazol-5-ylidene. This strategy can also be applied to produce imidazolin-2-ylidenes.[70,146] Other adducts, obtained from a 1:1 reaction between imidazolin-2-ylidene and alcohols, can also be cleaved to release the free NHC, as illustrated in **Scheme 31**.[146,162] However, masking NHCs with alcohols cannot be applied to generate imidazol-2-ylidenes (unsaturated NHCs).

The above methods were exploited by the group of Hedrick and Waymouth in the generation of NHCs for the organocatalyzed ROP of various esters.[141–143,146–149] For instance, they reported the synthesis of a series of primary and secondary alcohol adducts of imidazolin-2-ylidenes, as single-component latent catalyst/initiators for the ROP of LA, giving PLA of controlled molar masses, in THF solution at room temperature within 10 min (**Table 5**, entry 3).[146] These adducts were stable as solids at room temperature, but they readily released alcohol and a free saturated NHC in solution. Di- and trifunctional adducts were also prepared to access, respectively, two-arm linear and three-arm star (**Scheme 32**) based on PLA.

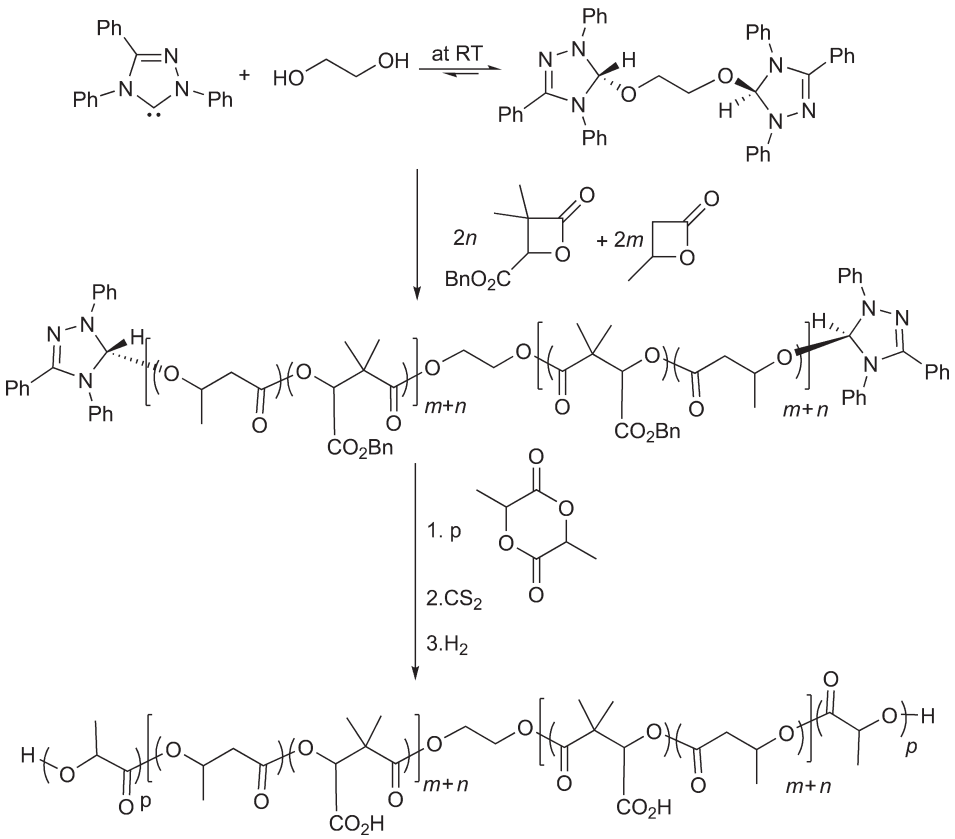
Similarly, and on the basis of observations made by Enders *et al.*,[161] the group of Dubois designed alkoxytriazolines derived from the commercially available 1,3,4-triphenyl-4,5-dihydro-1*H*-1,2,4-triazol-5-ylidene carbene, as latent unimolecular catalyst/initiator systems.[142,147] When used at room temperature to carry out the ROP of LA, such triazole carbenes exhibited a low reactivity, owing to the reversible formation of alcohol adducts. Polymerizations of either LA or β-BL were thus performed at 90 °C in the presence of a variety of initiating alcohols in 1 M toluene solution, which gave nearly quantitative monomer conversion in ~50 h and PLAs of controlled molar masses and low dispersities (entries 3 and 4). An interesting feature of polymerization utilizing these alkoxytriazolines was that the hydroxy-terminated PLA and the free triazole carbene reacted together in a reversible manner, forming a dormant polymer adduct. Such a reversible termination process helped in minimizing the concentration of propagating alkoxides, thus preventing the occurrence of side transesterification reactions between polymer chains. In this way, activation/deactivation cycles of polymer chain ends were possible simply by heating/cooling the reaction mixture on demand. This high level of control also facilitated chain extension experiments: after full conversion of a first load of monomer, the NHC-catalyzed ROP of a second monomer readily occurred, even after precipitation.

This strategy was next applied to macromolecular engineering, through the design of block copolymers and 'hybrid dendrimer/star' copolymer made of a dendritic core surrounded by 24 PLA branches. For block copolymer synthesis, adducts of hydroxy-functionalized oligomers or bifunctional 'double-headed' initiators were employed, by combining disparate polymerization techniques (typically NMP or RAFT with the NHC-catalyzed ROP). A multifunctional hydroxylated three-generation dendrimer derived from 2,2′-bis(hydroxymethyl)propanoic acid served as thermolabile multifunctional macroinitiator to access the hybrid dendrimer/star copolymer.

In another contribution, the same group reported the synthesis of amphiphilic ABA-type triblock copolymers based on PLA and poly(dimethyl malic acid) (poly(dMMLA)), via the triazole carbene organocatalysis.[143] A statistical poly(dMMLABz-*co*-β-BL) was first prepared by carrying out the NHC-catalyzed ring-opening copolymerization of dMMLABz and β-BL in a toluene/*t*-BuOH solvent mixture at 80 °C, in the presence of ethylene glycol as initiator (**Table 5**, entry 3). Under such conditions, the dMMLABz monomer was preferentially incorporated in the resulting aliphatic polyester chains, both monomers being polymerized via a selective *O*-acyl ring opening. This precursor was further employed as a difunctionalized macroinitiator for the ROP of LA at 90 °C. After a deprotection step by catalytic hydrogenation of the pendant benzylic ester groups of poly(dMMLABz), the expected PLA-*b*-poly(dMMLA-*co*-β-BL)-*b*-PLA triblock copolymer was obtained (**Scheme 33**). Investigations into the self-assembling



Scheme 32 ROP of LA employing a tri-NHC-alcohol adduct and leading to three-arm star PLAs.[146]

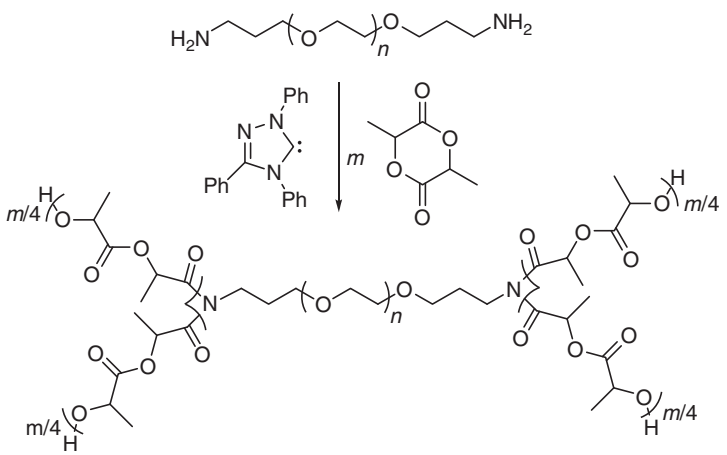


Scheme 33 Synthesis of PLA-*b*-poly(dMMLA-*co*-β-BL)-*b*-PLA triblock copolymer via the triazole carbene organocatalysis.[143]

properties in aqueous solutions of these amphiphilic compounds revealed the formation of 'flower-like' micelles at 4 °C. Increasing the temperature to 25 °C induced the microgelation of the above micelles, which upon further increase in temperature to 40 °C led to a disruption of the microgel. This demonstrated the temperature-dependent reversible sol–gel transition of these self-assembled triblock copolymers.

In addition to alcohols, the same triazole carbene was employed in the presence of primary amino-containing precursors serving as initiators.[148] In this case, however, the primary amino-function was shown to act as a bifunctional initiating site in the ROP of LA in the presence of the triazole carbene (**Table 5**, entry 7). By making use of multifunctional (macro) initiators based on PEO and featuring multiple primary amino-functionalities, 'H-shaped' and 'super-H-shaped' architectures based on PEO/PLA could be synthesized. Initiation from each primary amine indeed created imide-type functions corresponding to branching points (two chains per initiating amine).

In other words, polymerization occurred from all four N–H-bonds of the PEO macroinitiator (**Scheme 34**). A model primary amine initiator, namely 1-aminomethylpyrene, was



Scheme 34 Synthesis of H-shaped PEO/PLA-based block copolymers by NHC-catalyzed ROP of LA.[148]

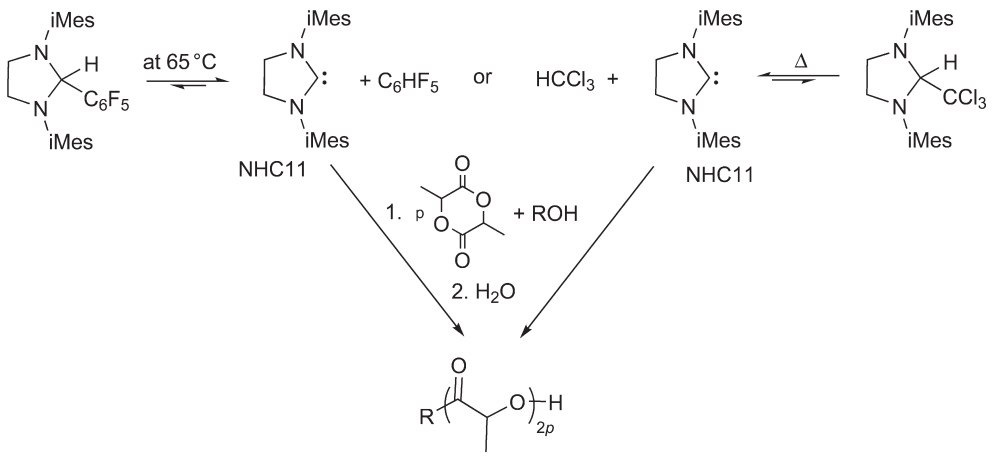
first employed for the ROP of LA using triazole carbene as catalyst in benzene. Initiation of LA at both N–H groups of the initiator (i.e., both the amine and resulting amide functionality) was established. For instance, ROP of LA from a 1:1 mixture of PEO-$(OH)_2$ and PEO-$(NH_2)_2$ at 90 °C catalyzed by the triazole NHC led to a mixture of diblock copolymers of $M_n = 20\,000$ and $9000\ g\ mol^{-1}$, corresponding to the formation of a mixture of the H-shaped architecture derived from PEO-$(NH_2)_2$ and having twice the molar mass of the linear block copolymer grown from PEO-$(OH)_2$. The ability for an amido-group to initiate the ROP of LA was then verified using ε-caprolactam as initiator. Using a telechelic tetrakis-amino-functionalized PEO precursor allowed the authors to synthesize the 'super-H-shaped' copolymers.

Nyce *et al.*[149] also developed the synthesis of NHC adducts featuring substituents with a good leaving group ability in C-1 position, by condensation of diamines with fluorinated benzaldehydes. In the solid state, these adducts were found to cleave at temperatures between 80 °C and 165 °C, depending on the fluorinated substituent and the carbene used, as investigated by thermal analysis and spectroscopic techniques. In contrast to adducts derived from chloroform, the adducts from pentafluorobenzene were stable at room temperature. Such adducts were successfully employed as organic precatalysts for the ROP of LA (**Scheme 35**) carried out in THF, toluene, or *o*-xylene solution (**Table 5**, entry 8), though elevated temperatures were required to release the carbene catalyst (between 60 °C and 144 °C, as a function of the structure of the precatalyst).

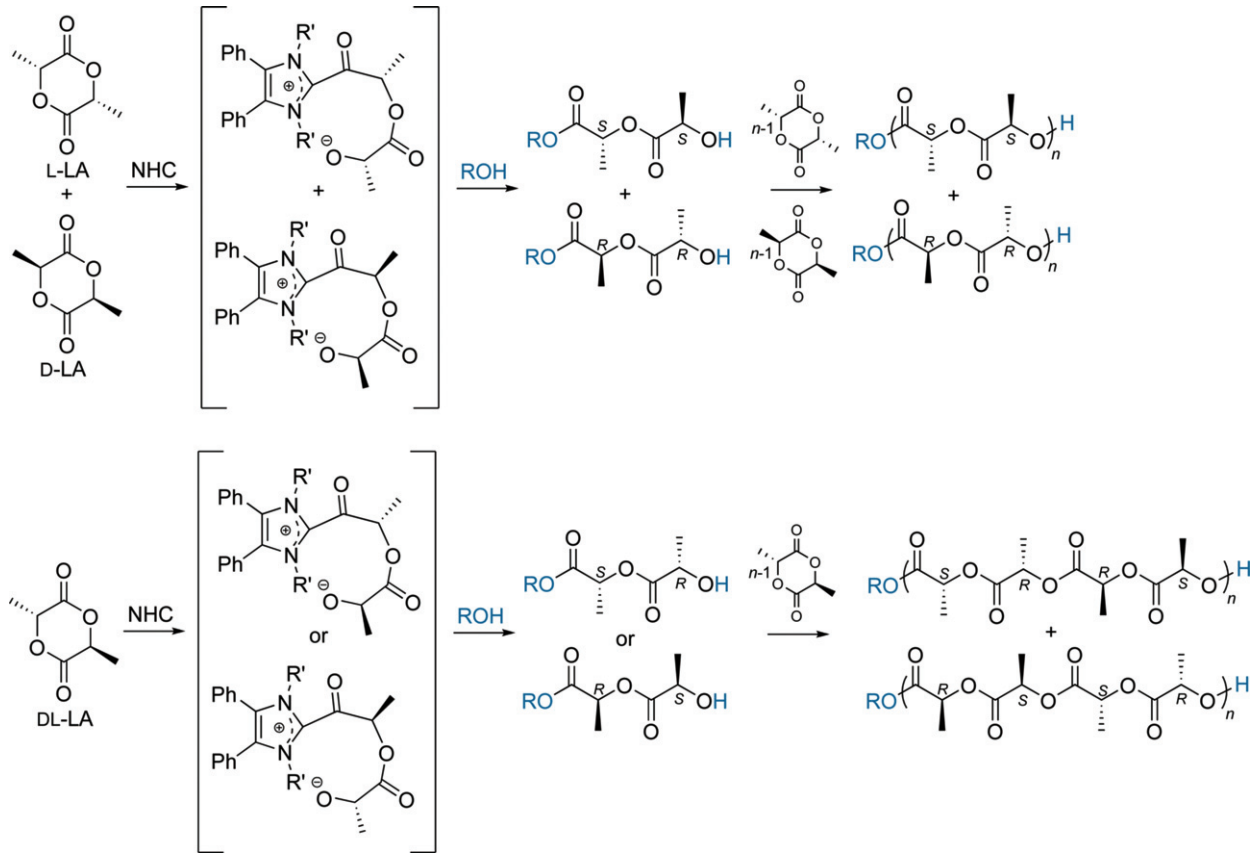
In 2004, Jensen *et al.*[150] discovered that the free achiral NHC, 1,3-dimesitylimidazol-2-ylidene, triggered the stereoselective polymerization of *rac*-LA (**Table 5**, entry 9). While the bimetallic Zn-based complex formed by addition of benzyl alcohol to the complex (1,3-dimesitylimidazol-2-ylidene)$ZnEt_2$ produced heterotactic PLA, the metal-free catalyzed ROP of *rac*-LA mediated by the same NHC led to isotactic enriched PLA under similar conditions (CH_2Cl_2, 25 °C). Actually, other NHCs, namely 1,3-di-*tert*-butylimidazol-2-ylidene and 1,3-bis(2,6-diisopropylphenyl)imidazol-2-ylidene, also formed isotactic enriched PLA, showing semicrystalline properties. No clear explanation, however, was provided by the authors to differentiate the behavior of the free NHCs and the metal-based complex.

Dove *et al.*[151] reported that sterically hindered unsaturated free NHCs catalyzed the polymerization of *rac*-LA, leading to highly isotactic PLA or *meso*-LA to give heterotactic PLA at low temperature (from −70 °C to −15 °C). Both the chiral and achiral versions of these NHCs were purposely designed. It was first noted that these catalysts exhibit a very high activity ($95\ min^{-1}$) at room temperature, providing PLA of controlled molar mass and low dispersity (entry 10). Highly isotactic PLA, with blocks of (*R*,*R*)-LA and (*S*,*S*)-LA in the PLA chain, as suggested by NMR characterization of these materials, was next generated at low temperature, with an increase in the probability of isotactic enrichment (P_i), from 0.59 at room temperature to 0.90 at −70 °C. The high level of stereoselectivity with this NHC was ascribed to the steric hindrance brought by the phenyl groups at the back of this catalyst. The ROP of *rac*-LA using the chiral NHC also formed highly isotactic PLAs at low temperature. It was, however, suggested that the stereocontrol was mainly dominated by the steric congestion of the active site (**Scheme 36**) rather than by the chirality of the catalyst. The polymerization of *meso*-LA mediated by a chiral NHC yielded a heterotactic PLA. All these observations (highly isotactic polymer formed from *rac*-LA and heterotactic polymer with *meso*-LA) were in agreement with a chain end control mechanism for both achiral and chiral NHCs, despite the presence of chiral groups close to the active site. In the case of *rac*-LA, both D- and L-LA should be subjected to a stereoselective attack by the terminal alkoxide of the last inserted monomer unit, leading to isotactic enrichment. In the case of heterotactic-enriched PLA obtained from *meso*-LA, the oxygen adjacent to the last chiral center of the PLA chain end (either *R* or *S*) might attack the activated monomer with the same stereogenic configuration adjacent to it.

While NHCs are highly active in the ROP of LA, they are much less efficient in the ROP of ε-CL.[140,141] However, the more electron-rich and sterically unhindered carbenes 1,3-diisopropyl-4,5-dimethylimidazol-2-ylidene (NHC9) and 1,3,4,5-tetramethylimidazol-2-ylidene (NHC10) proved to be active organocatalysts for the synthesis of well-defined PCL, again corroborating that the catalytic activity is sensitive to the steric and electronic nature of the carbene (entries 1, 2, and 11 in **Table 5**).[144] The ROP of ε-CL was performed at room temperature in THF solution (0.5–2.0 M), in the presence



Scheme 35 Synthesis of PLA catalyzed by fluorinated or chlorinated NHC adducts.[149]



Scheme 36 Stereoselectivity of PLA during the ROP of *rac*-LA or *meso*-LA (controlled chain end mechanism).[151]

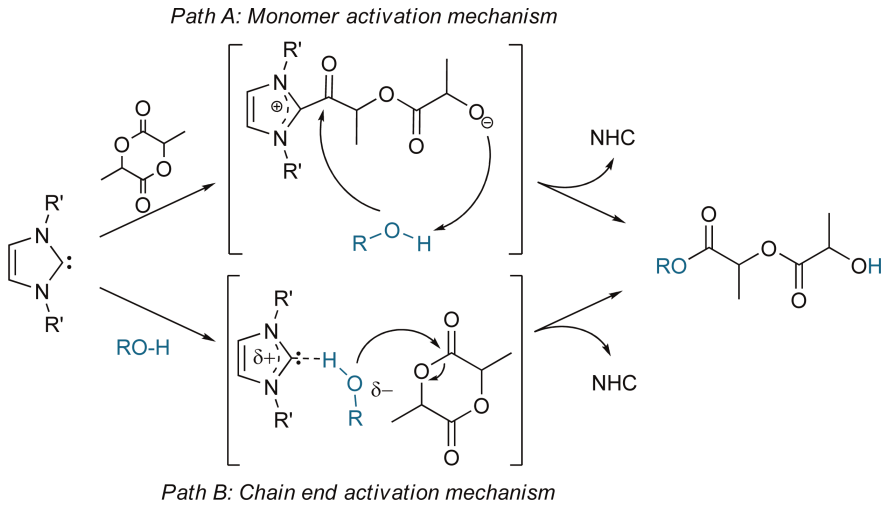
of BnOH and 4-pyren-1-ylbutan-1-ol as a monofunctional initiator, or using multihydroxylated initiators such as ethylene glycol, 1,1,1-tris(hydroxymethyl)propane, and pentaerythritol. Heterodifunctionalized PCL and three- and tetra-arm poly (ε-CL) stars were thus generated. Low NHC/ε-CL ratios were required to obtain PCL of low molar masses, so as to avoid side transesterification reactions and formation of cyclic oligomers.

The NHC-catalyzed ROP of TMC was also shown to be a controlled process (**Table 5**, entry 12).[99] NHC catalysis (5 mol.%) allowed fast conversion (> 99% after 30 min), yielding polymers with dispersity as low as for the best of the other organocatalysts used. However, the use of a more reactive NHC did not allow a good control.

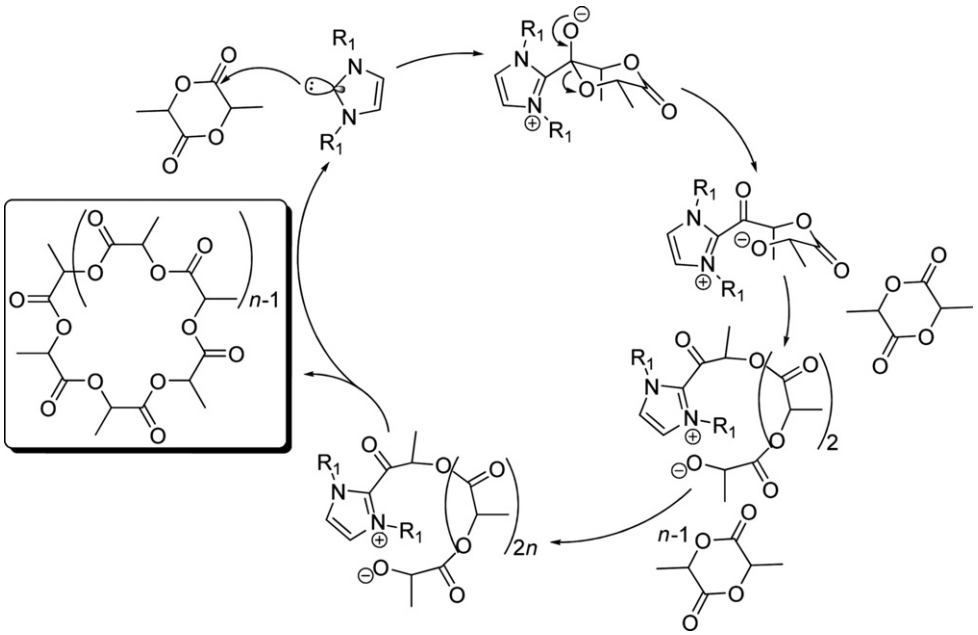
The two mechanisms already discussed above for other organocatalysts were eventually proposed to account for the 'controlled/living' character of NHC-catalyzed ROPs of cyclic esters, in general. In the AMM, the carbonyl group of the cyclic ester substrate is first subjected to a nucleophilic attack by the carbene catalyst (Path A, **Scheme 37**). The activate initiator/chain end mechanism (ACEM) involves interaction of the O–H group of the alcohol initiator with the NHC lone pair (Path B, **Scheme 37**) and the nucleophilic attack of the monomer by the oxygen of this alcohol.

Evidence for both mechanisms was discussed, according to the nature of the NHC catalyst. First, Connor *et al.*[140] argued that NHCs were unable to deprotonate alcohols and initiate an anionic polymerization from the corresponding iminium alkoxide. However, theoretical calculations predicted that the ACEM involving H-bond had a lower barrier than the AMM.[163] Interactions involved in alcohol complexes of IMes (NHC6) were studied by NMR spectroscopy and by X-ray crystallography. Such adducts were greatly sensitive to the solvent and to the structure/nature of the alcohol:[164] the more sterically hindered the alcohol, the weaker the interaction with the carbene. A more acid alcohol thus led to greater involvement of imidazolium alkoxides in equilibrium with other hydrogen-bonded complexes.

Evidence of a direct attack of the nucleophilic NHC IMes to the cyclic ester was given by polymerizing LA in total absence of an alcohol initiator.[152,153] In this case, cyclic PLAs could be obtained by a kinetically controlled zwitterionic ROP mechanism (referred to as the ZROP mechanism). In this case, deactivation of polymeric zwitterionic species occurred intramolecularly (**Scheme 38**), even at relatively high monomer concentrations (0.6–1.0 M in THF). Under such conditions, molar masses were directly controlled by the initial ratio of the monomer to the NHC (**Table 5**, entry 13). In other words, NHC played in this case the role of initiator, though it was released after intramolecular cyclization (macrolactonization reaction). These polymerization reactions proved to be very fast ($k_p = 48.7\,l\,mol^{-1}\,s^{-1}$), yielding high molar mass cyclic PLAs ($M_n = 5000$ and $30\,000\,g\,mol^{-1}$) with narrow dispersities ($D < 1.32$) in only a few seconds (5–900 s). Polymerization reactions were quenched by adding carbon disulfide trapping the NHC by forming an irreversible zwitterionic NHC–CS_2 adduct.



Scheme 37 Initiation of the ROP of LA and subsequent propagation to form PLA.



Scheme 38 ZROP of LA catalyzed by IMes and synthesis of cyclic PLAs.[152,153]

The cyclic architecture was supported by a combination of techniques, including NMR, MALDI-TOF MS, and viscometry of the cyclic polymers in comparison with the linear homologs of the same molar mass (prepared in the presence of alcohol initiators). In addition, thermogravimetric analysis (TGA) suggested that cyclic PLAs were more thermally stable than the respective linear polymers. When IMes-mediated ROP was applied to optically pure L-LA, a crystalline isotactic cyclic PLA was formed, indicating that the polymerization occurred without epimerization of the chiral center.

Investigations into the kinetics of these ZROPs mediated by NHC6 (IMes) allowed the authors to account for these experimental observations.[153] If the rate of cyclization is of the same order than the rate of propagation, cyclization would be the result of an intramolecular chain transfer, releasing NHC that would create new chains. In the latter case, the molar masses should not evolve linearly but should remain constant with monomer conversion, while the dispersity should be equal to 2.0. Since this was not observed experimentally, it was proposed that the IMes-mediated ZROP involved a slow initiation step (which was second order in monomer concentration, $k_i = 0.274\ l^2\ mol^{-2}\ s^{-1}$), a propagation step (first order in monomer concentration) that was found much faster than initiation, cyclization ($k_c = 0.0575\ s^{-1}$), and depropagation ($k_d = 0.208\ s^{-1}$). As a matter of fact, few chains could be reinitiated by the carbenes released upon cyclization. The very fact that the dispersity increased at high conversions was explained by the occurrence of either competitive transesterification reactions of the propagating zwitterions or transesterification reactions of the cyclic polymers by the zwitterions or the carbene molecules. These kinetic data were supported by numerical and stochastic simulations.

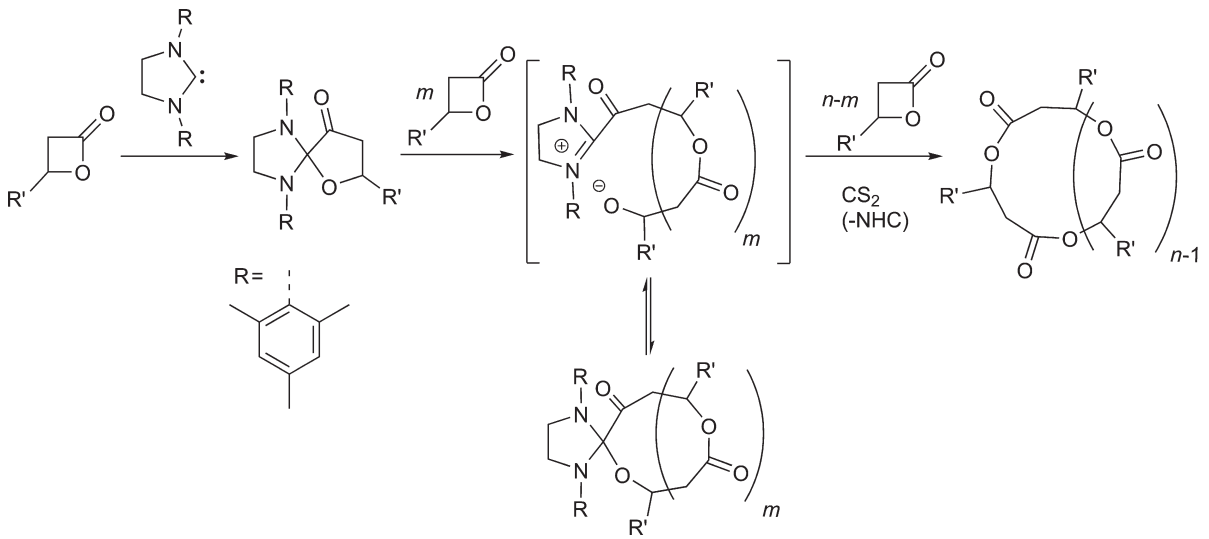
In complement to the previous studies on IMes-mediated cyclization of PLA, the reaction of the saturated homologue of IMes, that is, 1,3-dimesitylimidazolin-2-ylidene (NHC11), with four-membered lactones (β-butyrolactone and β-propiolactone) was investigated (Table 5, entry 14).[145] Equimolar amounts of that carbene generated zwitterionic species by nucleophilic attack of the carbene on the lactone, which was followed by ring closure. This led to the formation of a neutral and stable imidazolidine spirocycle which was isolated and characterized by crystallography. Interestingly, this spirocyclic intermediate could serve as a latent initiator that did undergo propagation steps in the presence of excess β-BL monomer. In other words, the controlled ROP of both β-PL and β-BL operated by reversible opening and closure of labile spirocyclic imidazolidine intermediates, affording well-defined aliphatic poly(β-BL) and poly(β-PL), as illustrated in Scheme 39. The use of CS_2 allowed quenching of these polymerizations and release of the cyclic polyesters.

If other organocatalysts were capable of catalyzing mostly the polymerization of carbonyl-containing monomers (see previous sections), NHCs were found advantageous to polymerize a variety of monomers, including not only heterocycles such as lactones, lactide, cyclic carbonates, cyclic siloxanes, epoxides, NCAs but also bis-aldehydes and both acrylates and methacrylates.

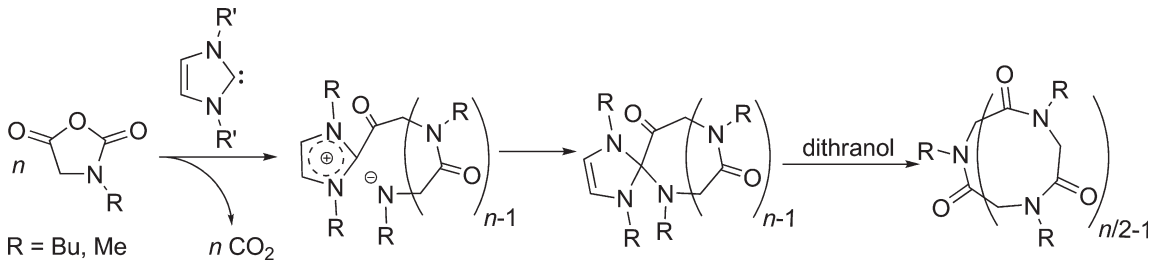
For instance, Guo *et al.*[154] reported the synthesis of poly(α-peptoid)s that are structural mimics of poly(α-peptide)s, via the direct NHC-initiated ROP of *N*-substituted NCAs (^{N}R-NCA) (Table 5, entry 15). In contrast to poly(α-peptide)s whose well-defined secondary structures are stabilized through hydrogen bonding interactions, poly(α-peptoid)s are free of such interactions. As with regular NCA monomers, ^{N}R-NCA can be polymerized through a nucleophilic chain-growth pathway that entails regioselective insertion of a nucleophilic initiator (e.g., primary amine) into the anhydride carbonyl group, followed by elimination of CO_2 reforming an amino propagating chain end. These ^{N}R-NCA monomers could be polymerized in the presence of various amounts of NHC used as a direct initiator, thus controlling the polymer chain length (ZROP mechanism). It is interesting to note that the activated functional group (i.e., anhydride) of the ^{N}R-NCA monomer is different from that of the polymer backbone (i.e., amide). As NHCs have not been reported to trigger transamidation reactions, it is likely that inter- and intrachain transfer (side) reactions, if existing, are *de facto* reduced. This situation differs from that of aliphatic polyesters discussed above, which can be subjected to NHC-catalyzed transesterifications.

Analysis by mass spectroscopy revealed that the carbene moiety was retained as spirocycle adduct when precipitated in hexane. Thus, after complete conversion of the initial monomer, chain extension could be performed upon addition of a second batch of ^{N}R-NCA monomer, confirming the living nature of the polymerization. Analysis by MALDI-TOF MS showed that the resulting polymers mainly consisted of cyclic poly(α-peptoid)s formed by ZROP, followed by intramolecular cyclization and release of the NHC moiety (Scheme 40). The cyclic architecture was confirmed by viscometric measurements. Interestingly, control over polymer molar mass and dispersity could be maintained even at relatively high concentrations of monomer, in contrast to common synthetic strategies for cyclic polymers that generally require dilute conditions. Cyclic diblock copoly(α-peptoid)s could even be obtained by sequential ZROP of ^{N}Me-NCA and ^{N}Bu-NCA monomers.

NHCs were also employed to catalyze the ROP of cyclosiloxanes (hexamethylcyclotrisiloxane and octamethyltetracyclosiloxane referred to as D_3 and D_4, respectively) and carbosiloxanes in the presence of initiating alcohols. For instance, Rodriguez *et al.*[139] reported the ROP of D_4 in THF solution at 25 °C, using NHC2 or NHC3 as catalyst, in the presence of methanol, *tert*-butyl alcohol, or benzyl alcohol as initiator. PDMS of relatively broad molar mass distribution (dispersity 1.58–1.70) was obtained (Table 5, entry 16), likely due to undesirable intra- (back-biting) and intermolecular transfer reactions. The authors also observed faster polymerization as the amount of NHC catalyst increased. This was attributed to the affinity of carbenes to the silicon atom and the propensity of Si to hypervalency,[78] favoring ring opening of D_4. Thus, either the AMM or the ACEM is plausible in these polymerizations, detailed mechanistic investigations being necessary.



Scheme 39 Formation of a spirocycle from β-butyrolactone (R′= CH_3) and the saturated NHC 1,3-dimesitylimidazolin-2-ylidene (R = mesityl; NHC11).[145]



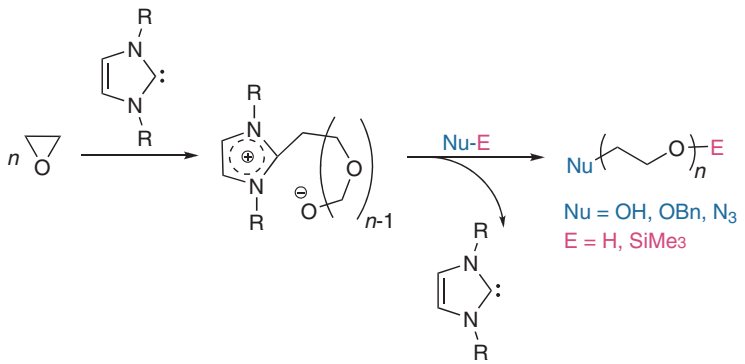
Scheme 40 NHC-catalyzed ROP of carboxylic anhydrides.[154]

The ROP of 2,2,5,5-tetramethyl-1-oxa-2,5-disilacyclopentane (TMOSC, Figure 2) catalyzed by the strongly basic NHC9 in the presence of the initiating alcohol was found to be very fast (99% conversion in 1 min, $k = 1.65\ s^{-1}$), forming poly(carbosiloxane) having a molar mass 10 200 g mol^{-1} and a dispersity equal to 1.19 (Table 5, entry 17).[100] The polymerization was slower with the NHC IMes (80% after 30 min, $k = 0.044\ s^{-1}$). An initiator (of the alcohol-type)/chain end (of the silanol-type) activation mechanism was proposed. However, activation of the silicon atoms of the monomer could be also envisaged in this case.

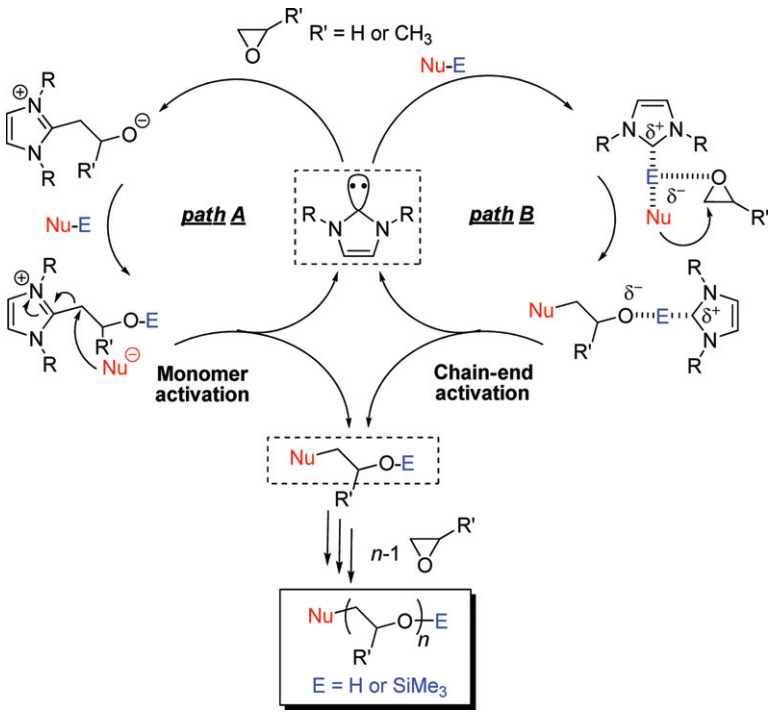
Raynaud *et al.*[155] reported that NHCs could directly open EO, a less polar monomer substrate than any of the aforementioned heterocycles. NHCs could serve not only as direct initiators (via a ZROP mechanism) but also as organocatalysts when used in conjunction with chain regulators of the NuE type, where Nu and E are the nucleophilic and electrophilic moieties, respectively (e.g., Nu = $PhCH_2O$, $HC{\equiv}CCH_2O$, and N_3 and E = H and $SiMe_3$). In both cases, linear α,ω-heterodifunctionalized PEOs could be synthesized (entries 18 and 19). For instance, 1,3-diisopropylimidazol-2-ylidene (NHC1) directly initiated the metal-free ROP of EO at 50 °C in DMSO, in the absence of any other reagents. In other words, the latter polymerization proceeded via ZROP. Without any other reagent added in the beginning, the PEO chain length was strictly controlled by the EO to the NHC molar ratio (typically, [EO]/[NHC] = 100/1). No competitive intra- or intermolecular transfer reactions are expected during anionic ROP of EO, the possible side reactions being transfer reactions to protic impurities or cyclization of the growing zwitterionic PEO chains. The resulting polymer, namely 1,3-diisopropylimidazol-2-ylidinium alkoxide, was quenched on the completion of ZROP by the NuE functionalizing terminator, leading exclusively to linear α-Nu,ω-OH (or α-Nu,ω-$OSiMe_3$)-difunctionalized PEOs, unlike the zwitterionic polymerization of LA described above. The quantitative introduction of the Nu moiety in α-position and of OH (or $OSiMe_3$) in ω-position of PEO chains occurred through the nucleophilic substitution of the imidazolium moiety by $Nu^{\delta-}$ and the concomitant reaction of the ω-growing alkoxide of PEO chain with $H^{\delta+}$ (or $Me_3Si^{\delta+}$), as illustrated in Scheme 41. In particular, difunctionalized α,ω-dihydroxy-telechelic, α-benzyl, ω-hydroxy, and α-azido, ω-hydroxy-PEOs were synthesized by NHC-initiated ZROP, using H_2O, $PhCH_2OH$, and N_3SiMe_3 as terminating agents. A well-defined PEO-*b*-PCL diblock copolymer could also be directly synthesized by sequential ZROP in DMSO, using the same NHC as organic initiator, without isolation of the zwitterionic PEO block intermediate.

Instead of using NHCs as direct initiators, the same group also reported the ROP of EO with NHCs as real organocatalysts (instead of initiators), in conjunction with not only alcohol but also trimethylsilylated initiators (the same NuE-type compounds mentioned above) introduced at the beginning.[156] Typical amounts of NHC catalyst equal to 10 mol.% relative to NuE were employed in this case, leading to PEOs with molar masses in the range 1800–10 500 g mol^{-1} and dispersities lower than 1.15.

Similarly to ROP of cyclic esters, two distinct mechanisms of initiation and chain growth were proposed (Scheme 42). NHCs might be nucleophilic and silicophilic enough to activate the electrophilic part (E = H or $SiMe_3$) of NuE chain regulators. Thus, both trimethylsilylated and hydroxylated chain regulators can be activated by NHCs, followed by monomer insertion (ACEM, path B). However, a nucleophilic attack by the NHC catalyst on the monomer is also plausible (AMM, path A). Protonation (or silylation) of the zwitterionic intermediate species by an alcohol (or a silyl ether), followed by addition of the resulting



Scheme 41 Functionalizing terminators in the ZROP of EO.[155]



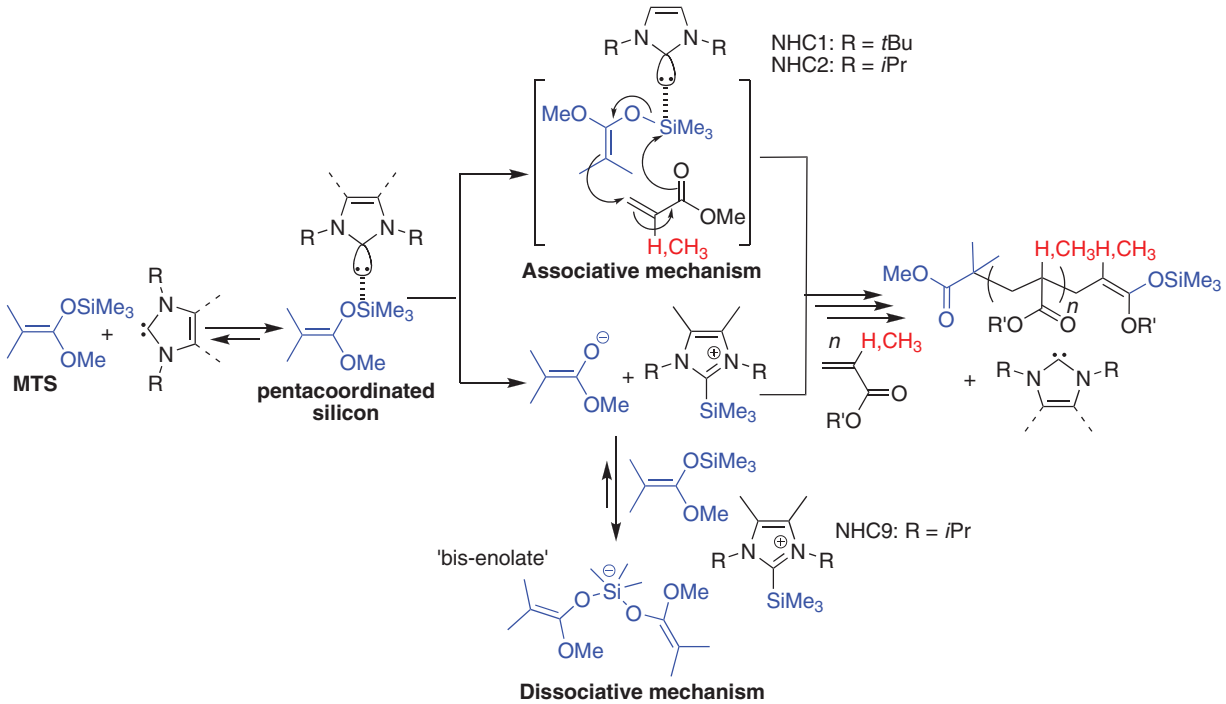
Scheme 42 AMM (path A) and ACEM (path B) in ROP of EO (R′ = H) and PO (R′ = CH_3) catalyzed by NHCs.[155,156]

alkoxide on the activated azolium, generates a new alcohol (or silyl ether) with an incorporated monomer unit. In the meantime, the NHC catalyst is released and can activate another EO molecule. The monoadduct, Nu-CH_2CH_2O-E, can serve for subsequent chain propagation. At this stage of their investigations, the authors acknowledged that it was unclear whether the NHC directly attacks the monomer, forming a zwitterionic intermediate, or activates the E moiety of the chain regulator, then the ω-OE moiety of the PEO chain. The fact that Tris(dimethylamino)sulfonium difluorotrimethylsilicate ($TASF_2SiMe_3$) did not yield any polymer in the presence of an *O*-TMS reagent might favor the AMM, as it was expected that this catalyst could generate benzylic alkoxide to initiate the ROP of EO by activation of the initiator. However, no polymer was formed under these conditions. Likewise, when used with EO in the absence of any other reagent, no PEO was obtained, $TASF_2SiMe_3$ being a too weak nucleophile to directly attack EO.

In a subsequent contribution, the same group applied the two methods discussed above, that is, with NHCs employed either as direct initiator in ZROP or as true organocatalyst in the presence of the aforementioned NuE-type reagents to the ROP of PO.[157] Both methods allowed the authors to derive α,ω-difunctionalized PPOs using NHC1 under metal-free and solvent-free conditions, whereas PPO is generally obtained by anionic ROP in low polar media from alkali metal-based initiators.[27] When NHC was used as a direct organic initiator, the polymerization was simply quenched by H_2O, leading to dihydroxytelechelic PPOs with molar masses up to 4500 g mol^{-1} (**Table 5**, entry 20). Targeting PPO of higher molar masses, however, showed the presence of a small extent of allyl-ended PPO chains, as observed by ^{1}H NMR, which was characteristic of the occurrence of the chain transfer to monomer of active PPO chains. With NHC as catalyst and the hydroxylated or trimethylsilylated reagents as initiators, the ROP of PO at 50 °C permitted the synthesis of PPOs of molar masses up to 8000 g mol^{-1} with a dispersity lower than 1.18. Both routes implied PO polymerization in bulk and incomplete monomer conversion (≤ 40% in all experiments), allowing an easy removal – and possible recycling – of the residual low-boiling monomer by simple evaporation.

Although focusing mainly on organocatalyzed ROP, this chapter underscores that organocatalysis has much broader scope and has been used in other chain polymerizations. For instance, Scholten *et al.*[130] on the one hand and Raynaud *et al.*,[131] on the other hand, reported that the GTP of (meth) acrylic monomers can advantageously be catalyzed by NHCs. GTP was proposed in the mid-1980s as a convenient method to control the polymerization of (meth)acrylic monomers at ambient temperature and above.[165] It is based on the repetition of Mukaiyama–Michael reactions[166] involving the addition of silyl ketene acetal (SKA) onto an incoming (meth)acrylic monomer. GTP is generally catalyzed by a metal-free nucleophile (Lewis base) or a metal-based Lewis acid, for methacrylic or acrylic monomers, respectively.[167] The absence of a unique catalytic system that could be generalized for both families of monomers did not permit, however, the synthesis of block copolymers featuring both monomer units by sequential GTP.[168] However, new developments in GTP via an organocatalysis pathway have been recently disclosed.

Webster[168] originally suggested the name 'group transfer polymerization' to account for the fact that the trimethylsilyl group remained at the end of the 'chain it created with throughout polymerization'. In other words, an associative (concerted) mechanism of GTP involving the transfer of the trialkylsilyl group from the polymer chain end to the inserted monomer was originally put forward. However, this pathway was further



Scheme 43 Associative and dissociative mechanisms for NHC-mediated GTP.[130,132]

questioned. In particular, Quirk proposed that GTP occurred by a dissociative mechanism through minute amounts of propagating enolates.[169] These anionic species would be the real active centers and be temporarily trapped by the SKAs, forming dormant trimethylsilyl bis-enolates (Scheme 43). In fact, the mechanism of GTP seems to strongly depend on the overall polymerization conditions and, in particular, on the nature of the catalyst.[170] NHCs were themselves reported to induce either the dissociative or the associative mechanism, depending upon the one used (Scheme 43).

While Scholten *et al.*[130] postulated a dissociative mechanism forming enolate-type species using NHC9 as catalyst, Raynaud *et al.*[132] provided a series of experimental evidences suggesting that GTP occurred by an associative (concerted) mechanism, when catalyzed by NHC1 or NHC2 (Scheme 43). This difference was explained by the varying nucleophilicity/silicophilicity of the different NHCs used. NHC9 is indeed slightly more nucleophilic than NHC1 and NHC2. Though the two mechanisms lead to the same polymer, the polymerization kinetics and the properties of the final polymers associated with each of them are yet different.[167,170] These NHC-catalyzed GTPs were further applied to the synthesis of all-acrylic block copolymers.[133]

The NHC-catalyzed GTP of (meth)acrylic monomers was typically performed at room temperature, using 1-methoxy-2-methyl-1-[(trimethylsilyl)oxy]prop-1-ene (MTS) as initiator, in polar (THF) or nonpolar (toluene) medium. In this way, polymethacrylates and polyacrylates with molar masses in the range 10 000–300 000 g mol^{-1}, corresponding to the initial [monomer]/[MTS] ratio and with dispersities lower than 1.2, were obtained in quantitative yields. Several features were observed with NHC1 and NHC2 as GTP catalysts, supporting the existence of the associative mechanism involving the formation of hypervalent siliconate intermediates:

- Though the first-order kinetic plot $\ln[M]_0/[M]$ versus time deviated from linearity at high monomer conversions, no inhibition period was noted at low monomer conversion. Moreover, the polymerization rate dramatically increased as the concentration of initiator increased, with first-order kinetic dependence of the initiator.
- When mixed in 1:1 molar ratio, MTS and NHC1 did not reveal the formation of enolate-type species by ^{29}Si or ^{13}C NMR spectroscopy.
- The production of well-defined poly(methyl methacrylate)s (PMMAs) using the 1:1 adducts of NHC1 and MTS as initiating system.
- The controlled polymerization of butyl and *tert*-butyl acrylates in the presence of NHC1 or NHC2, suggesting that back-biting and internal isomerization could be minimized, presumably because no enolates were generated.
- The preparation of block copolymers based on acrylate-type and methacrylate-type monomer units, irrespective of the order of addition of the two monomers, which would not be possible from pure enolates formed by a dissociative mechanism.

It is very likely, however, that the more slightly nucleophilic NHC9 used by Scholten *et al.*[130] brought about the GTP of (meth)acrylics via a dissociative pathway.

In a subsequent contribution, Raynaud *et al.*[133] exploited the potential of NHC1 and NHC2 to catalyze the MTS-initiated GTP of a variety of monomers in THF or toluene at room temperature. Monomers include not only acrylics (i.e., butyl acrylate, *tert*-butyl acrylate, and 2-(dimethylamino)ethyl acrylate) and methacrylics (methyl methacrylate (MMA) and 2-(dimethylamino)ethyl methacrylate), but also an

acrylamide-type monomer, namely, *N*,*N*-dimethylacrylamide. The NHC-catalyzed MTS-initiated GTP of methacrylonitrile using DMF as solvent was also reported for the first time. Like in the case of MMA, the GTP of *tert*-butyl acrylate showed a first-order kinetics and a direct dependence of the rate of polymerization on the concentration in MTS, again suggesting the occurrence of the associative mechanism.

4.06.9 Polymerization Catalyzed by Weak, Strong, and 'Super Strong' Bronsted Acids

Cationic ROP of cyclic ethers occurring in the ACEM consists, first, in the protonation of the monomer oxygen generating a secondary oxonium ion, followed by ring opening of the latter species by the oxygen atom of another cyclic ether molecule (Figure 8). The resulting tertiary oxonium ion propagates the polymerization by successive ring opening by the incoming monomer (Scheme 44).

Chain transfer to polymer, either by intramolecular (back-biting) or intermolecular reaction, characterizes many cationic ROPs.[27,91,92] This is due to the nucleophilicity of heteroatoms along the polymer backbone which compete with that of the monomer (Scheme 45). For instance, 1,4-dioxane is predominantly formed as the cyclic dimer in the cationic ROP of EO. Cyclic trimers or tetramers are also generated by cationic ROP of PO or epichlorohydrin. Under optimal conditions, the cationic ROP of THF can proceed, however, in a 'controlled/living' manner,[195,196] because the rates of back-biting and intermolecular transfer are slow relative to the rate of propagation.

In the late 1980s, Penczek *et al.*[27,91,92] unveiled AMM and applied it to the cationic ROP of oxiranes. These early works utilizing acid catalysts such as BF_3 or HPF_6 paved the way for precision polymer synthesis of a metal-free approach. This

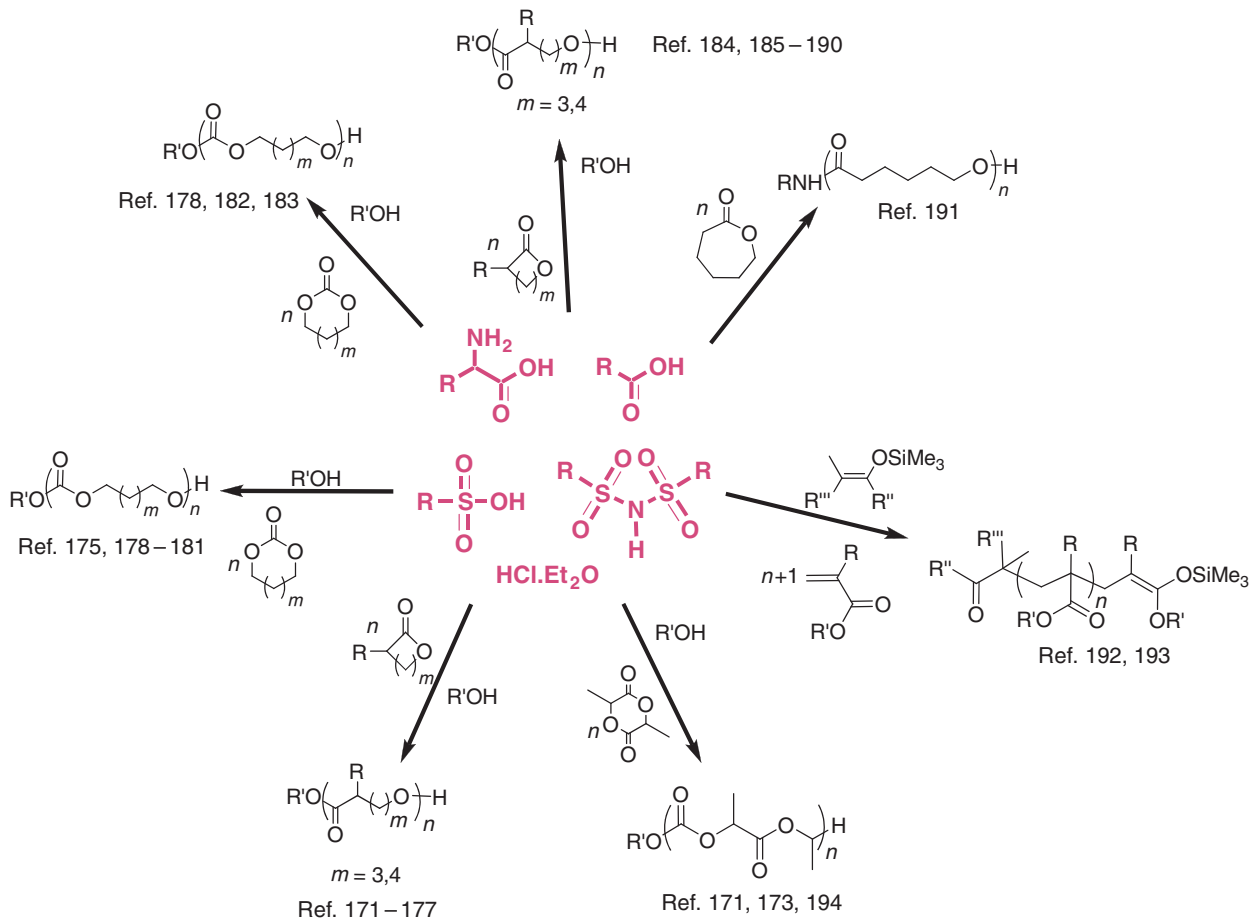


Figure 8 Overview of polymers obtained from acids as catalysts.

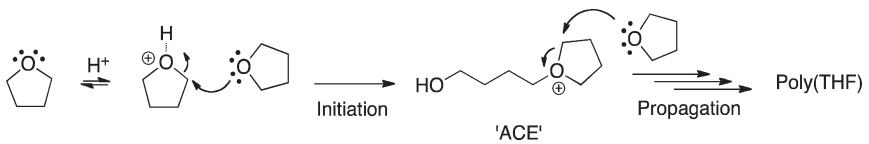
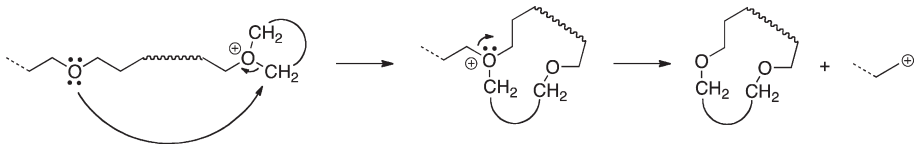


Scheme 44 Cationic ROP of THF initiated by acids.



Scheme 45 Intramolecular side reactions in cationic ROPs of cyclic ethers.

could be achieved using a protic reagent (typically ROH) and a catalytic amount of strong acid, while maintaining a low instantaneous concentration of monomer (by its continuous slow addition). The amount of cyclic oligomers can indeed be reduced thanks to the presence of the alcohol, playing the role of a chain transfer agent/initiator, which controls the polymer chain length.[27,91,92] The AMM involves, in this case, oxonium-type active centers that are located on the monomer, whereas the polymer chain exists in a (neutral) dormant form with a terminal OH-functionality (see **Scheme 4**). Under such conditions, back-biting is minimized, allowing for the synthesis of well-defined polyethers, including telechelics and macromonomers derived from ethylene and POs, epichlorohydrin and glycidol, and cyclic acetals. However, a relatively limited molar mass could be achieved by this synthetic strategy.

To favor AMM over ACEM, a slow monomer addition process is beneficial as the instantaneous concentration of monomer is kept low. In the ideal case where the ACEM is totally suppressed, the molar mass of the final polymer is controlled by the initial [ROH]/[monomer] ratio and a linear relationship is observed between M_n and [ROH]/[monomer]. However, exclusive AMM is rarely observed.

In recent years, a few groups revisited such Bronsted acid-mediated ROP which was applied to heterocycles other than cyclic ethers. In particular, organic acid catalysts were employed, mainly to polymerize cyclic esters. A better insight into the influence of the catalyst on the kinetics of the reaction was gained through a combination of experimental and theoretical studies. It turns out that the catalyst efficiency does not simply correlate with its acidity, suggesting a more complicated situation. Nevertheless, and for the sake of clarity, Bronsted organocatalysts will be divided into three subgroups in the following sections according to their acidity, that is, according to the nature of the acid group: sulfonic (RSO_3H), sulfonimide $(RSO_2)_2NH$, and carboxylic acids (RCOOH). Although HCl is not an organic catalyst, this metal-free polymerization system nonetheless shares common features with Bronsted organocatalysts, and so it may be included in this section for comparison.

4.06.9.1 Sulfonic Acid-Mediated ROP

In the past 10 years, efforts were devoted to the controlled polymerization of not only lactones such as δ-VL, ε-CL, and LA but also cyclic carbonates, using strong sulfonic acid catalysts, in the presence of an alcohol initiator.

Both methanesulfonic acid (MSA) and HOTf permitted a 'controlled/living' ROP of ε-CL, at 30 °C, in the presence of primary or secondary alcohol as initiators (entries 1 and 2, **Table 6**).[171,172] Polymerizations proceeded within hours for a typical [ROH]/[cat] ratio comprised between 0.5 and 1. The activity of MSA was similar to that of TfOH, despite a difference in pK_a of more than 10 units (MSA: $H_0 = -1$; TfOH: $H_0 = -14$; H_0: Hammett acidity). For comparison, HCl proved far less active than the two sulfonic acids, in spite of its intermediate acidity ($H_0 = -8$). A faster reaction was observed in toluene than in chlorinated solvents, which was thought to result from a slightly tighter interaction between the acid catalyst and the monomer in a less polar solvent. With both acids, the experimental M_n values varied linearly with the monomer-to-initiator ratio and agreed well with those calculated from the monomer feed. Molar masses up to 11 000 g mol^{-1}, narrow distribution ($1.07 < M_w/M_n < 1.21$), and reliability of the end-group presence were reported. The controlled character of the MSA- and TfOH-catalyzed polymerizations was further supported by chain extension experiments; expected M_n and narrow dispersity M_w/M_n were obtained. Interestingly, increasing the concentration of MSA induced faster polymerization, while a higher concentration of TfOH slowed down the reaction. It was proposed that the difference in behavior between the two acids could result from the competition between the activation of the monomer and the deactivation of the initiating/propagating alcohol (**Scheme 46**).

The stronger TfOH acid would deactivate the alcohol, while MSA would lead to more efficient monomer activation. ROP of ε-CL, catalyzed by sulfonic acid, was investigated by density functional theory (DFT), using a model reaction involving the nucleophilic addition of MeOH to ε-CL, followed by ring opening.[197] For both elementary steps, the sulfonic acid was actually predicted to behave as a bifunctional catalyst, operating as a proton shuttle via its acid hydrogen atom and basic oxygen atoms. The computed activation barriers were consistent with the relatively fast polymerizations observed experimentally at room temperature.

Other sulfonic acids such as p-toluenesulfonic acid (PTSA), 1,1,2,2,3,3,4,4,4-nonafluoro-1-butanesulfonic acid (NfOH), and 1,1,2,2,3,3,4,4,5,5,6,6,7,7,8,8,8-heptadecafluoro-1-octanesulfonic acid (PfOH), whose Hammett acidity ranged from −2.3 to −12.3, also proved efficient catalysts for the ROP of ε-CL. Although the control and livingness of the polymerization were not investigated, low catalyst loading (0.1 mol.% relative to the initiator) led to complete monomer conversion within 3–5 h at 50 °C in toluene (**Table 6**, entry 3).[174]

Controlled polymerization of LA catalyzed by TfOH, in the presence of an alcohol initiator (ROH), was also described by Bourissou *et al.*[194] and Baśko and Kubisa.[171] The solvent for polymerization was somewhat restricted to dichloromethane, toluene being a poor solvent of PLA and THF being polymerized by TfOH.[194] In dichloromethane, polymerization proceeded at 25–35 °C within hours for a typical [ROH]/[cat] between 0.5 and 1, with various initiators, including H_2O, *i*-PrOH, PrOH, and pentan-1-ol (entries 7 and 8). Other catalysts such as CF_3COOH and HCl in the presence of *i*-PrOH were found completely ineffective for LA polymerization, under identical conditions. LA was thus found much less

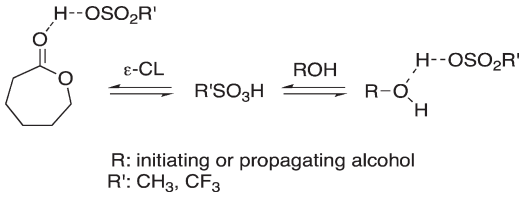
[a]Initiation by $–NH_2$ group.



Scheme 46 Competitive monomer activation and alcohol deactivation.[171,172]

reactive than ε-CL or δ-VL, in sharp contrast to the situation prevailing with Bronsted bases (see previous sections); both ε-CL and δ-VL could indeed be polymerized with HCl at room temperature.[175,176] PLAs with molar masses ranging from 1500 to 20 000 g mol^{-1} and relatively low dispersity ($1.13 < D < 1.50$) were obtained. The controlled character of these polymerizations was demonstrated by the linear evolution of experimental M_n values with the monomer conversion. This was supported by a second feed experiment, a quantitative reinitiation of chain ends being observed. Both ^{1}H NMR and mass spectra analyses evidenced quantitative initiation of the polymerization by the alcohol, without a trace of adverse transesterification reactions up to 93–96% conversion. However, prolonged reaction times caused the formation of odd and even numbers of lactate units, as seen by MALDI-TOF MS, owing to the occurrence of transesterification.[171]

Investigations into the kinetics of polymerization revealed a first-order kinetics dependence on LA concentration, with a k_{obs} of 6.8×10^{-3} min^{-1} at room temperature, which was comparable with the activity of DMAP, although a temperature of 35 °C and longer reaction times were required.[24]

From a mechanistic viewpoint, protonation of LA and its subsequent ring opening by the alcohol initiator or the growing polymer chain were shown to occur selectively. The chain growth involved an acyl cleavage of LA rather than alkyl cleavage, as could be deduced from the presence of isopropyl ester chain ends in the NMR spectra of the resulting PLAs (Scheme 47).

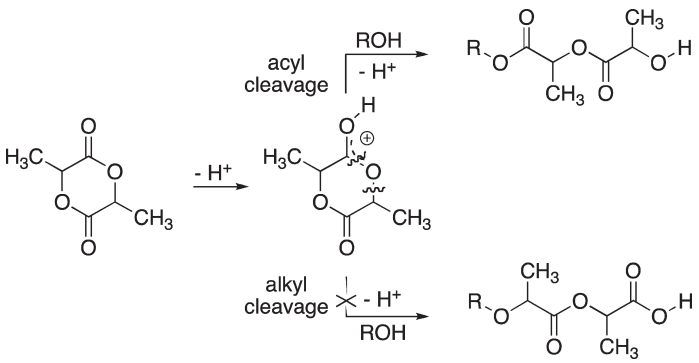
No configuration change on the chiral carbon atom was observed during the L-LA polymerization in dichloromethane at room temperature, a perfectly isotactic PLA being obtained.

Baśko and Kubisa[171,173] studied the copolymerization of ε-CL and L-LA catalyzed by TfOH in dichloromethane at 35 °C, in the presence of an alcohol initiator such as PrOH or ethylene glycol. L-LA was preferentially incorporated into the copolymer, despite its slower rate of homopolymerization (relative to that of ε-CL), a situation reminiscent of that observed for the homo- and copolymerization of LA and ε-CL by anionic or coordination mechanism.[198,199] This apparent discrepancy was explained by the twice higher probability of protonation of LA which contains two ester groups compared with ε-CL. Analysis by ^{13}C NMR of the copolymer microstructure was found to depend on the alcohol initiator (PrOH vs. ethylene glycol), on the LA to ε-CL ratio and the conversion. Thus the microstructure of the copolymer might be governed either by the relative reactivity of the comonomers[171] or by transesterification, regardless of the kinetics of comonomer incorporation.[173]

Shibasaki *et al.*[179] reported, in 1999, the use of HCl/H_2O as initiating system for the cationic ROP of 1,3-dioxepan-2-one (7CC) following an AMM (Table 6, entry 9). Polycarbonates with M_n ranging from 3000 to 12 400 g mol^{-1} and low dispersity (1.15–1.23) could be quantitatively obtained by ROP of 7CC in dichloromethane at room temperature. M_n values could be controlled by the initial amount of water; they were found to increase linearly with monomer conversion, regardless of the initial [M]/[I] ratio. According to NMR spectroscopy, no decarboxylation was noted under these conditions, a side reaction commonly observed during cationic ROP of cyclic carbonates.[200]

At the same time, Nakano[180] reported the organocatalytic ROP of a six-membered cyclic carbonate, namely 5,5-dimethyl-1,3-dioxan-2-one, catalyzed by MSA in the presence of BuOH as initiator (entry 10). Polymerization proceeded homogeneously at 50 °C in toluene within 3–10 h, yielding polycarbonates with M_n ranging from 2300 to 9300 g mol^{-1} and a relatively narrow dispersity (1.13–1.24). However, GPC profiles proved unimodal only for [M]/[I] < 20 but bimodality was observed for the ratios higher than 30. Although some polymer chains were effectively initiated by BuOH, according to ^{1}H NMR spectroscopy, side reactions such as back-biting occurred to a significant extent.

In 2010, Delcroix *et al.*[181] revisited the ROP of cyclic carbonates catalyzed by sulfonic acids and investigated the scope and limitations of such an organocatalysis (Table 6, entry 11). Both MSA and TfOH were employed and compared, for the ROP of TMC, with water or pentan-1-ol as protic initiators. In contrast to TfOH, MSA yielded a PTMC free of ether linkage, even under forcing conditions. Increasing the catalyst concentration induced a faster polymerization in the case of MSA, while the



Scheme 47 ROP of LA in the presence of sulfonic acid.

kinetics slowed down with TfOH, in line with the observations made for the ROP of ε-CL. In the case of the MSA-catalyzed pentan-1-ol-initiated ROP of TMC, the molar mass of PTMC was only controlled for [M]/[I] < 20. For higher ratios, lower M_n experimental values were obtained, owing to the occurrence of competitive AMM and ACEM. Importantly, no cyclic structures could be identified, suggesting the absence of back-biting reactions. It is noteworthy that such a competition between the AMM and the ACEM is unprecedented for the polymerization of carbonyl-containing monomers by strong Bronsted acids, but is similar to that observed during the ROP of cyclic ethers.[27,91,92] By analogy with the aforementioned works by Penczek with oxiranes, ACEM could be minimized, by decreasing the instantaneous concentration of TMC, using multifeed experiments or a continuous slow monomer addition. Controlled M_n values up to 4000 g mol^{-1} were obtained with the multifeed approach, while M_n values up to 9000 g mol^{-1} were reached with the continuous addition of the monomer. In the latter case, SEC analysis revealed a unimodal but slightly asymmetric distribution of molar masses, due to a small contamination of polycarbonate chains grown by the ACEM, besides the main population of chains derived from AMM. Under these optimized conditions, the molar mass of PTMC increased linearly with monomer conversion.

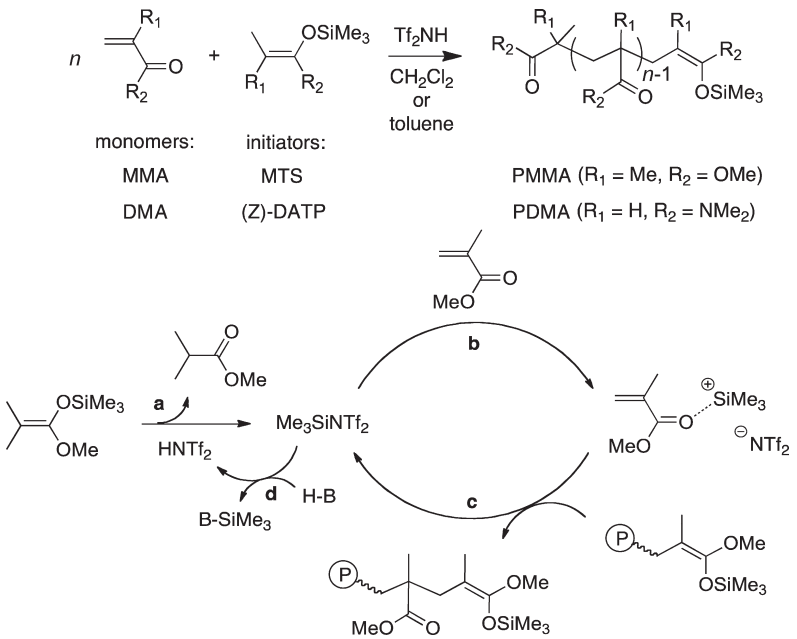
4.06.9.2 Sulfonimide-Based Catalysts for ROP

Introduction of these organocatalysts in polymer chemistry was reported by Kakuchi *et al.*[192] in 2009 who reported the GTP of (meth)acrylic monomers (see below). Bis(perfluoroalkanesulfonyl)imides such as Tf_2NH and Nf_2NH were also found particularly active in the Bronsted acid-catalyzed ROP of δ-VL and ε-CL.[174,177]

PVL with molar mass up to 9400 g mol^{-1} (reaction time: 9 h) and low dispersity (M_w/M_n = 1.09) could be obtained in dichloromethane at 27 °C, with a catalyst loading of 0.1 mol.% (relative to the initiator) and 3-phenylpropan-1-ol as initiator (**Table 6**, entry 12).[177] The controlled nature of the polymerization was demonstrated: the M_w/M_n remained low (1.09–1.16), molar masses increased linearly with increasing the initial [M]/[I] ratios, and a chain extension experiment was successfully performed. In addition, PVL featuring functionalized chain ends could be prepared using a heterodifunctional alcohol initiator, incorporating an azido, pentafluorophenyl, or maleimido group.

In 2011, Oshimura *et al.*[174] reported that Tf_2NH and Nf_2NH efficiently catalyzed the ROP of ε-CL (entry 13). PCL with M_n ranging from 2000 to 6400 g mol^{-1} and relatively narrow dispersities (1.10–1.48) was synthesized in toluene, using a low catalyst loading (0.1 mol.% relative to the initiator). Quantitative monomer conversion could be obtained in 8–10 h at 25 °C, while the reaction time could be shortened to 2.5–3 h by increasing the temperature to 50 °C. When THF was used as solvent, its incorporation into PCL was observed, by analogy with the ability of TfOH to initiate THF polymerization. Although a postpolymerization experiment was performed, no evidence of the controlled/living character of the polymerization was provided. Interestingly, Nf_2NH could be recycled for a subsequent polymerization by simple extraction of the reaction mixture with water. Several reaction parameters such as rate constants, activation energies, enthalpy of activation, entropy, and Gibbs energy for the ROP of ε-CL were determined, but no clear relationship between the catalyst acidity and rate of polymerization, on the one hand, and the solvent polarity and rate of polymerization, on the other hand, was established.

The group of Kakuchi applied the organocatalysis based on Tf_2NH to the GTP of (meth)acrylate derivatives such as MMA[192] and *N*,*N*′-dimethylmethacrylamide (DMA)[193] (**Scheme 48**; see also Section 4.06.8 for a general discussion about GTP and recent developments employing NHCs as catalysts).



Scheme 48 GTP of (meth)acrylics using $HNTf_2$ (MTS: $R_1 = CH_3$, $R_2 = OCH_3$; (Z)-DATP: $R_1 = H$, $R_2 = NMe_2$).[192,193]

In contrast to traditional metal-based Lewis acid-mediated GTP,[170] only 5 mol.% of $HNTf_2$ (relative to the initiator) was required for quantitative monomer conversion to be reached. PMMA with M_n up to 17 000 g mol^{-1} and low dispersity ($M_w/M_n = 1.04–1.08$) could be obtained in dichloromethane solution with MTS as initiator, in 24 h at 27 °C. Polymers with M_n values ranging from 6000 to 54 000 g mol^{-1} in dichloromethane solution and dispersity from 1.06 to 1.20 were synthesized by GTP of DMA in toluene solution, at 0 °C, within 3–9 h. In the latter case, (*Z*)-1-(dimethylamino)-1-trimethylsiloxy-1-propene, (*Z*)-DATP, was found more appropriate as initiator than MTS (**Scheme 48**). The controlled character of the GTP of both MMA and DMA was evidenced through (1) the increase in molar mass with increasing the [MMA]/[MTS] ratio, (2) the increase in molar mass with increasing monomer conversion, (3) the reliability of the presence of end groups, and (4) postpolymerization experiments. From a mechanistic viewpoint, the polymerization presumably proceeded in a similar way as the Mukaiyama aldol molecular reaction catalyzed by strong Bronsted acids, as described by the groups of Yamamoto and List[82–84,201] First, $HNTf_2$ reacts with the initiator to generate the actual catalytically active species Me_3SiNTf_2 (step a, **Scheme 48**). Coordination of Me_3SiNTf_2 to MMA increases the electrophilicity of the monomer (step b), which can thus undergo nucleophilic addition of the propagating SKA chain end (step c). This results in the formation of PMMA containing $(n + 1)$ units while the catalyst is regenerated. Note that this Tf_2NH-mediated reaction is also characterized by a 'self-repair' mechanism (step d), which further consumes MTS to regenerate Me_3SiNTf_2 due to the presence of a very low amount of impurities (BH). This mechanism was consistent with the slightly higher molar mass observed for PMMA synthesized by the Tf_2NH-catalyzed GTP of MMA. These results contrasted with those reported for the $CF_3SO_3SiR_3$-catalyzed GTP, which was found to lose livingness ($M_w/M_n = 2.35$) and to yield incomplete monomer conversion.[202]

Interestingly, the Tf_2NH-catalyzed GTP produced a predominantly syndiotactic PMMA at room temperature (*mm*/*mr*/*rr* = 1/27/72). Lowering the temperature to −55 °C allowed the author to reach 90% syndiotacticity (*mm*/*mr*/*rr* = 0/10/90), which compared with *t*-BuLi/AlR_3, one of the most established transition metal-based synthetic pathways to syndiotactic PMMA. In the case of PDMA, the dyad tacticity (*m*/*r*) was influenced by both the solvent polarity and the temperature of polymerization: the (*m*/*r*) values determined vary from 35/65 in dichloromethane to 44/56 in toluene at 0 °C and from 27/73 in dichloromethane to 38/62 in toluene at −78 °C.

4.06.9.3 Carboxylic Acid-Mediated Polymerizations

Various carboxylic acids, including not only trifluoroacetic acid (TFA) but also naturally occurring α-hydroxyacids and α-amino acids, have attracted great interest in polymer chemistry over the last 10 years. This is due to their broad availability from renewable resources as well as their air and moisture stability.[15] Unlike enzymes, these small molecules display a higher thermal stability and better solubility in organic solvents. Compared with stronger acids, the carboxylic acid derivatives with pK_a around 3–5 usually lead to few side reactions, while providing high chemoselectivity.[15] Moreover, these catalysts allow the polymerization to be performed under solvent-free conditions, which is of prime relevance in the context of green chemistry. Most lactones have been polymerized so far, including ε-CL, δ-VL, and LA. The polymerization of cyclic carbonates was also briefly investigated.

Naturally occurring α-hydroxyacids such as lactic acid, citric acid, mandelic acid, tartaric acid, and other α-amino acids proved efficient for the ROP of ε-CL. Complex polymer architecture such as dendrimer-like PCLs could be obtained via such an organocatalyzed pathway. The selective modification of saccharides and even cellulose fibers was also described. In most cases, the ROP of ε-CL catalyzed by carboxylic acids was performed in bulk at 120 °C. α-Hydroxyacids such as lactic, tartaric, and citric acids proved more efficient than nonhydroxylated carboxylic acids (hexanoic and propionic acids), which was thought to result from the higher acidity of the former catalysts (pK_a = 3.8 vs. 4.5). Casas *et al.*[184] showed that high monomer conversion (80–90%) was obtained in 4 h with tartaric acid as catalyst ([I]/[cat] = 3) and benzyl alcohol as initiator (**Table 6**, entry 14). PCLs with molar masses up to 2700 g mol^{-1} and dispersity around 1.3 could be synthesized. In contrast, with aliphatic carboxylic acids such as propionic and hexanoic acids, low monomer conversions (10%) were observed and only oligomers (M_n = 450 g mol^{-1}) were formed. In the absence of an external alcohol initiator, α-hydroxyacids were also found to initiate the polymerization. This situation is reminiscent of the amino acid-mediated ROP of ε-CL described by Liu *et al.*, which afforded PCL terminated with an amino acid (entry 15).[191] L-Alanine, L-proline, L-phenylalanine, and L-leucine could serve as both catalysts and initiators for the bulk ROP of ε-CL at 160 °C, quantitative monomer conversion being reached in 24–48 h. PCL of relatively well-controlled molar mass, ranging from 3700 to 26 800 g mol^{-1}, but of rather high dispersity (1.50–1.89), could be obtained by varying the initial [ε-CL]/[amino acid] feed ratio.

In contrast to strong Bronsted acids, the softer carboxylic acids were expected to display a high functional group tolerance which could provide the opportunity to readily access polymers incorporating multifunctional groups. A difunctional initiator featuring two types of OH groups (phenol and alkanol) was shown to exclusively initiate via its alkanol group the tartaric acid-catalyzed ROP of ε-CL.[185] Increasing the [I]/[cat] ratio from 0.7 to 3.5 led to a slight decrease in the PCL molar mass from 10 300 to 8900 g mol^{-1}, suggesting initiation by tartaric acid itself. PCLs with a dendrimer-like architecture were also prepared using, in this case, a hexahydroxy-functional initiator in the presence of lactic acid ([I]/[cat] = 0.125) as catalyst (entry 16).[185] The polymerization was carried out at 120 °C for 1 h under solvent-free conditions, affording dendrimer-like structures with molar mass M_w = 12 550 g mol^{-1} and a dispersity of 1.4. According to ^{1}H NMR spectroscopy, however, the dendritic structures were found to be contaminated with linear PCL chains that were directly initiated by tartaric acid. Interestingly, the lactic acid catalyst could be recycled twice, without affecting the yield of the dendrimer-like PCLs. Upon subsequent recycling, however, the molar mass decreased from 12 550 to 10 800 g mol^{-1}, while the dispersity broadened significantly (from 1.4 to 2.1 in the first and third run, respectively). Although it was claimed that the high chemoselectivity of this system prevented the aryl ester functions of the initiator from being transesterified by

growing chain end of PCL, the transesterification involving PCL alkyl ester groups likely occurred.

Persson *et al.*[186] showed that various sugars such as methyl-β-D-glucopyranoside, sucrose, and raffinose could initiate the ROP of ε-CL in bulk at 120 °C, in the presence of L-lactic acid catalyst ([I]/[cat] = 1–4) (**Table 6**, entry 17). Depending on the initiator used, PCLs with molar mass ranging from 1600 to 6500 g mol^{-1} and relatively narrow dispersity (1.3–1.5) were obtained in high yields (up to 95% based on consumed ε-CL). It was found that these sugar-initiated PCLs were contaminated with some lactic acid-initiated PCL, in line with previous observations made with other initiators (*vide supra*). Interestingly, the first direct catalytic ROP from cellulose fibers was described with the mild, tartaric acid-catalyzed bulk polymerization of ε-CL at 120 °C, initiated by cotton and paper cellulose. Such an organocatalytic pathway to polyester–polysaccharide composites might be suitable biomaterials for various applications.[203]

Three- and four-arm star PCL polymers have been prepared by Sanda *et al.*[187] by ROP of ε-CL with a triol (1,1,1-tris(hydroxymethyl)propane) and a tetrol (pentaerythritol) initiator respectively, in the presence of various acid catalysts such as HCl.Et_2O, TFA, CCl_3COOH, maleic, and fumaric acids (entry 18). With carboxylic acids, the polymerization was carried out in bulk at 70–90 °C for 6–24 h; star PCL (61–95% yield) of molar mass ranging from 4400 to 15 800 g mol^{-1} could be obtained (M_w/M_n = 1.07–1.98).[187]

The synthesis of lipid-functionalized PCL was recently described by Oledzska *et al.*[188] by ROP of ε-CL in bulk at 70–150 °C, initiated with *threo*-9,10-dihydroxyoctadecanoic acid and catalyzed by oxalic, succinic, or fumaric acids (entry 19). Functionalized PCL of molar mass ranging from 7500 to 15 200 (M_n/M_w = 1.11–1.48) was obtained in 28–95% yield.

Block copolymers based on pseudo-poly(amino acid) and PCL have been prepared by Lee *et al.*[189] by ROP of ε-CL in bulk, using an OH-terminated pseudo-poly(L-proline) derivative as initiator and DL-lactic acid as catalyst (**Table 6**, entry 20). Within 1.5–24 h, block copolymers of 2900–13 030 g mol^{-1} could be obtained at 140 °C, with a low catalyst loading ([C]/[M] = 0.1–1). The ability of these amphiphilic copolymers to form micelles in aqueous media was also studied.

The feasibility of a carboxylic acid-mediated ROP of δ-VL was first reported by the group of Córdova in 2004 (**Table 6**, entries 21 and 22).[184,190] PVLs with molar mass of 2600 g mol^{-1} were obtained in 7 h (conversion > 95%) by ROP of δ-VL in bulk at 120 °C, using tartaric acid ([I]/[cat] = 0.33) as catalyst and benzylalcohol as initiator. Further development of this methodology by Zeng *et al.*[190] allowed the polymerization to be controlled, giving an access to complex polymer structures, such as six-arm star PVL and some star-block copolymer derivatives. The polymerization of δ-VL in bulk at 60–70 °C, in the presence of fumaric acid as catalyst and dipentaerythritol as hexafunctional initiator, yielded hexa-arm star PVL exhibiting higher molar masses than expected, owing to the poor initiator efficiency (less than 0.3). Raising the temperature to 100 °C allowed the authors to increase the initiator efficiency to 0.9 and to synthesize PVLs with molar mass ranging from 6150 to 99 100 g mol^{-1} and a dispersity of 1.07–1.36, using a relatively high catalyst loading ([I]/[cat] = 0.1). The molar masses calculated from the ^{1}H NMR spectra were in good agreement with the theoretical values.

The group of Endo[175,182] investigated the organocatalytic ROP of six- and seven-membered cyclic carbonates (6CC and 7CC, respectively) in the presence of a protic initiator (entry 23). In particular, among a variety of organic acids screened, only TFA proved efficient in the ROP of both carbonates. High monomer conversion (77–98%) was reached for the polymerizations of 6CC and 7CC in dichloromethane at 0 °C and in toluene at 50 °C, respectively, using a low catalyst loading ([I]/[cat] = 2) and a primary alcohol (BnOH or BuOH) as initiator. Polycarbonates with molar masses ranging from 2500 to 6800 g mol^{-1} and relatively narrow dispersities (M_w/M_n = 1.16–1.24) could be synthesized in 24–30 h. It was shown that molar masses of poly(6CC) and poly(7CC) increased with conversion, indicating a controlled character of the polymerization. This situation contrasted with the HCl-catalyzed ROP of 7CC, where the molar mass of the resulting polymers increased linearly with increasing the initial [M]/[I] feed ratio, a good agreement between calculated and theoretical molar masses being observed.[175] These differences might arise from the inability of HCl to mediate ROP of cyclic carbonates in the absence of a protic initiator, while TFA was shown to induce an ACEM when used as direct initiator, in spite of higher acidity of HCl. Importantly, no decarboxylation occurred in these two systems, in contrast to what was observed under typical cationic polymerization conditions.[200] In dichloromethane, the rate of polymerization of 7CC is ca. 30 times higher than that observed for the polymerization of 6CC, which is thought to result from the higher ring strain of 7CC. Interaction of TFA with both 6CC and 7CC in $CDCl_3$ could be established by ^{1}H and ^{13}C NMR spectroscopy, following a polymerization by AMM, as proposed by the authors.

A further development of the carboxylic acid-mediated ROP of cyclic carbonates was reported in 2009 by Zhang *et al.*[183] for the synthesis of triblock polycarbonates (**Table 6**, entry 24). The authors showed that the polymerization of 2-(benzyloxy) propane-1,3-diyl carbonate could be conducted at 150 °C under solvent-free conditions, with 2.0 wt.% of the fumaric acid catalyst, using a dihydroxylated macroinitiator. Under these conditions, A-B-A triblock copolymers of predictable molar mass could be synthesized with moderate to excellent yields (41–91%), by varying the initial feed ratio of comonomers. The molar mass of the A blocks could be varied from 2650 to 9450 g mol^{-1}, while only a slight increase in the dispersity of the triblock copolymer, compared with that of the macroinitiator for B-block, was observed.

4.06.10 Conclusion

Tremendous research efforts are currently being made in organic synthesis, focusing on the development of more sustainable processes, taking into account mild conditions, energy savings, high selectivities, reduced by-products, and wastes. In this regard, both enzymatic catalysis and organocatalysis offer new opportunities for activating various substrates and accessing functional building blocks. General concepts of organocatalysis have been applied to polymer synthesis, allowing significant breakthroughs such as enhancement of polymerization rates and high selectivity of propagation relative to adverse chain breaking by termination or transfer reactions. Organocatalysis has also allowed the preparation of

polymeric structures that would be hard to access by a metal-mediated polymerization. Moreover, this metal-free approach has led to the production of biocompatible polymers without metal residues, which could be used in biomedical applications. It might be anticipated that organocatalysis could be applied in the near future to the synthesis of polymer for optoelectronic applications, where metallic impurities are also problematic.

The field of organocatalyzed polymerization, however, is still in its infancy. Since organic catalysts may operate differently as compared with metal-based ones, they offer a diversity of mechanistic pathways to control the polymerization. In some cases, it has not been clearly established whether the organic catalysts activate the monomer or the initiator/polymer chain ends or operate by cooperative dual activation. It turns out that the polymerization mechanism dramatically depends on the catalyst structure/reactivity. In this context, DFT calculations appear as a complementary tool to better understand the polymerization mechanism.

Thus, challenges still remain in macromolecular synthesis by an organocatalyzed pathway. For instance, only a few monomer candidates have actually been investigated so far, carbonyl-containing monomers such as cyclic esters and cyclic carbonates being the most studied in the context of ROP. This can be explained by the relatively high reactivity of polar carbonyl group. Also polymer molar masses of polymers are somehow limited in most of the examples reported. On the other hand, asymmetric polymerizations using chiral catalysts have to be investigated in much more detail, since they are far from competing with organometallic catalysts.[204]

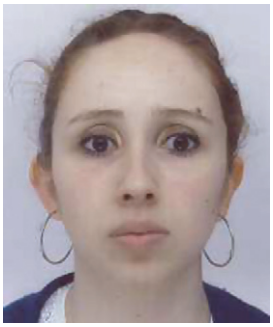
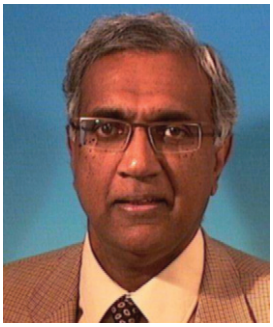
Biographical Sketches



Maréva Fèvre received her masters degree from the National Graduate School of Physics and Chemistry of Bordeaux in 2009. During her undergraduate education, she worked at Schering Plough (Holland) as an intern on solid state characterization of APIs. She performed her master's thesis in the team of Prof. J.-C. Leroux at the ETH Zürich working on liposomal formulations. She then started her PhD under the supervision of Prof. D. Taton at the Laboratoire de Chimie des Polymères Organiques (CNRS-Université de Bordeaux). Her work is mainly focused on organic catalytic systems for polymerization reactions.

Joan Vignolle was born in Biarritz (France) in 1979. He studied biology at the Université de Pau (France) and chemistry at the Université de Toulouse (France). He then started his PhD (2003–2006), working under the supervision of Prof. G. Bertrand and Dr. D. Bourissou both at the University of Toulouse and at the University of California, Riverside. After a 2-year postdoctoral stay at the University of California, Berkeley (Prof. T. D. Tilley), he joined the LCPO-CNRS-Université de Bordeaux 1 (France) as a research associate (Prof. D. Taton). He is presently working as a *Chargé de Recherches CNRS* on organocatalyzed polymerization reactions.



Dr. Yves Gnanou is a director of research for the 'Centre National de la Recherche Scientifique' and currently the vice-president for Education at Ecole Polytechnique. He has coauthored more than 160 publications in peer-reviewed journals, 40 book chapters, and 25 patents. He has published two textbooks coauthored by Prof. M. Fontanille and coedited a four-volume book along with Dr. L. Leibler and Prof. K. Matyjaszewski. His research interests include the design of complex polymeric architectures, the investigation of 'living' chain and step-growth polymerizations, the study of the self-assembling properties of copolymers in selective media leading to nanostructured morphologies, and the synthesis of polymers in dispersed media. Of late, he has developed an activity in the area of polysaccharide-based block copolymers, nanostructured assemblies based on polymeric ionic liquids, and the design of environmental-friendly processes through the study of organocatalyzed polymerizations.

Pr. Daniel Taton is 42 years old and received his PhD in polymer chemistry in 1994 at the University Pierre et Marie Curie (Paris VI). He has been appointed as an assistant professor at the University of Bordeaux in 1995. He develops his research activities at the Laboratoire de Chimie des Polymères Organiques (LCPO). From 2000 to 2002, he was temporarily attached to the research center of Rhodia, where he contributed to the research and development of synthetic specialty polymers.

He has been appointed as a full professor at the University of Bordeaux 1 in 2008. He has published 91 articles in peer-reviewed journals and 12 patents. His contributions are in the field of macromolecular engineering, through the development of original methodologies based on controlled radical or ionic polymerizations for the synthesis of 'complex' macromolecular architectures, including star-like polymers, dendrimer-like polymers, nanogels, and for the design of block copolymers featuring specific blocks (oligosaccharides, polypeptidic, or polymeric ionic liquids). More recently, he has launched a research program on the development of multitask organic catalysts based on *N*-heterocyclic carbenes for different chain-growth and step-growth polymerization reactions.

4.07 Anionic Ring-Opening Polymerization of Epoxides and Related Nucleophilic Polymerization Processes

A Deffieux and S Carlotti, Université Bordeaux, Pessac, France
A Barrère, Université Paris, Villetaneuse, France

4.07.1 Introduction

Among cyclic ethers, three-membered ring epoxides – with the exception of some four-membered ring oxetanes – are the only ones that can be polymerized by an anionic or a related nucleophilic polymerization mechanism. Larger cyclic ethers polymerize exclusively by a cationic or electrophilic ring-opening mechanism.

The conventional anionic ring-opening polymerization of epoxides can be described by the set of reactions shown in Scheme 1 for a monosubstituted epoxide.

Initiation is a bimolecular nucleophilic substitution that leads to the formation of an alkoxide species more or less ionized according to the nature of the associated counterion Mt provided by the initiating species AMt. The alkoxide must have a high enough nucleophilicity to attack a new epoxide molecule and propagate. Initiation and propagation of the ring-opening polymerization by nucleophilic species involving a preliminary complexation of the monomer can be considered as related processes.

The polymerizability of epoxides is determined by the negative change of Gibbs energy in the polymerization reaction, ΔG_p.

$$\Delta G_p = \Delta H_p - T\,\Delta S_p < 0$$

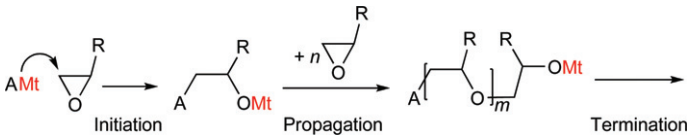
with ΔH_p and ΔS_p the enthalpy and entropy changes in the polymerization, respectively, and T the absolute temperature (in kelvin). For the small epoxide ring, the polymerizability is mainly under the control of the enthalpy term and the important ring strain. Repulsion between substituents is also an effective parameter.

Epoxide reactivity and polymerization kinetics are also influenced by electronic and steric factors associated with the ring substituents, as well as by the initiator nature, the solvent, and reaction conditions, which determine the characteristics of the active species of polymerization. The ability of epoxide monomers to be activated by complexation with an electrophile may also strongly facilitate nucleophilic ring opening.

In this chapter, the anionic and related nucleophilic polymerizations of epoxides are reviewed. The elementary mechanisms involved in the presence of different initiators and catalysts and the main synthetic strategies developed for the preparation of epoxide homopolymers and copolymers are described. In the second section, the anionic polymerization of epoxides involving alkali metal derivatives is described. The use of organic derivatives as counterions or catalysts is presented in the third section. The fourth section is devoted to epoxide-coordinated polymerization. Finally, in the last section, monomer-activated epoxide polymerization is described. The cationic polymerization of epoxides is described in another chapter.

4.07.2 Anionic Epoxide Polymerization Initiated by Alkali Metal Derivatives

Alkali metal derivatives, including hydrides, alkyls and aryls, hydroxides, alkoxides, and amides, have been used as initiators for the anionic polymerization of epoxides. Sodium, potassium, and to a lesser extent cesium are the most often used alkali metals.[1] Lithium derivatives are generally avoided since after the insertion of the first epoxide unit, they yield alkoxide species that are unable to properly propagate the polymerization, due to strong association. Anionic polymerization of



Scheme 1 Ring-opening polymerization of epoxides involving nucleophilic species AM.

epoxides can be conducted in aprotic solvents such as dioxane, tetrahydrofuran (THF), hexamethylphosphoramide (HMPA), and dimethyl sulfoxide (DMSO), or in the bulk monomer.

Alkali metal dispersions can also be used to initiate the polymerization of epoxides via electron transfer, but these systems show very poor efficiency. For an almost similar reason, initiation by alkali metal hydrides, which proceeds mostly at the surface of metal hydride particles, is slow and not controlled.[2,3] Addition of complexing agents such as crown ethers to alkali metal hydrides in THF was found to strongly accelerate epoxide polymerization.[4,5] However, the initiation mechanism seems unclear; instead of the expected hydrogen as the initiator fragment, most of the polyethers possess a hydroxyl head group. This suggests the reaction of residual water with the alkali metal hydride to form a metal hydroxide, which is the true initiating species.[5,6]

Detailed studies on the mechanisms of initiation and propagation of epoxide polymerization have been conducted using well-defined and stable initiators. Ethylene oxide (EO) was generally chosen as the reference monomer, owing to the living character of its polymerization,[7,8] whereas the anionic polymerization of most other epoxides, including propylene oxide (POx),[9] is subject to side reactions.

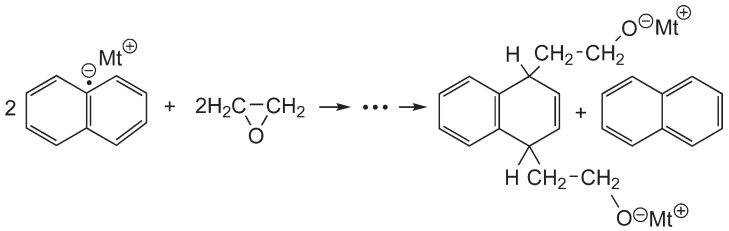
4.07.2.1 Ethylene Oxide

Anion radicals such as sodium naphthalene can react with monomers in two ways, via electron transfer to monomer or by direct addition of the monomer to the anion radical. The second addition mechanism applies to EO.[10] Indeed the reaction of EO with naphthalene results in the formation of a bifunctional initiator through addition of two monomer molecules on a same naphthalene molecule (Scheme 2).

The kinetics and mechanisms of initiation of EO polymerization by alkali metal salts of carbanions (polystyryl (PS^-), cumyl, and fluorenyl (F^-)[11,12]) and of nitranions (carbazyl (N^-) and dibenzocarbazyl (DBN^-) derivatives[13]) (Scheme 3) have been investigated in detail in ethereal solvents.

The intrinsic reactivity of ion pairs and free ions in EO addition was determined. In the case of weakly delocalized anions, illustrated by PS^- and N^-, free ions are more reactive than ion pairs. In contrast, for more delocalized anions (F^-, DBN^-), the reactivity order was opposite. For instance, the rate of cleavage of EO by alkali salts of 9-methylfluoren-9-yl[12] decreases from tight ion pairs to solvated ion pairs and free ions. It was suggested that electrophilic activation of the epoxide by the metallic counterion (step 1 of Scheme 4) makes an important positive contribution to the ring-opening reaction (step 2) which overcomes the energy required for ion-pair dissociation. For more localized N^- or PS^- anions, the interaction of the anion with the cation is stronger and the energy required for separating the charges lowers the reactivity of ion pairs compared to free ions.

Initiation of the EO polymerization by alkali metal alkoxides has also been investigated in detail since the structure of these derivatives is close to that of alkoxide propagating species. In aprotic solvents of low-to-medium polarity, such as ethers, alkali metal alkoxides show a strong tendency to aggregate and yield complex reaction kinetics. This is particularly significant for small metals such as lithium or sodium. If the reactions follow a monomer order of 1, the order in alkoxide propagating species varies according to the counterion and



Scheme 2 Initiation of EO polymerization by naphthalene alkali metal salts (for a detailed mechanism, see Reference 10).

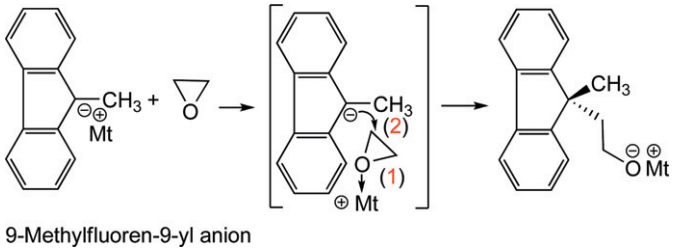
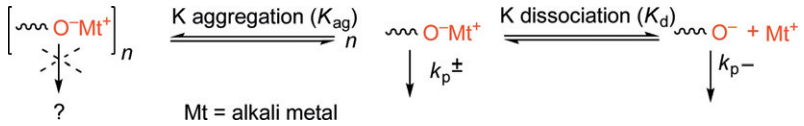


Scheme 4 Mechanism of initiation of EO polymerization by alkali salts of 9-Methylfluoren-9-yl.



Scheme 5 Aggregates, ion pairs, and free ions in EO polymerization and their ability to contribute to propagation.

the solvent. This can be related to the presence of various amounts of aggregates, ion pairs, and free ions of different intrinsic reactivity. The main types of poly(EO) ends and their corresponding propagation rate constants are indicated in Scheme 5. EO polymerization within alkoxide aggregates is extremely slow and negligible in most cases.

The kinetics of EO propagation reactions have been investigated in media of various polarities. In HMPA ($\varepsilon = 30$, 20 °C) using the sodium, potassium,[7] and cesium[14] salts of the monomethylether of diethylene glycol as initiators, the reaction rates were found to be first order in monomer, zeroth order with respect to sodium alkoxide, and between zero and unity with respect to potassium alkoxide. This is explained by association of alkoxide chain ends as shown by viscometric measurements performed on living and dead polymerization mixtures. With cesium as counterion, aggregates are absent and the propagation rate constant, k_p, is a linear function of 1/[propagating species]$^{1/2}$, indicating that propagation proceeds by ion pairs and free ions.[14] Although the latter are present in very low proportion (see K_D value in Table 1), they are of much higher reactivity.[15] At 40 °C, k_p^- is approximately 100 times higher than $k_p^{\pm}$ of Cs ion pairs.

Several papers report studies on the anionic polymerization of EO in DMSO. The use of potassium *tert*-butoxide (*t*-BuOK) as initiator was reported to yield living poly(EO)s with molar masses controlled by the ratio [monomer]/[initiator][14,16,17] although dimsyl ion resulting from transfer to the solvent (Scheme 6) has been considered by some authors as the principal polymerization initiator.[18,19]

In the case of K and Cs salts, EO polymerization in DMSO proceeds almost exclusively by free ions[17] in agreement with a higher dissociation constant in this solvent ($K_d = 9.4 \times 10^{-2}$ mol l^{-1} at 50 °C for Cs counterion), in line with the high permittivity of DMSO (dielectric constant; $\varepsilon = 48$, 20 °C). With Na counterion, both ion pairs and free ions contribute to the propagation.[17] The estimated $k_p^{\pm}$ and k_p^- values are given in Table 1. It is worth noting the much higher propagation rate constants are observed in HMPA (at 40 °C) compared to DMSO (at 50 °C); if we neglect the difference in reaction temperatures, which would increase the gap, the ratio of about 1800 is observed between k_p^- in the two solvents. This large difference may be accounted for by an important stabilization of the free anion via hydrogen interaction with DMSO.

The kinetics of polymerization of EO have also been investigated in pure ethereal solvents.[20,22,24] In THF ($\varepsilon = 7.6$, 25 °C) in the presence of sodium, potassium, and cesium naphthalene as initiators, a living polymerization takes place,[20,22] the rate of propagation increasing with the size of the counterion.[1] The kinetics are however complicated by strong association of alkoxide end groups manifesting itself by the low fractional kinetic order of the reactants, that is, 0.25 for Na alkoxide and 0.33 for K and Cs salts.[20] Dissociation constants are very low (see Table 1).

Table 1 Dissociation constant and ion-pair and free ion propagation rate constants for EO polymerization in different solvents

Solvent	*T (°C)*	*Counterion*	K_D *(mol l^{-1})*	$k_p^{\pm}$ *(l mol^{-1} s^{-1})*	k_p^- *(l mol^{-1} s^{-1})*	*Reference*
THF	20	K	1.8×10^{-10}	0.05	-	20
	20	K + 222	3.0×10^{-7}	0.03	1.7	21

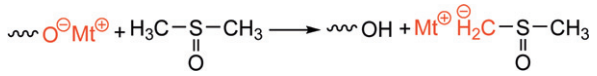
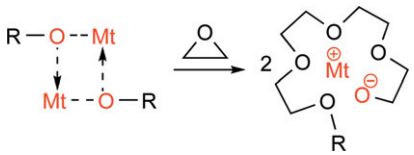
	50	K	4.7×10^{-2}			17
	50	Cs	9.4×10^{-2}			17



Scheme 6 Formation of dimsyl ion through transfer to DMSO.

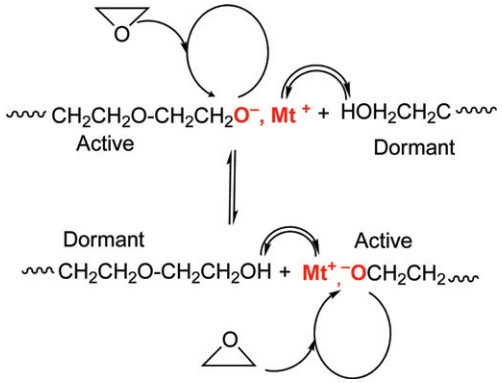


Scheme 7 Solvation of the alkoxide propagating species by the polyether growing chain.

The presence of an acceleration period at the beginning of the polymerization in ether solvents was interpreted as the increasing solvation by the polyether growing chain of alkoxide aggregates, until the chain reaches up to 4–6 EO units (Scheme 7).[22]

Addition of complexing agents of alkali metal cations, such as crown ethers or cryptands,[13,21,23] was shown to drastically increase the EO propagation rate in ether solvents. They both reduce the aggregation of alkoxide polymer ends and increase the proportion of free ions. For example, at 20 °C in THF, the dissociation constant of poly(EO)$^-$K$^+$ (Table 1) is 1700 times higher when K$^+$ is complexed by cryptand 222 (see Scheme 8). In this system, the reactivity of free ions is about 60 times higher than that of cryptated ion pairs. Surprisingly, the reactivity of cryptated ion pairs was found to be very close to or even lower than that of the corresponding noncomplexed ion pairs, though the charges are more separated.[21] A similar tendency was reported for cryptated Cs.[23] This has been explained by partial insertion of the oxygen anion in the cavity of the complexing agent.[1,25]

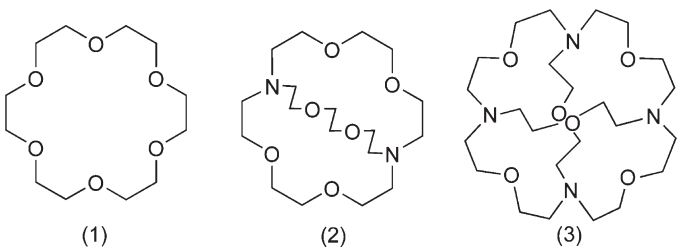
Early studies of EO polymerization in ether solvents dealt with initiating systems involving alkoxides, RO$^-$Mt$^+$, associated with their parent alcohol ROH to improve their solubility and limit the aggregation phenomenon.[15] Indeed, these systems are composed of two types of chains: growing chains with an alkoxide end and dormant chains possessing a -CH_2CH_2OH terminus. Since alcohols act as efficient chain transfer agents, true living poly(EO) is not formed in these conditions. However, the reversibility of the transfer process resulting from rapid exchanges between the two chain ends ensured the growth of both chains allowing control of the molar mass of poly(EO) ($M_n = [EO]/([RO^-Mt^+] + [ROH])$). The propagation and reversible transfer reactions are illustrated in Scheme 9.



Scheme 9 Exchange reactions between active and dormant species in ROMt/ROH polymerization systems.

The presence of alcohol in the medium leads to a reduction of the apparent polymerization rate; the greater the proportion of alcohol introduced into the reaction medium, the lower the EO polymerization rate.[26,27] It was proposed that the hydroxy-terminated chains contribute to decrease the polymerization rate by hydrogen-bonding interactions with alkoxide ends. The combination of alkoxide with the parent hydroxy compound has been used to initiate EO polymerization in various media (THF, DMSO). This was used for the preparation of multibranched poly(EO). Typically, a polyhydroxy compound to be used as multifunctional initiator is partially deprotonated by the addition of 0.2–0.8 molar equivalent of an alkali metal derivative.[28,29] This limits aggregation of alkoxide species and preserves solubility, thus allowing a better control of the initiation and propagation of EO polymerization, but to the detriment of reaction kinetics.

Poly(EO), also often referred to as poly(ethylene glycol) (PEG), is a reference biocompatible polymer used in the biomedical field[30] as a result of its unique properties, namely, its chemical stability, solubility in both organic and aqueous media, nontoxicity, low immunogenicity, and low antigenicity.[31] PEG derivatives have been widely used as conjugates (PEGylation reaction) to increase the circulation half-life of biologically active molecules (e.g., enzymes, peptides, proteins), to improve the solubility of various anticancer agents (e.g., taxol or camptothecin), to impart enhanced permeability and retention, and to increase passive targeting of anticancer drugs.[32–35] PEG is also used as an efficient spacer in delivery systems such as PEG-grafted liposomes and nanoparticles. Several PEG-conjugated proteins are already available as clinical therapeutics.[36] Applications of PEO often require α,ω-heterodifunctional PEO-based oligomers possessing



Scheme 8 Crown ether 18C6 (1) and cryptands 222 (2), and sphere (3) used to complex alkali metal cations in EO polymerization.

tailored reactive end functions to react with a variety of ligands.[28,36–39] Their preparation can be achieved readily owing to the living character of anionic EO polymerization.

In addition to these biomedical applications, PEG also serves as an inert support in liquid-phase organic synthesis[40] or as a polyelectrolyte in the presence of salts.[41–45]

4.07.2.2 Monosubstituted Epoxides

For monosubstituted epoxides such as POx, the monomer ring opening can proceed in two ways: attack on the methylene (1) or methine (2) carbons, leading respectively to the break of the CH_2–O or R–CH–O bond (Scheme 10). Indeed, in contrast to cationic polymerization, the nucleophilic attack of the alkoxide proceeds selectively on the methylene carbon (1). The secondary alkoxide generated by ring opening attacks a new monomer following the same mechanism. As a result of the high selectivity in the ring opening, polyethers with only head-to-tail enchainment are obtained.

The ring-opening mechanism is of the S_N2 type with inversion of the configuration at the methylene carbon atom of the epoxide ring where it is cleaved. This was shown using deuterated POx (Scheme 11).

Since racemic (*RS*)-POx monomer mixtures are most generally utilized, the resulting polymers are atactic and amorphous. Proportions of isotactic, heterotactic, and syndiotactic triads can be determined through resolution of the stereosensitive asymmetric carbon signal by ^{13}C NMR.[46] However, anionic polymerization of (*R*)- or (*S*)-epoxides yields the corresponding isotactic polyethers. This is the case for polymerization of the (–)-(*S*)-POx by potassium hydroxide, which yields a crystalline poly(POx).[47]

In the presence of K^+ as counterion (*t*-BuOK as initiator, 40 °C) and on the basis of overall polymerization rates, the reactivity of racemic POx in HMPA is about one-fourth that of EO.[48]

In contrast to the living character of the polymerization of EO, the anionic polymerization of substituted epoxides like POx[16,49] initiated by alkali metal derivatives is subject to transfer reactions to the monomer. Indeed, the highly basic alkoxide propagating species can pull out a proton of the monomer substituent, leading to chain termination and the formation of a new growing chain bearing a terminal double bond, as indicated in Scheme 12 in the case of POx.

Bulk polymerization of POx at 90–150 °C yields poly(POx) with molar masses limited to about 6000 g mol^{-1}, which corresponds to the ratio of the apparent rate constant and the rate constant of chain transfer to monomer (k_p/k_{trM}) of 100.[49] In HMPA at 40 °C, this ratio is equal to 75. Indeed, several factors influence the extent of this chain transfer reaction:[50] temperature, initiator, and nature of the counterion. Chain transfer to monomer decreases in the order $Na^+ > K^+ > Cs^+$, in agreement with interactions between the metal cation and the oxygen of the monomer.

The reactivity of other monosubstituted epoxides depends on both electronic and steric factors associated with the substituent attached to the epoxide ring.[6] For instance, the reactivity of 2,2-dimethyloxirane (DMO) is 10 times lower than that of POx, whereas glycidyl ethers such as *tert*-butyl glycidyl ether (*t*-BuGE) are more readily polymerized than POx[48] (see also Table 2). The complexation of the counterion by crown ethers significantly increases the reactivity. This can be explained both by a reduction of aggregates and by a larger charge separation of ion pairs accompanied by an increase in ion dissociation constant.

In relation to the different acidic character of the hydrogens on the α-carbon of the monomer, the nature of the epoxide substituent plays an important role in the chain transfer process.[3,27,51] For instance, the anionic polymerization of long-chain alkylene oxides employing potassium and cesium alkoxides as initiators is much less subject to chain transfer processes than that of POx. This is shown by the higher poly(2-butyloxirane) molar masses obtained at temperatures ranging between 20 and 80 °C (see Table 3).[52]

Owing to the increase in reactivity in the presence of crown ethers, the polymerization temperature of 2-butyloxirane (BO) and of higher 2-alkyloxiranes could be reduced below 0 °C. This allowed the elimination of side reactions almost completely (Table 4). However, very long reaction times were required (4–8 days). The best results were obtained with potassium alkoxides and 18-crown-6 in toluene at –10 to –23 °C (Table 4). Poly(2-ethyloxirane), poly(2-butyloxirane), and poly(2-hexyloxirane) homopolymers with molar masses of up to 50 000–100 000 g mol^{-1}, close to theoretical values, and $M_w/M_n < 1.1$ were synthesized in this way.

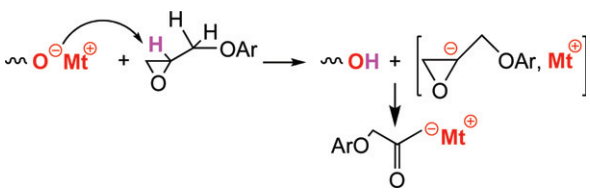
Another mechanism of chain transfer to the monomer has been highlighted by Stolarzewicz[27] in the case of phenyl glycidyl ethers (PGEs). As shown in Scheme 13, it involves abstraction of a proton from the methine carbon of the ring and the formation of new carbonylated initiating species. The author argues that this reaction could also occur during the polymerization of propylene and styrene oxides.

The world market for poly(alkylene oxide)s, which is mainly based on poly(POx), is estimated to be over 4 million tons since 2007.[53] Poly(POx) is mainly produced as a telechelic oligomer for polyurethane industry and as a di- and triblock copolymer



Scheme 13 Second type of chain transfer to the monomer in glycidyl ether polymerizations.[27]

with EO for surfactant applications. Poly(alkylene oxide)s are usually produced worldwide, according to the same anionic process using sodium, potassium, or cesium hydroxide in the presence of glycerol or other triol or tetrol in a discontinuous batch process. The use of multihydroxy compounds as initiators allows compensation of the loss of OH functionality of the chain due to chain transfer to monomer. Commonly, a small amount of EO is added at the end of the reaction to convert the secondary hydroxyl end group to primary hydroxyl end group, which has a higher reactivity in urethane formation.[54] Cesium hydroxide, which allows faster polymerization and reduces the amount of mono-ol resulting from transfer by half, is also used. Recently, a competitive process based on multimetal cyanide (MMC) catalyst,[55] which yields poly(POx) with almost no chain unsaturation, has also been used industrially.

4.07.3 Initiation by Organic Bases as Initiators

Complexation of alkali metal counterions was shown to significantly increase the reactivity of propagating species in anionic polymerization. Besides the use of crown ethers or cryptands, the use of large organic molecules as metal-complexing agents or directly as organic counterions has been studied.

4.07.3.1 Organic Bases as Counterions

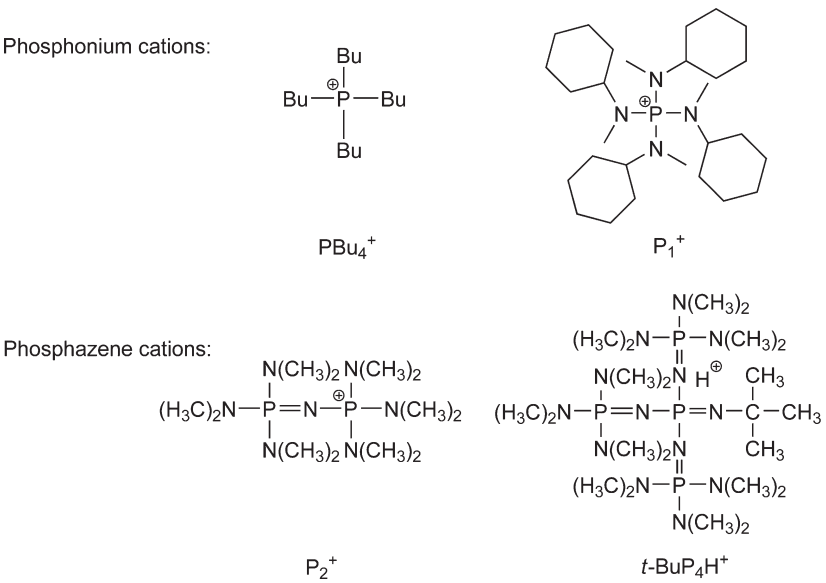
The use of tetraalkyl ammonium as counterions was explored but remains limited due to the low thermal stability of the compound. As an example, didodecyldimethylammonium hydroxide was employed by Maitre *et al.*[56] to polymerize PGE. The polymerization was performed in bulk at 60 °C and complete conversions were obtained for short polymerization times, but molar masses of poly(PGE) did not exceed 3000 g mol^{-1}. Transposition of this system to miniemulsion leads to several oligomeric populations, with the highest polymerization degree of 8.[56]

Phosphonium salts and phosphazene bases developed by Schwesinger and Schlemper[57] and Schwesinger *et al.*[58] (**Scheme 14**) are of broader interest for epoxide polymerization. These soft and highly delocalized organic compounds reduce aggregation phenomena and favor ionic dissociation by increasing the interdistance between charges in ion pairs.

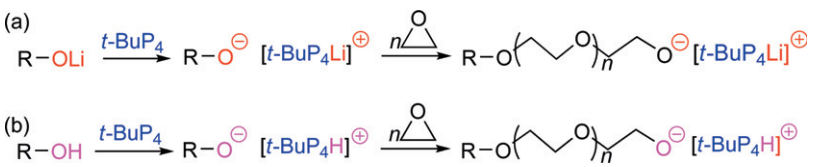
Phosphonium and phosphazene bases have been successfully used as counterions for polymerizing siloxanes,[59] lactones, and (meth)acrylates.[60–62] Their use in the synthesis of poly(EO)[63,64] and poly(POx)s[53,65,66] and in the preparation of linear and branched copolymers with polyether blocks has been reported.

The polyaminophosphazene base *t*-BuP$_4$ was used in combination with alkyllithium as initiator for the anionic polymerization of EO[67] (**Scheme 15(a)**). The space inside the molecule is sufficient to host the compact lithium cation and the base works as a cryptand for Li$^+$ ions with the polar amino and imino groups located inside the globular molecule and the outer shell formed by alkyl substituents. The equilibrium between complexed lithium alkoxide ion pairs and reactive free anions is thus shifted allowing polymerization.

One major interest in these organic bases is the activation of living polymer chains with lithium counterions toward epoxide polymerization. This is of particular interest for the synthesis of poly(EO)-containing block copolymers by sequential anionic



Scheme 14 Phosphonium and phosphazene cations used as counterions for the anionic polymerization of oxiranes.



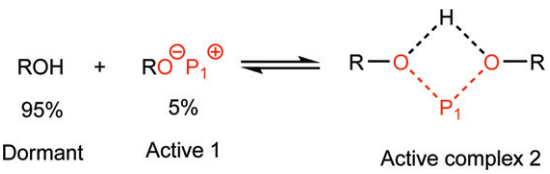
Scheme 15 Initiation of EO polymerization involving activation of lithium alkoxide (a) and alcohol (b) by phosphazene *t*-BuP$_4$.

polymerization. Using *t*-BuP_4 as an additive to living polymers prepared using organolithium initiators has the advantage that the block poly(EO) can be prepared without an exchange of the cation. This strategy was successfully applied to the synthesis of polystyrene-*block*-poly(EO), although the presence of an induction period resulting from the slow disaggregation of the lithium alkoxide ends complicates the EO polymerization.[68]

Additionally, Esswein *et al.*[63] have directly used the strong poly(aminophosphazene) base *t*-BuP_4 in the presence of mono- and plurifunctional alcohols without any metallic cation to generate the alkoxide of the protonated base and initiate the anionic polymerization of EO (**Scheme 15(b)**). Using methanol as initial alcohol, poly(EO) oligomers, with M_n up to 6000 g mol^{-1} and low polydispersity ($M_w/M_n \approx 1.1$), were obtained in THF or toluene after 48 h reaction at 80 °C. Graft copolymers of poly[ethylene-*graft*-(vinyl alcohol)] (PEVA) with poly(EO) were synthesized in high yields in this way.[64]

Anionic ring-opening polymerization of POx initiated by partially deprotonated dipropyleneglycol (DPG) in the presence of the phosphonium cation tetrakis[cyclohexyl(methyl) amino]phosphonium as counterion (P_1^+; **Scheme 14**) has been reported by Rexin and Mülhaupt.[65,66] An alcohol/phosphonium alkoxide mixture (95/5) was utilized to control reactivity, making use of a fast proton exchange reaction between dormant hydroxy compounds and active phosphonium alkoxide ends (**Scheme 16**).

The reaction was performed at 100 °C in pure POx under reflux. Polymerization rates and hydroxyl functionalities of poly(POx)s prepared in the presence of K^+ and other phosphonium and phosphazene base counterions were compared (**Table 5**).[66] Polymerization rates of POx vary in the following order: $PBu_4^+ < K^+ < P_1^+ < t\text{-}Bu_4PH^+ < P_2^+$. These differences were explained by a more or less pronounced delocalization of the charge inside the counterion. Indeed, for a similar steric



Scheme 16 Equilibrium between active and dormant species.

tris(Phosphazenyl) phosphine oxide (PZO)

Scheme 17 Tris(phosphazenyl) phosphine oxide(PZO) used in presence of glycerol for POx polymerization.

hindrance, P_1^+ involves a 6 times faster polymerization than PBu_4^+, whose charge is not delocalized. Similarly, phosphazenes, whose delocalization is more pronounced than the delocalization of P_1^+, lead to a better separation of the charge and consequently to a faster polymerization.

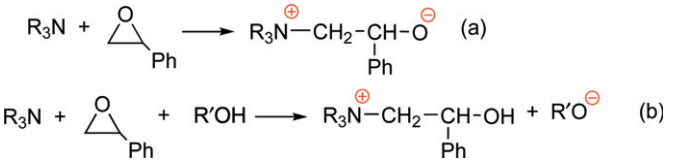
Polyether polyols were produced also at varied temperatures in the presence of DPG and bulky iminophosphonium counterions $R_4P_1^+$, whose substituents, R, were varied as propyl, octyl, and cyclohexyl (denoted as P_1^+ in **Scheme 14**).[66]

All polyols show unimodal and narrow molar mass distributions with values for M_w/M_n of about 1.20 without any subdistribution. The varied substituents, propyl, octyl, and cyclohexyl, have no influence on the propagation rate or on the total degree of unsaturation. The equilibrium between active alkoxide and dormant species, depicted in **Scheme 16**, permits the control of molar masses and the maintenance of a low poly (POx) dispersity. Indeed, in spite of faster polymerization, a better control of POx polymerization is not achieved compared to K^+; the increase of polymerization rate is accompanied by an increase in the proportion of carbon–carbon double bonds, and only poly(POx) oligomers can be synthesized.

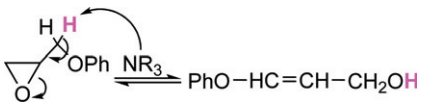
In a recent paper, Nobori *et al.*[53] claimed an increase of the POx polymerization rate (450 times) and a reduction of the transfer to monomer corresponding to the reduction of mono-ols by a factor of 5 and the formation of poly(POx) up to 20 000 g mol^{-1} using glycerol in the presence of *t*-BuP_4 or tris (phosphazenyl) phosphine oxide (PZO) (**Scheme 17**).

4.07.3.2 Organic Bases as Nucleophilic Initiators

Tertiary amines like benzyldimethylamine, pyridine, and imidazole have been widely used as a base to initiate the anionic polymerization of PGE and its derivatives as well as for the synthesis of epoxy resins of diglycidyl ether of bisphenol A (DGEBA). Even if initiation occurs with amine alone, the introduction of an alcohol is a common procedure to suppress the observed induction period and increase the polymerization rate.[69] Two initiation mechanisms have been proposed[70,71] (**Scheme 18**): (1) direct nucleophilic attack of the amine onto the cyclic monomer to yield the zwitterion (a); and (2) formation of alkoxide (b) via proton transfer in the presence of alcohol. Fast exchange between dormant alcohol and active alkoxide allows chain growth from both initial amine (a) and alcohol (b).[72] Poly(PGE) oligomers whose degree of polymerization does not exceed 5 are obtained. The presence of terminal double bonds indicates significant transfer to the monomer via



Scheme 18 Initiation steps in the PGE polymerization initiated by tertiary amines in the presence of an alcohol.



Scheme 19 Formation of allylic alcohol from PGE in the presence of tertiary amine.

hydride abstraction. This may involve alkoxide chain ends or direct proton abstraction by the amine initiator (Scheme 19).[70]

4-(Dimethylamino)pyridine can initiate readily the anionic polymerization of PGE.[71] This is explained by its conjugated structure in which the tertiary amine has a positive charge while the pyridine nitrogen brings a negative charge which can attack the epoxide monomer (Scheme 20). PGE conversions are complete in 1 h at 80 °C or in 10 min at 110 °C. However, only low-molar-mass poly(PGE) polymers ($< 1000\,g\,mol^{-1}$) were obtained due to an intramolecular transfer reaction involving attack of the pyridine ring by the terminal alkoxide (Scheme 20).

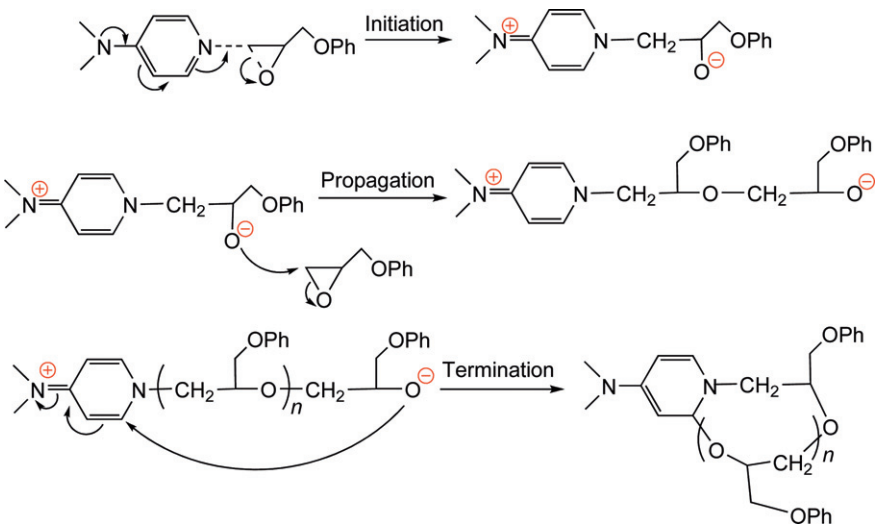
Recently, N-heterocyclic carbenes (NHCs), such as 1,3-diisopropylimidazol-2-ide (**1**), were found to initiate the ring-opening polymerization of EO at 50 °C in DMSO.[73] In the presence of **1**, poly(EO)s of narrow dispersity and molar masses perfectly matching the [monomer]/[**1**] ratio are obtained, attesting to the controlled/living character of such carbene-initiated EO polymerizations. However, long reaction times are needed. It is argued that NHC adds to EO via nucleophilic attack onto one methylene group of EO to form a zwitterionic species, namely 1,3-diisopropylimidazolidin-2-ylium alkoxide, which further propagates by a zwitterionic ring-opening polymerization (ZROP) mechanism (Scheme 21). In this process, the attached imidazolidinylium moiety at the chain head also plays the role of the counter cation.

End-functionalized poly(EO) chains were generated by adding at the end of the polymerization a functional terminating agent Nu-E, in which Nu and E represent a nucleophilic and electrophilic moiety respectively (Scheme 21). Nu was found to substitute the imidazolium head group (see above), whereas E terminates the chain. α,ω-Dihydroxy, α-benzyl-ω-hydroxy, and α-azido-ω-hydroxy difunctionalized poly(EO)s were obtained in this way.

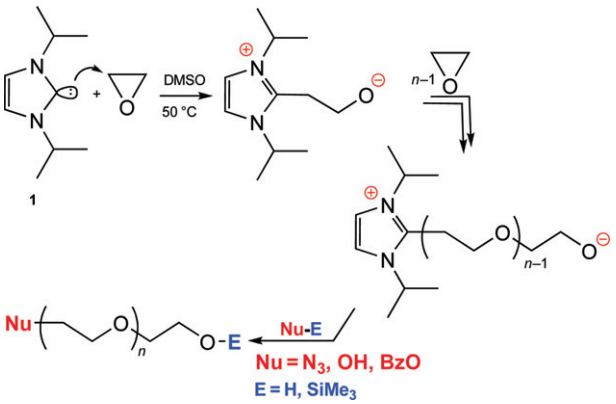
Controlled EO polymerization was found to proceed also with catalytic amounts of the NHC in the presence of Nu-E as polymerization additives in DMSO at 50 °C, typically in molar proportions [NHC]/[Nu-E]/[EO] = 0.1/1/100.[74] In this case, the poly(EO) molar masses match the [EO]/[Nu-E] ratio. Characterization of poly(EO)s confirmed the quantitative introduction of the nucleophilic moiety (Nu) and of its electrophilic component (E = H or $SiMe_3$) in the α- and ω-positions, attesting that Nu-E controls the poly(EO) molar masses and functionality.

Two possible mechanisms are considered (Scheme 22): (a) nucleophilic attack of the NHC catalyst onto EO and the formation of a zwitterionic intermediate; or (b) activation of the E moiety by the NHC followed by EO polymerization initiated by the Nu moiety. In the second case, the NHC behaves similarly to phosphazene bases. Reversible exchanges with Nu-E molecules involving the formation of active and dormant chains then yield α-Nu-ω-E poly(EO)s.

Access to α,ω-difunctionalized poly(POx) (PPO) oligomers based on a metal-free and solvent-free polymerization using an NHC serving as either direct initiator or organocatalyst has also been recently described by the same group.[75] Dihydroxytelechelic poly(POx) oligomers were synthesized by quenching the NHC-initiated ring-opening polymerization of POx with water,



Scheme 20 Polymerization of PGE initiated by 4-(dimethylamino)pyridine.



Scheme 21 Proposed mechanism of ZROP of EO initiated by 1,3-diisopropyl-2,3-dihydroimidazol-2-ide.

whereas α-benzyl-ω-hydroxy and α-propargyl-ω-hydroxy difunctionalized PPOs were prepared via an NHC-catalyzed ring-opening polymerization, using $PhCH_2OH$, $PhCH_2OSiMe_3$, and $HC{\equiv}CCH_2OH$ as functionalizing agents. Characterizations of all α,ω-difunctionalized poly(POx)s attest to the quantitative introduction of functional groups at both α- and ω-positions and the formation of narrow-molar-mass oligomers.

4.07.4 Coordination Anionic Polymerization

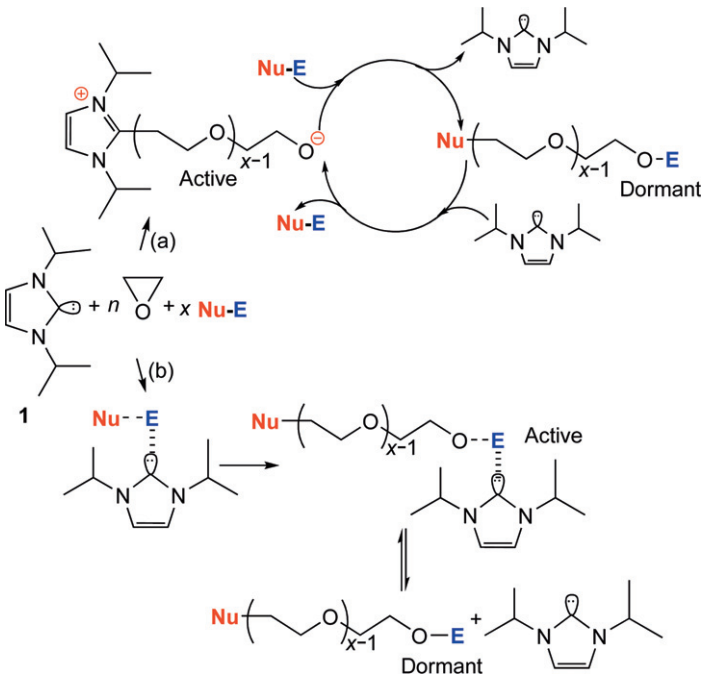
Coordination organometallic polymerization catalysis can be considered as borderline to anionic polymerization processes since epoxide ring opening involves a nucleophilic-like mechanism, which is assisted by monomer coordination on a metal atom of the catalytic system. In this preliminary coordination step ascribed to the Lewis acidity of the metal, the epoxide ring is activated for a nucleophilic attack, while the catalyst metal–X bond is weakened, increasing the nucleophilic character of the X moiety.

These systems can yield high-molar-mass polyethers, which could not be obtained using conventional anionic polymerization except for poly(EO). The possibility to synthesize stereoregular and/or optically active polyethers with crystalline properties is also an important particularity of these coordination processes.

4.07.4.1 Monometallic Coordinating Catalytic Systems

The first coordination epoxide polymerization catalytic system was reported by Pruitt and Baggett[76] in 1955. It was based on iron trichloride. Since that time, metal-based catalysts have been widely exploited for epoxide polymerization. The most studied systems are those based on zinc or aluminum derivatives. A first group consists of diethylzinc or trialkylaluminum associated to a 'cocatalyst', which is generally water or an organic compound (alcohol, amine, and other compounds) that reacts with the alkyl metal to form *in situ* new metal derivatives as the true catalytic system exploited (see **Table 6**). For a detailed review on the coordination polymerization of epoxides, see Kuran.[77]

Trialkylaluminum and dialkylzinc when used alone yield very low epoxide conversions with long polymerization times.[90] Addition of water[91,92] results in the formation of active metal oxides containing Mt–O–Mt bonds. Indeed these catalysts yield a mixture of several polymer populations that are produced according to different mechanisms.[93] For example, POx polymerization in the presence of $AlEt_3/H_2O$ yields three polymer fractions: (1) the first fraction constituted by isotactic high-



Scheme 22 Proposed mechanism for epoxide polymerization in the presence of NHC and additives constituted of nucleophilic and electrophilic parts.

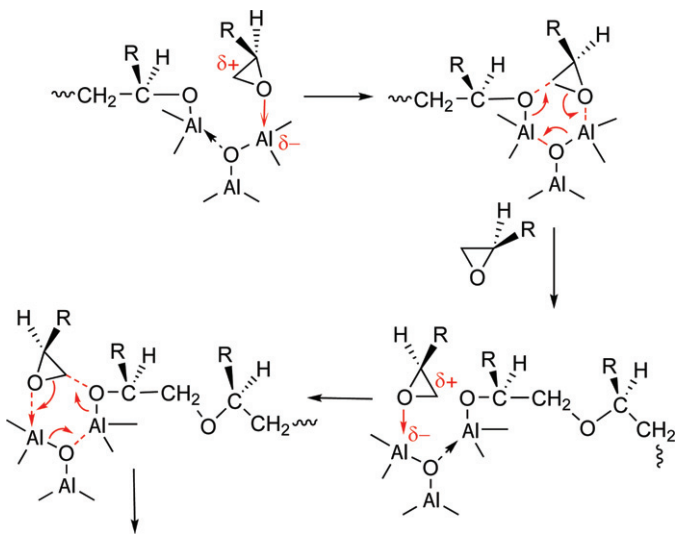
molar-mass chains arising from a living-like coordination polymerization mechanism;[92] (2) the second fraction corresponding to low-molar-mass amorphous chains; and (3) the last fraction composed mainly of tetramers. The last two populations are attributed to a cationic polymerization process associated with the presence of highly acidic metal sites as indicated by the presence of irregular head-to-head and tail-to-tail enchainments and the presence of oligocyclic structures.

Isotacticity of poly(POx) chains corresponding to the crystalline fraction is explained by steric constraints and orientation of the complexed monomer, which induces stereoselectivity in the nucleophilic attack by the chain end. It was demonstrated that monomer insertion proceeds by attack at the carbon atom of the epoxide ring where it is cleaved with inversion of the carbon configuration. This necessitates an attack of the complexed monomer by the nucleophile from the back, which requires the participation of two adjacent aluminum atoms and chain transfer from one aluminum atom to the other one at each monomer addition. The coordination polymerization mechanism proposed by Vandenberg[94] for the trialkylaluminum/water system is shown in **Scheme 23**.

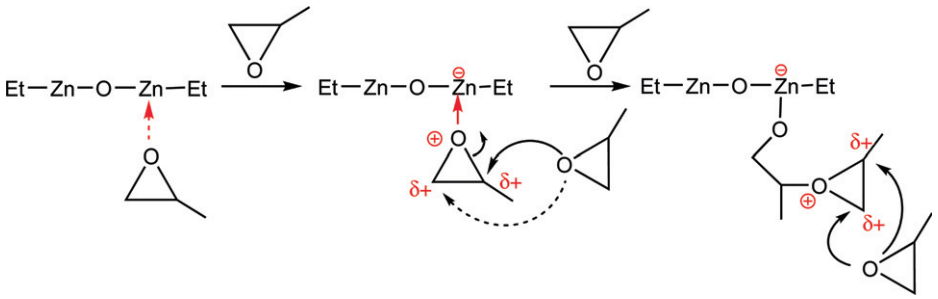
The complexation results in partial electron transfer from the epoxide to the metal, rendering the methylene carbon atom of the ring more prone to nucleophilic attack. Coordination also induces a concerted electron transfer between the two adjacent aluminum atoms, which weakens the polymer–aluminum bond, increasing reactivity of the corresponding alkoxide moieties toward the electrophilic carbon of the neighboring epoxide.

The cationic polymerization mechanism that takes place aside from the coordinative process is illustrated in **Scheme 24** in the case of the $ZnEt_2/H_2O$ catalytic system;[84] coordination of an epoxide molecule to a highly acidic metal atom leads to the formation of 'oxonium'-like species making the two-ring carbon atoms strongly electrophilic, thus allowing nonregiospecific ring opening by attack of another epoxide molecule.

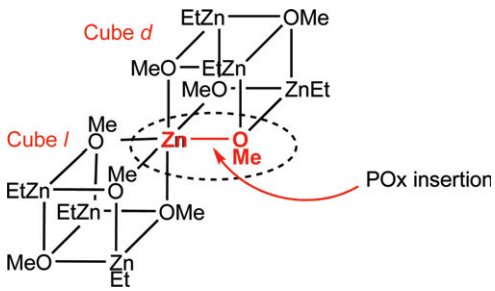
Additives such as pyridine, tertiary amines, or acetylacetone have been used to modulate the metal acidity and improve the selectivity toward high-molar-mass polymers. As an example, the addition of acetylacetone as chelating agent to AlR_3/H_2O or ZnR_2/H_2O systems permits, by limiting the cationic process, to



Scheme 23 Mechanism proposed for epoxide activation and polymerization by AlR_3/H_2O.[94]



Scheme 24 Mechanism proposed for cationic polymerization of epoxide by the ZnR_2/H_2O system. Electron transfer to the epoxide rendering the two-ring carbon atoms highly electrophilic is illustrated by δ+ charges.



Scheme 25 Structure of $[Zn(OMe)_2{\cdot}(EtZnOMe)_6]$.

increase the proportion of crystalline polymer.[94] Also by decreasing the amount of the most acid sites, addition of pyridine or tertiary amines leads to the same effect.[81,95] As a consequence, the crystalline polymer fraction is higher but the overall polymerization rate is decreased.

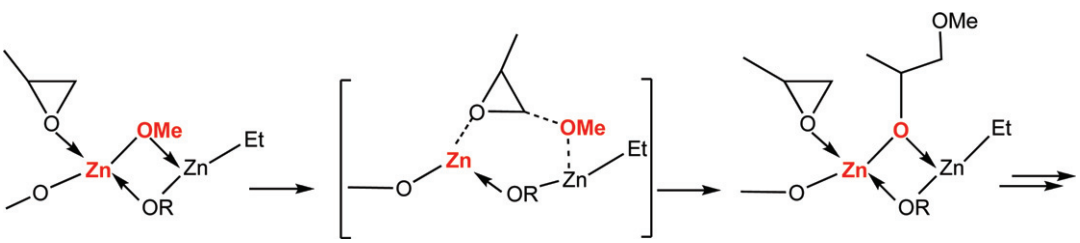
Tsuruta *et al.* have investigated diethylzinc/alcohol systems for the polymerization of epoxides. Several well-defined active complexes such as $[Zn(OMe)_2 \cdot (EtZnOMe)_6]$[96–98] (Scheme 25) and $[Zn(OCH(Me)CH_2OMe)_2 \cdot (EtZn(OCH(Me)CH_2OMe))_2]$ have been identified as initiating species[99] for the coordinated POx polymerization.

Initiation takes place at the central zinc–internal methanolate bond,[100,101] represented in red in Scheme 25. Indeed the diethylzinc/alcohol systems may lead to the formation of two polymer fractions: one essentially isotactic with high molar masses and a second one atactic with lower molar masses. Both contain 95% of head-to-tail enchainments, which suggests that the amorphous fraction is not formed by cationic polymerization. The high molar masses, typically 10^5 g mol^{-1}, result from a slow initiation and only 10^{-4}–10^{-3} mol of polymer is obtained per 1 mol of initiator. On the basis of a continuous increase in molar mass with conversion, the polymerization of POx was qualified as living-like by Ishimori *et al.*[97] and Tsuruta.[100]

In contrast to the above-reported coordinated polymerization mechanisms, it was proposed that oxirane molecules coordinate to the same zinc atom prior to undergoing a nucleophilic attack on their less substituted carbon (Scheme 26).[102,103]

4.07.4.1.1 Stereoselective and stereoelective coordination polymerizations: tacticity control

Complexes such as $[Zn(OMe)_2 \cdot (EtZnOMe)_6]$, shown in Scheme 25, possess a centrosymmetric structure consisting of two enantiomorphic cubes whose common vertex is a zinc atom.[102] According to Tsuruta,[104] these cubes constitute enantioselective *d* and *l* sites, which in the presence of racemic monomer mixtures, such as POx, favor the incorporation of either the (*R*) or the (*S*) enantiomer and yield isotactic and crystalline chains constituted of either (*R*) or (*S*) monomer units. For instance, when the nucleophilic attack is achieved by a methanolate of the *d* cube, the insertion of *l* enantiomers will be favored. Similarly when methanolate of *l* cubes are involved the formation of *d* enantiomers is privileged.[104] Since in this complex the two enantioselective sites are in equal proportion, the two enantiomeric forms of the monomer will be incorporated selectively into distinct isotactic chains. This corresponds to a stereoselective polymerization. This interpretation was confirmed later by Furukawa *et al.*[80] and Kuran and Listos,[103] who used a chiral amino acid and a chiral alcohol, respectively, for the alcoholysis of diethylzinc. In this case, the enantioselective sites are not equivalent and one of the two enantiomers of the monomer is preferentially polymerized. This yields an optically active polymer while the residual monomer is enriched in the opposite enantiomer, corresponding to the stereoelective polymerization.



Scheme 26 Mechanism proposed for POx polymerization initiated by the $ZnEt_2$–MeOH system. Other interactions between Zn and oxygen atoms, not directly involved in POx insertion, are omitted.

4.07.4.2 Porphyrin Salts

Epoxide polymerization catalysts of quite different characteristics are those constituted by the metalloporphyrins of aluminum and zinc, such as (5,10,15,20-tetraphenylporphinato)aluminum chloride ((TPP)AlCl), (5,10,15,20-tetraphenylporphinato) aluminum methoxide ((TPP)AlOMe) (see Scheme 27), and (5,10,15,20-tetraphenyl-21-methylporphinato)zinc methoxide ((MTPP)ZnOMe).[105–109]

The covalent nature of the aluminum–X bond suggests that polymerization occurs following a coordination process. This hypothesis is reinforced by the exclusive presence of regular head-to-tail enchainments[109] and tacticity which is dependent on porphyrin structure.[110] Indeed the substituents in ortho positions of peripheral phenyl groups affect the reactivity of the Al–X bond; polar groups lead to a very high initiation activity, whereas nonpolar substituents result in an opposite effect.

When compared to the abovementioned highly associated multinuclear coordination catalysts of very low initiation efficiency, metalloporphyrins with mononuclear Mt–X species have been reported to be excellent catalysts for the living polymerization of epoxides.[105,111,112] The molar mass distribution of the polyethers obtained is narrow, and their molar mass can be controlled by changing the epoxide-to-catalyst mole ratio. As illustrated in Figure 1, poly(POx) chains with molar masses up to 70 000 g mol^{-1}, in good agreement with theoretical ones, have been synthesized, with a unimodal distribution and dispersity lower than or equal to 1.5.[109] Absence of chain transfer reactions allowed the synthesis of a series of block copolymers, including POx-*b*-EO, BO-*b*-POx, POx-*b*-ECH (ECH, epichlorohydrin), lactone-*b*-POx, and lactone-*b*-EO.[113,114]

Aluminum porphyrins are also effective polymerization catalysts for lactones[114,115] and acrylates.[116] Porphyrins based on manganese or zinc, for example, present similar characteristics.[117]

Although EO polymerization can be achieved quite rapidly (reaction half-time is about 30 min at room temperature for [EO]/[(TPP)AlCl] = 400 in dichloromethane), other epoxides show a lower reactivity. In similar conditions, it requires several hours for POx and 1,2-epoxybutane (BOx),[105] whereas for styrene oxide or 1,2-epoxy-2-methylpropane conversions do not exceed 15% after 8 days of reaction (Table 7).[109]

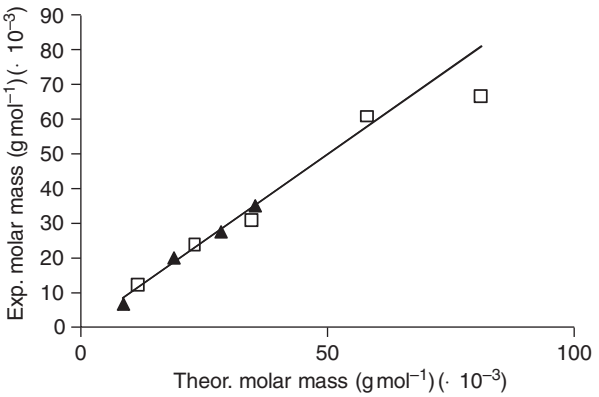


Figure 1 Evolution of experimental molar masses as a function of theoretical ones in the bulk polymerization of POx (□) and of EO (▲) initiated by (TPP)AlCl[109] at 20 °C in CH_2Cl_2.[105]

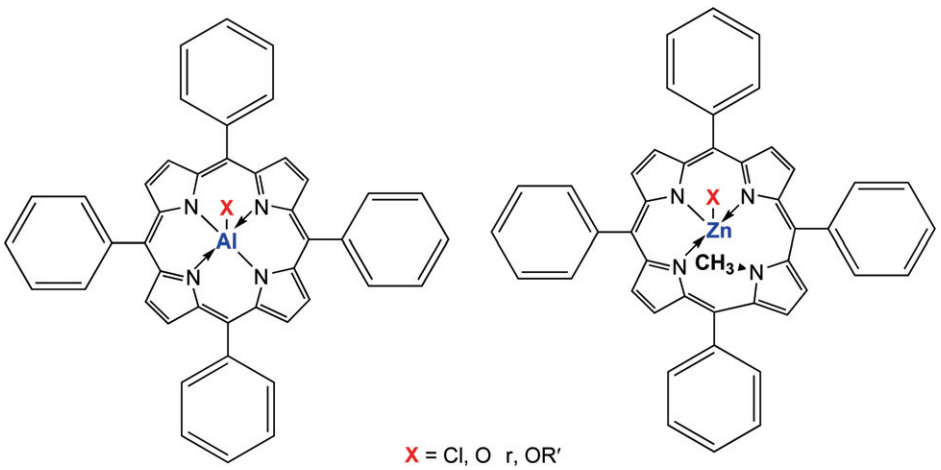
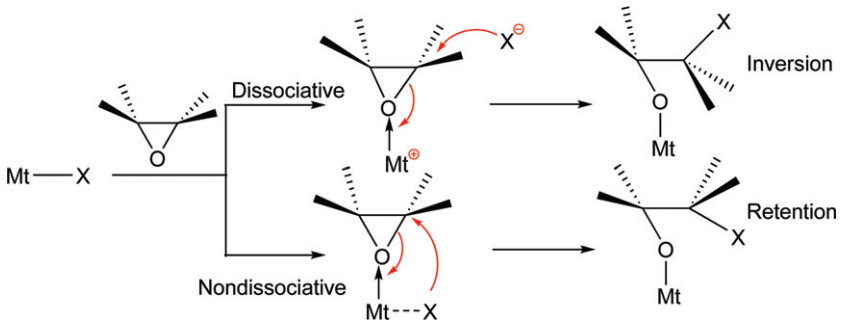
[a]Bulk polymerization.

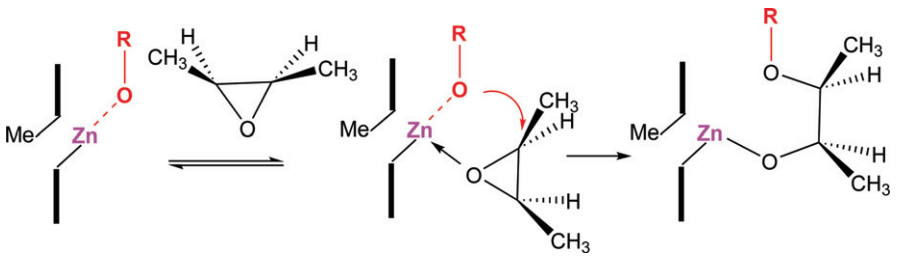
In contrast to conventional anionic polymerizations, in which epoxide insertion involves an inversion of the configuration at the carbon atom of the epoxide ring where cleaved, some porphyrin systems were shown to operate by a nondissociative reaction mechanism, with retention of configuration at the carbon atom of the epoxide ring where cleaved (Scheme 28).



Scheme 27 (Tetraphenylporphinato)aluminum (TPP)AlX and *N*-methyltetraphenylporphinatozinc (*N*-(MTPP)ZnX) derivatives.



Scheme 28 Inversion and retention of configuration during monomer insertion into mononuclear active species operating via a dissociative and a nondissociative mechanism.



Scheme 29 Proposed mechanism for insertion of (*Z*)-2,3-epoxybutane with retention of configuration into *N*-(MTPP)ZnOR.

Indeed systems that proceed in this way are mostly zinc derivatives in which the monomer and the growing polymer end are located on the same side of the porphyrin plane (Scheme 29). It was also suggested that retention of configuration may result from a double-inversion mechanism.[118]

Indeed the polymerization of 2,3-epoxybutane with aluminum porphyrin revealed a coordinative process with inversion of configuration,[119] which counters the above nondissociative reaction. Aida and Inoue proposed a mechanism involving two porphyrin molecules, one activating the monomer via coordination on the opposite face of the X group while the other proceeds as nucleophilic attack of the activated monomer (see Scheme 30).[107] Initiation results from the insertion of the monomer into the Al–X bond leading to an aluminum alkoxide which becomes the propagating species. Consequently, the synthesized polyether chains possess an X and a hydroxyl group at their extremities.[112]

Aluminum porphyrins were shown to be active toward epoxides in the presence of protic compounds, like alcohol, carboxylic acid, or hydrochloric acid, which act as reversible chain transfer agents. The polymerization pathway is described in Scheme 31. When an active chain reacts with a protic species, either a chain transfer agent or a dormant chain, a new initiating species and a new dormant chain are created. In turn, each 'transferred' species can initiate a new chain or undergo a new chain transfer reaction, whereas no termination occurs. The rate constants of chain transfer reactions were found to be about 8–10 times larger than the propagation rate constants, thus leading to relatively low polydispersity of the polyethers[108] and a number of polyether chains corresponding to the total amount of initiator and transfer agent. Inoue named this polymerization reaction as 'immortal'. Chain ends are constituted by the nucleophilic fragment X coming from the porphyrin initiator and a hydroxyl group after hydrolysis of the Al–O bond.[106]

Addition of protic agents allows control of the polymer molar masses and chain end functionality but at the same time drastically slows down the polymerization rate. As can be seen in Table 8, increasing the number of methanol equivalents with respect to the initiator from 10 to 50 necessitates an extremely long reaction time to achieve monomer conversion.

An increase in the reactivity of metalloporphyrin systems via monomer activation involving a Lewis acid additive will be discussed in the following section.

Other systems have been examined as porphyrin substitutes, such as chiral Schiff bases[120] or calixarene complexes[121] (Scheme 32). In all cases, no significant improvement was made in comparison to porphyrins, and molar masses of the polyethers obtained remained quite low ($< 5000\ g\ mol^{-1}$).

4.07.4.3 Bi- and Plurimetallic Coordination Catalytic Systems

To improve the characteristics of coordination polymerization catalysts, the combinations of different metal derivatives have been investigated. The association of zinc chloride to aluminum alcoholates improves the reactivity significantly and results in higher conversions (see **Table 9**). However, two polymer fractions are still obtained: an isotactic and crystalline polymer of high molar mass and an amorphous and atactic polymer (mole fraction of isotactic dyads is less than 0.6). In contrast to AlR_3/H_2O or ZnR_2/H_2O, the latter consists of regular head-to-head and tail-to-tail enchainments.[122,123]

Several μ-oxo-bimetallic complexes with Mt_1–O–Mt_2 bonds were prepared by condensing a metal (Mt_1) alkoxide and a metal (Mt_2) ester derivative[126,127] (**Scheme 33**), and investigated as coordination catalysts.

These systems, soluble in hydrocarbons, exhibit characteristics that depend on metals Mt_1 and Mt_2, on the R group, and on the association degree *n*. The combination of Al and Zn as Mt_1 and Mt_2 leads to the best results.[126] Comparative polymerization experiments show that EO and POx are the most reactive monomers.[128] Other oxiranes investigated have an intermediate reactivity, with ECH being less reactive.

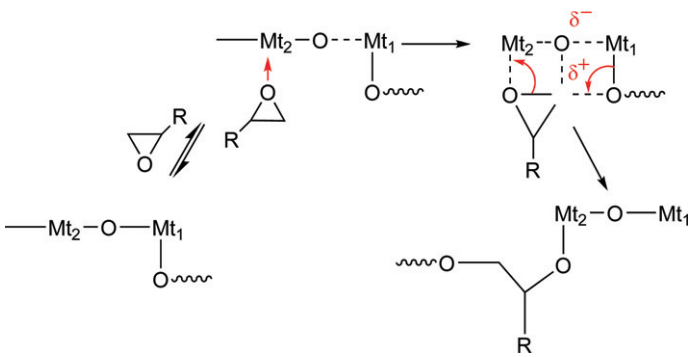
In most cases, three polymer populations are obtained:[129] a highly isotactic and crystalline fraction, ranging from 25% to 95%, whose molar masses reach $10^6\,g\,mol^{-1}$; a second one amorphous with high molar masses; and a third one constituted of oligomers. According to Kohler *et al.*,[128] oligomers are not formed by a cationic process since THF, which polymerizes only by a cationic mechanism, does not react with these complexes. The catalyst composition and the reaction conditions strongly influence the relative proportion of these different populations. Oligomer formation is favored by the presence of protic additives, owing to reversible exchanges between growing chains and protic compound.[130]

Scheme 33 General formula for μ-oxido-dinuclear complexes.

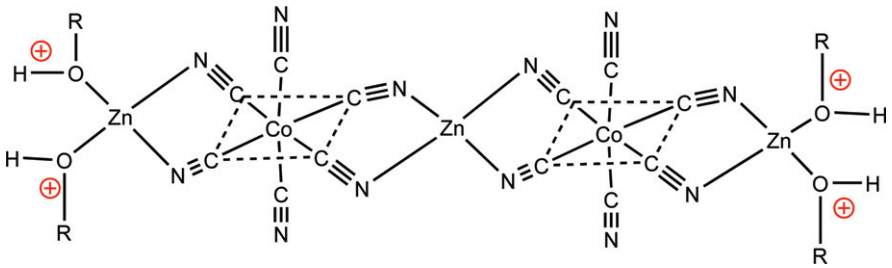
A mechanism close to the one proposed by Vandenberg was proposed by Teyssié and co-workers[126–128] for the polymerization of epoxide in the presence of dinuclear μ-oxoalkoxides (**Scheme 34**). Polymerization proceeds by the insertion of the monomer into a metal–oxygen bond with inversion of configuration. The growing chain is between the two metals.

4.07.4.4 Double Metal Cyanide Complexes

Originally discovered by General Tire Inc.[131] in the 1960s, double metal cyanide (DMC) complexes are important catalytic systems for the polymerization of epoxides and in particular for the synthesis of POx oligomers. DMC (**Scheme 35**) catalysts are obtained by the reaction of potassium hexacyanocobaltate (III) ($K_3[Co(CN)_6]_2$) and zinc chloride ($ZnCl_2$) in the presence of an alcohol, *tert*-BuOH, as complexing reagent. This is worthy of mention in this review even though some authors have proposed that the polymerization of epoxides may proceed by a cationic coordination mechanism.[132] Compared to conventional anionic catalysts, DMC catalysts give high-quality poly(POx) products that have low levels of unsaturation, narrow molar mass distribution, and low viscosity. ^{13}C NMR analysis showed that the polyols have head-to-tail regiosequence and a random distribution of the configurational sequences with an amount of [rr] triads larger than that of polyol obtained with conventional KOH catalyst. The presence



Scheme 34 Mechanism of POx polymerization initiated by μ-oxido-dinuclear complexes.



Scheme 35 Structure proposed for DMC catalysts.[132]

of some regioirregular sequences supports some cationic character of the active sites.[132]

While DMC catalysts offer significant advantages compared to KOH, first-generation catalysts required long activation times, increasing polymerization cycles, which has undercut the economic advantages of these systems. DMC catalysts should be activated over 2 h before the epoxide is continuously added to the reactor at high temperature (> 100 °C). Usually, a polyol initiator (or starter) and a DMC catalyst are combined and heated under vacuum prior to the addition of a small proportion of monomer.[133] In addition, heating the catalyst for a prolonged period at a temperature above 100 °C reduces its activity or deactivates it completely.[134]

DMC preparation and composition were revisited in the middle of the 1980s, with significant improvements made by some companies, including ARCO, Shell, and Asahi Glass, making DMC catalysts much more attractive for commercial manufacture of polyether polyols,[135–138] which are useful in a wide range of polyurethane applications.

Highly active catalysts with reduced induction periods are obtained by adding a polyether, poly(butane-1,4-diol), as a co-complexing agent[134] or using $CaCl_2$-modified Zn–Co(III) DMC.[139] The resulting poly(POx) shows a very low unsaturation level (0.003–0.006 mequiv. g^{-1}) and a narrow molar mass distribution ($\bar{D}$ = 1.02–1.04).

4.07.5 Polymerization Involving Monomer Activation by a Lewis Acid Additive

Anionic and anionic coordination polymerizations of epoxides are often slow processes that require long reaction times to achieve high monomer conversions. Moreover, as reported in previous sections, a majority of these polymerizations suffer from side reactions, illustrated by the chain transfer reaction to monomer in alkali metal anionic polymerization and by a very low initiation efficiency and the formation of several polyether populations in coordination polymerizations.

Anionic and related nucleophilic epoxide polymerizations involving an activated monomer have appeared to be of great interest in this context since they allow the nucleophilic ring-opening reaction to be speeded up drastically and the living character of the polymerization to be improved. Activation of epoxides toward nucleophilic attacks can be achieved by introducing in the reaction media an appropriate Lewis acid that will complex with the oxygen of the monomer, rendering it more prone to react with initiating and propagating nucleophilic species. Strategies developed so far are based on the association of aluminum porphyrin to highly encumbered aluminum phenoxides or on the use of alkali metal or tetraalkylammonium derivatives as initiators in the presence of trialkylaluminum.

4.07.5.1 Aluminum Porphyrins Associated with Lewis Acids

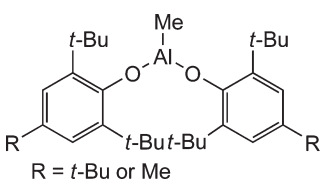
Inoue and co-workers were the first to report the use of bulky Lewis acid as additives to aluminum porphyrin initiators to enhance the polymerization rate. This was shown in particular for methacrylic esters[107,140,141] and POx.[107,141,142] For instance, in the presence of methylaluminum bis(2,4,6-trialkylphenolate) (MAlBP) as Lewis acid (**Scheme 36**), POx polymerization initiated by (TPP)AlCl (**Scheme 30**) is drastically accelerated. This is explained by coordination of the epoxide to the acid aluminum center of MAlBP. Electron transfer from the oxygen to the metal makes the ring carbon atoms electron-deficient, favoring an attack by even weak nucleophilic species[142] (**Scheme 37**, path 1).

The competitive complexation that could occur between the epoxide and the acidic aluminum center of MAlBP is minimized by the steric hindrance around the aluminum atom (**Scheme 37**, path 2).

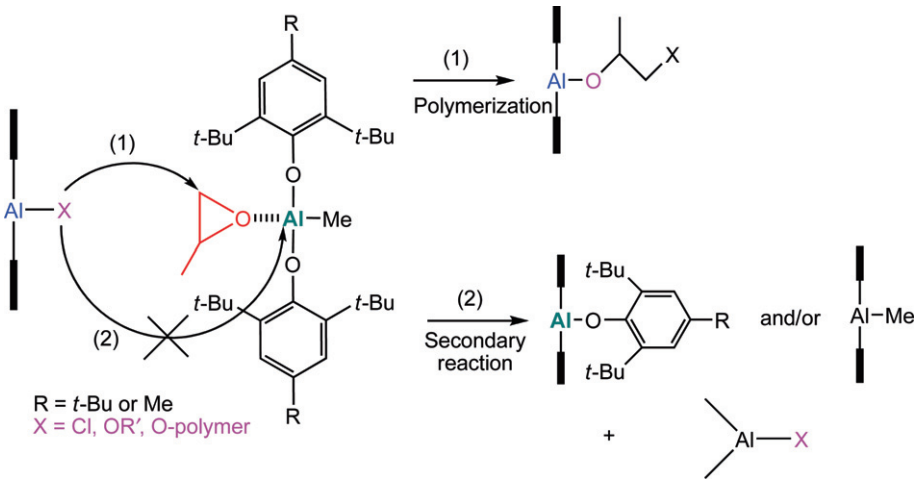
Owing to the monomer activation, polymerization undergoes a drastic acceleration while keeping a good control of molar masses and distributions. For instance, the polymerization rate of POx is multiplied by a factor of 460 after the addition of 0.25% methylaluminum bis(2,4,6-tri-*tert*-butylphenolate).[142]

The living/controlled and high-speed nature of the ring-opening polymerization of POx with aluminum porphyrin/a bulky organoaluminum compound was further demonstrated by the successful synthesis of block copolymers from POx and BOx.[142]

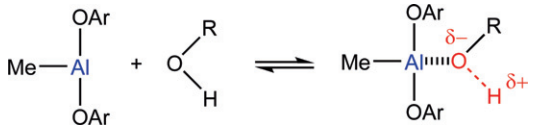
As reported earlier for porphyrin salts, protic reversible chain transfer agents, generally alcohols, can be used in association with aluminum porphyrin/bulky organoaluminum compound systems, reducing significantly the amount of aluminum in the polymer. Coordination of the Lewis acid to the alcohol increases alcohol acidity and accelerates exchange



Scheme 36 Bulky Lewis acid (MAlBP) used with aluminum porphyrin initiators for the monomer-activated polymerization of epoxides.



Scheme 37 Epoxide polymerization with porphyrin/bulky Lewis acid (MAlBP) systems involving monomer activation.



Scheme 38 Coordination of Lewis acid and alcohol.

reactions[143] (Scheme 38), thus allowing a good control of polymer molar masses and keeping the 'immortal' characteristics of the polymerization in high-speed conditions.[144]

4.07.5.2 Other Aluminum Derivatives

Based on the same monomer activation strategy, aluminum phthalocyanine and Schiff bases[142] have been used in association with MAlBP to initiate POx polymerization. Although the rate and control of polymerization are lower than those observed with aluminum porphyrins, the acceleration in the presence of MAlBP derivatives is extremely marked for all initiating systems.

Mixtures of trialkylaluminum and highly hindered di- or tetraphenol compounds have also been investigated recently as catalytic systems for the polymerization of EO and POx.[145] Ligands bearing four phenol groups form particularly active catalysts when combined with an excess of triisobutylaluminum (2 equiv.) and triethylamine (1 equiv.) as initiator. Productivities of $> 100\,g\,mmol^{-1}$ Al have been achieved in both EO and POx polymerizations. Chain transfer to alcohol (propan-2-ol or benzyl alcohol) has been demonstrated for porphyrin systems. A dinuclear insertion process was proposed. However, molar masses of the poly(POx) produced are not controlled and, moreover, the highly regioirregular structure observed with some of these catalytic systems suggests that the mechanism involved differs from the ones so far described.[145]

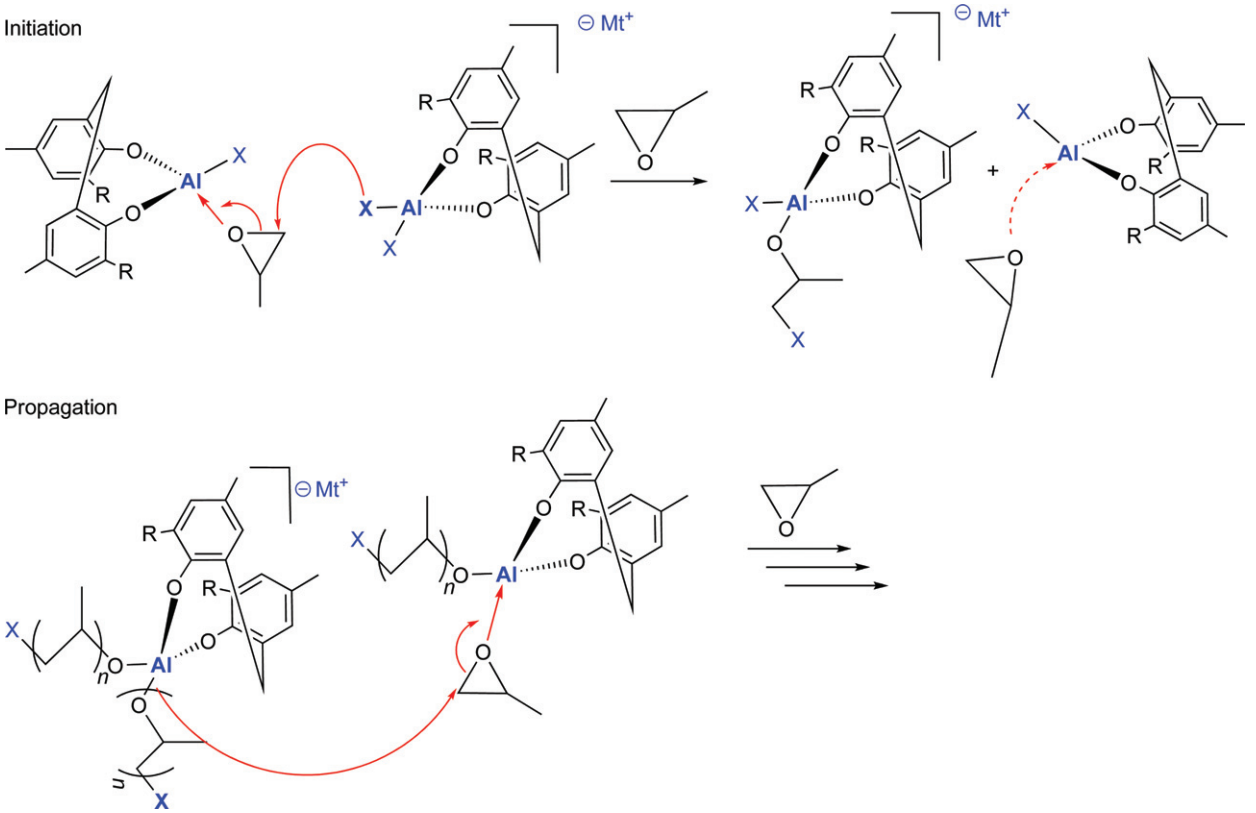
4.07.5.3 Alkali Metal Derivatives and Quaternary Onium Salts

Braune and Okuda[146] have shown that in the presence of some bulky diphenoxyaluminum compounds it is possible to replace aluminum porphyrins by cesium alkoxides or tetrabutylammonium salts as initiators for POx polymerization. The ring-opening polymerization proceeds under the synergic interaction of a phenolate–aluminum–oxirane complex forming an activated monomer with the corresponding 'ate' complex, which serves as initiator (Scheme 39). Ring opening takes place by transfer of an alkoxy group from the 'ate' complex regenerating an aluminate. The synthesis of poly(POx) with a molar mass up to $4000\,g\,mol^{-1}$ was reported.

Using relatively similar systems based on quaternary ammonium and quaternary phosphonium halides in conjunction with sterically hindered methyl(diphenoxy)aluminum, anionic coordination polymerization of the less reactive four-membered ring oxetane was shown to occur,[147] giving low-dispersity polyoxetanes with M_n up to $17\,000\,g\,mol^{-1}$, owing to strong monomer activation by complexation with the aluminum derivatives.

Simpler initiating systems based on the association of conventional anionic initiators, typically sodium or potassium alkoxides (ROMt), with trialkylaluminum (R_3Al) behave very similarly to porphyrin salts associated to bulky Lewis acid systems. For instance, sodium isopropoxide in combination with triisobutylaluminum in hydrocarbon solvents yields rapid POx polymerization at room temperature or below.[148] The chain transfer reactions are also strongly reduced in these conditions, thus allowing the synthesis of regioregular atactic poly(POx), with relatively high molar masses (up to $50\,000\,g\,mol^{-1}$).

The exclusive presence of head-to-tail enchainments in the polymer is indicative of an anionic coordination type mechanism. Increasing trialkylaluminum concentration, at constant monomer and alkali metal alkoxide concentrations, was shown to lead to a drastic increase in the polymerization rate (Figure 2), whereas the number of poly(POx) chains remained unchanged. In these systems, the trialkylaluminum derivative is involved in the formation of two distinct complexes (Scheme 40): one 1:1 'ate' complex with the alkali metal alkoxide; which serves as initiator; and the other one, at $[AlR_3]/[ROMt]$ ratio (r) higher than unity, with the POx monomer. Polymerization proceeds only at r higher than unity, indicating that only complexed POx molecules are susceptible to ring opening in these conditions, owing to



Scheme 39 Activated anionic polymerization of POx involving cesium or ammonium salts and diphenoxyaluminum compounds.

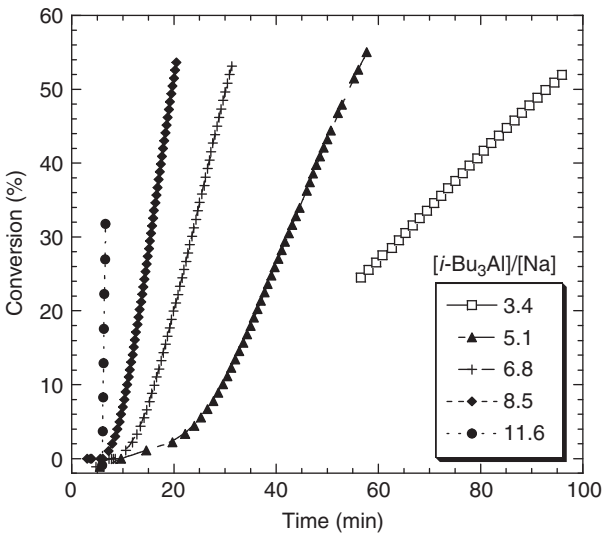


Figure 2 Conversion vs. time curves of POx polymerizations initiated by *i*-PrONa in the presence of increasing amounts of *i*-Bu_3Al in cyclohexane at 0 °C. [POx]/[*i*-PrONa] = 189. Reprinted with permission from Billouard, C.; Carlotti, S.; Desbois, P.; Deffieux, A. *Macromolecules* **2004**, 37, 4038–4043.[148] Copyright 2011 American Chemical Society.

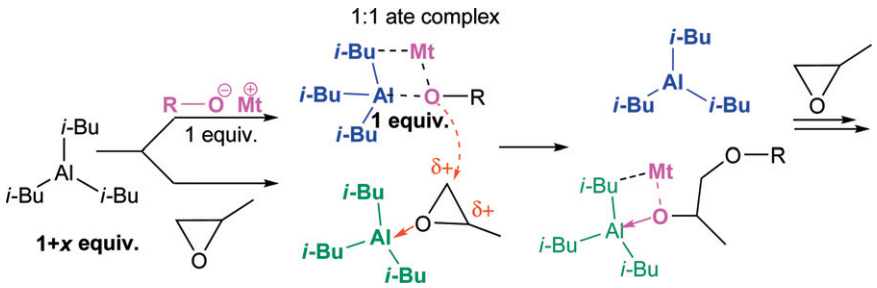
significant electron withdrawing, which renders the ring carbon atoms much more electrophilic. Moreover, since the withdrawing effect is less pronounced on the POx methyl group, the complexation also results, advantageously, in a higher selectivity toward the ring-opening reaction, to the detriment of the proton abstraction process responsible for chain transfer to monomer. The polymerization mechanism is shown in Scheme 40.

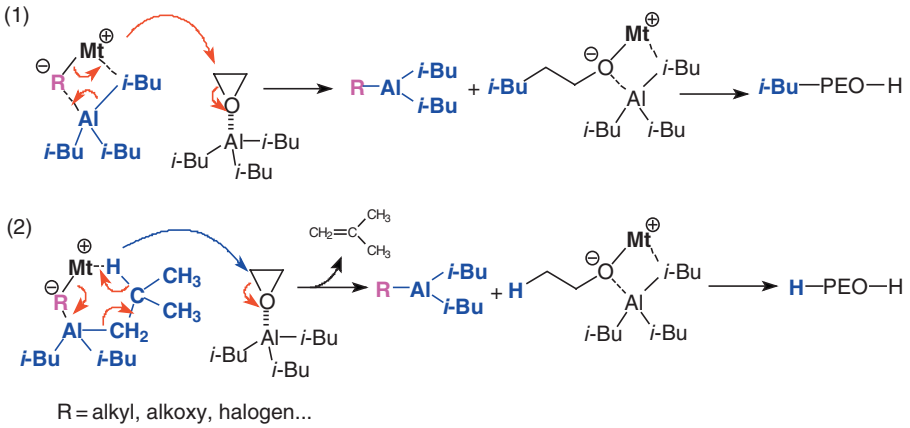
Initiation was shown to proceed mainly by attack of the alkoxide moieties of the aluminate complex, thus yielding poly-(POx) with an alkoxide head group and, after hydrolysis, a hydroxy chain end. The presence of small fractions of poly-(POx) with hydrogen or alkyl head groups indicates the minor contribution of other initiation mechanisms involving ligand reorganization in the initial complex (see Scheme 41), as well as some, but limited, chain transfer to monomer.

The possibility of using a similar strategy to initiate EO polymerization in the presence of alkyllithium associated to triisobutylaluminum was recently demonstrated with the synthesis of poly(EO) with molar masses up to 10 000 g mol^{-1}, at low temperature and in nonpolar media.[149] The presence of AlR_3 in excess with respect to the lithium initiator permits disaggregation of lithium alkoxide species by forming lithium aluminate complexes able to ring-open the AlR_3-complexed EO molecules. However, ligand exchanges in the lithium aluminate complex lead to slow deactivation of the propagating species during the polymerization, which limits the access to high-molar-mass poly-(EO) (Scheme 42).

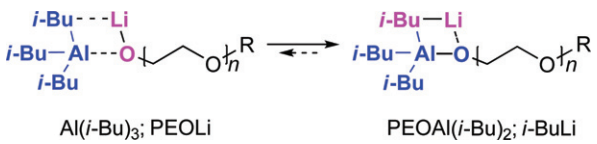
The replacement in the above systems of the alkali metal initiators by onium salts, typically tetraalkylammonium or tetraalkylphosphonium halides, drastically improves the synthesis of polyethers. For instance, poly(POx)s of controlled molar masses, up to 150 000 g mol^{-1},[150] are obtained in very short reaction times using tetrabutylammonium chloride and bromide as initiating species in the presence of a slight excess of



Scheme 40 Mechanism proposed for the POx polymerization involving alkali metal alkoxide in the presence of *i*-Bu_3Al.



Scheme 41 Secondary initiation processes involving ligand exchanges in aluminate complexes.



Scheme 42 Proposed ligand exchanges in lithium aluminate complexes leading to slow deactivation during the EO polymerization.

i-Bu_3Al (*i*-$Bu_3Al/NR_4X \sim 1.2$). The polymerization rate was shown to increase with the size of the counter cation (Figure 3).

These initiating systems have been applied to the polymerization of a wide range of epoxides and to the design of telechelic polyethers. Compared to conventional alkali metal initiators, the tetraoctylammonium bromide/*i*-Bu_3Al initiating system strongly enhances the rate of EO polymerization keeping the living character of the reaction.[151] At the ratio [*i*-Bu_3Al]/[$NOct_4Br$] = 1.5, the synthesis of poly(EO) of molar mass (MM) 20 000 g mol^{-1} with bromide and hydroxyl end groups is completed in 2 h at room temperature in dichloromethane. Monomer-activated anionic polymerization of ECH under similar conditions has also been described.[152] In contrast to conventional anionic polymerization, the aluminate species that ensures propagation in the AlR_3/onium systems selectively reacts with the activated ECH ring, leaving the chloromethyl function untouched.[152] The synthesis of poly(glycidyl methyl ether),[153] linear poly(2-ethoxyethyl glycidyl ether), and poly(*t*-BuGE)[154] with narrow chain dispersity and controlled molar masses has also been reported. The amount of Lewis acid required to trigger the reaction and achieve quantitative monomer conversions was shown to increase with the number of oxygen atoms in the monomer.

This approach allowed the direct synthesis from the corresponding ammonium salts of a broad series of heterofunctional polyethers bearing for instance a chloride, bromide, or azide head group[38] (Scheme 43) and a hydroxy-terminated chain. Poly(EO)- and poly(POx)-protected polyglycidol and poly(ECH) have been prepared in this way with a high functionalization efficiency.

The living/controlled character of the monomer-activated anionic polymerization involving onium salt/triisobutylaluminum systems has been applied to the synthesis of a series of random and block copolymers. EO/POx random copolymers with a gradient structure, molar masses up to 70 000 g mol^{-1}, and narrow dispersity have been synthesized by Rejsek *et al.*[151] Poly(POx-*co*-ECH) and amphiphilic poly(alkylene oxide-*co*-glycidol) were also prepared via the synthesis of poly(POx-*co*-EEGE) and poly(BOx-*co*-*t*-BuGE) copolymers, after deprotection of hydroxyl groups.[154] Interestingly, despite the

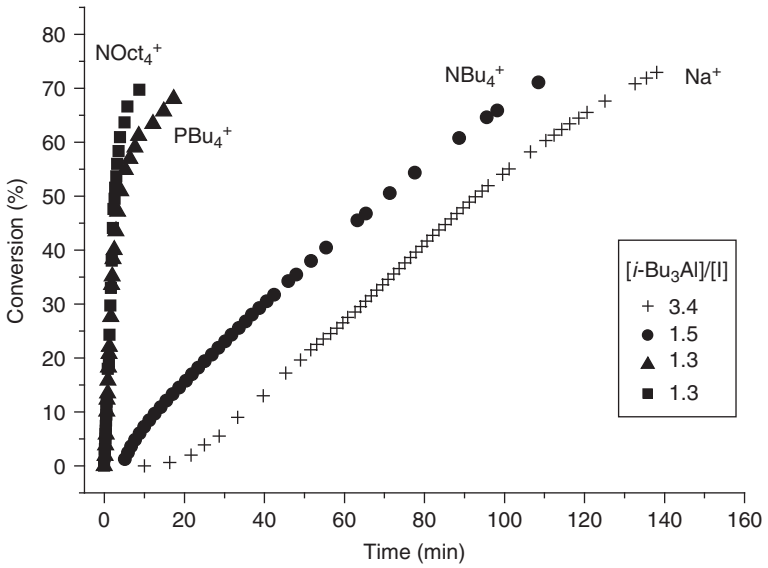


Figure 3 Conversion vs. time curves of POx polymerization initiated by *i*-PrONa (+), NBu_4Cl (●), $NOct_4Br$ (■), and PBu_4Cl (▲) in the presence of *i*-Bu_3Al at 0 °C in cyclohexane. Scheme 43 Synthesis of α-azido-ω-hydroxy polyethers using the tetrabutylammonium azide/*i*-Bu_3Al initiating system.

determining role of the monomer complexation in this polymerization process, the copolymerization ratios remain close to those reported for conventional anionic copolymerization.

Different diblock and triblock copolymers of various compositions and lengths have also been prepared by sequential monomer addition, as illustrated by the Size Exclusion Chromatography (SEC) trace reported in the synthesis of poly(EO-*b*-POx-*b*-PEO) triblock copolymers with $NOct_4Br$/*i*-Bu_3Al (Figure 4).[151]

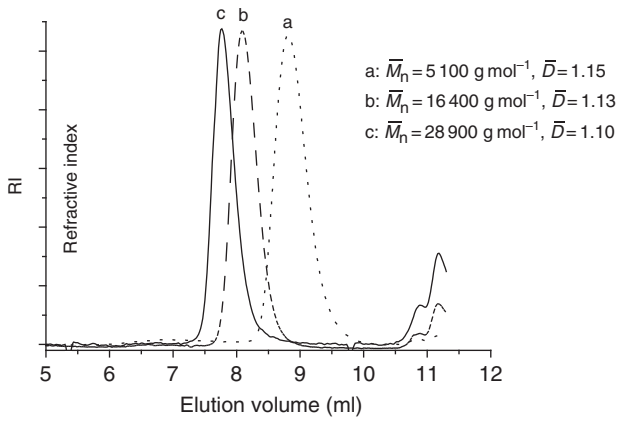

Figure 4 SEC traces corresponding to different stages of the synthesis of a poly(EO-*b*-POx-*b*-PEO) triblock copolymer with $NOct_4Br$/*i*-Bu_3Al system: (a) poly(EO) first block; (b) poly(EO-*b*-POx) diblock; and (c) poly (EO-*b*-POx-*b*-EO) triblock. Reprinted with permission from Rejsek, V.; Sauvanier, D.; Billouard, C.; et al. Macromolecules 2007, 40, 6510–6514.[151] Copyright 2011 American Chemical Society.

Poly(POx-*b*-ECH) block copolymers with MM ranging from about 6000 up to 30 000 g mol^{-1} and with various poly(POx) and poly(ECH) block lengths[152] were also prepared by sequential addition of the two monomers. The reinitiation efficiency starting from either poly(POx) or poly(ECH) as first block was shown to be quantitative.

Finally, block copolymerization of EO initiated by living polymer chains with lithium counterion was also recently described.[149] Although it is known that EO polymerization could not proceed properly when lithium alkoxide species are involved,[155,156] in the presence of AlR_3 it was shown that living polystyryllithium (PSLi) and polyisoprenyllithium (PILi) chains can play the role of a macroinitiator for EO polymerization, thus yielding in hydrocarbon solvent in short reaction times poly-(S-*b*-EO) and poly(I-*b*-EO) with poly(EO) block molar masses up to 10 000 g mol^{-1}.

In conclusion, epoxide derivatives constitute an important group of monomers that can be readily prepared by epoxidation of olefins. Their polymerization allows the synthesis of a broad series of polyethers, ranging from hydrophilic to highly hydrophobic, with biocompatible characteristics. Owing to the recent progress in their ring-opening polymerization, in particular via the use of an appropriate combination of weakly nucleophilic initiators and catalysts or activators, functional oligomers and block copolymers of a much broader series of epoxides can now be prepared, opening new application opportunities in several important areas.

4.07.6 Summary

Epoxide derivatives constitute an important group of monomers that can be readily prepared by epoxidation of natural and synthetic alkenes. Their polymerization by anionic and by related nucleophilic ring-opening reactions is described and discussed in this chapter. The mechanisms of initiation, propagation, and transfer reactions in the presence of ionic initiators, typically alkali metal derivatives, and their impact on the polyether characteristics are first examined. Following this, the recent use of organic derivatives as counterion or catalyst is presented. The last sections of the chapter are devoted to epoxide polymerizations involving a preliminary coordination/activation of the monomer before insertion. The recent progress achieved in the polymerization control of a broad series of epoxide monomers, including functional ones, via the monomer-activated polymerization is highlighted in particular since it opens interesting opportunities in the preparation and design of new polyether materials.

Biographical Sketches

Dr. Alain Deffieux, born in Libourne, France, did his PhD in polymer science in the group of Pierre Sigwalt at the University Pierre and Marie Curie, Paris VI, and then spent 2 years as associate researcher in the laboratory of Professor Vivian Stannett at North Carolina University. He joined the Centre National de la Recherche Scientifique (CNRS) in 1974 at Paris VI University and then moved to Bordeaux University in 1986 in the newly created Laboratoire de Chimie des Polymères Organiques where he became research professor. His research activities are focused on precision polymer synthesis ranging from studying the mechanisms of elementary reaction processes and reactivity control to the design and characterization of polymers with complex chain architecture such as combs, stars, dendrigrafts, and macrocycles.

Dr. Stéphane Carlotti has been an associate professor at the University of Bordeaux 1 since 2007. He completed his PhD course in the field of polymer science in 1998 at the University of Montpellier. After a postdoctoral stay at the Loker Hydrocarbon Research Institute (University of Southern California, Los Angeles, CA, USA), supervised by Pr. T. Hogen-Esch, he joined the Laboratoire de Chimie des Polymères Organiques (LCPO) in 1999 at the University of Bordeaux 1 as assistant professor. He worked mainly on the synthesis of polymers and copolymers with controlled architecture. He studied the living anionic polymerizations of ethylenic monomers in bulk at high temperature and cyclic ethers by an activated mechanism. Other interests are in the fields of ring-opening metathesis polymerization and chemical modification of polymers.

Dr. Amélie Barrère is associate professor at the University of Paris 13, France. Previously, she graduated from the University of Bordeaux 1, France, and obtained a PhD in 2007 on the activated anionic polymerization of epoxides under the supervision of Dr. A. Deffieux. She joined the laboratory 'Bio-ingénierie des Polymères Cardiovasculaires', supervised by Dr. D. Letourneur where her research area is oriented toward the development of coatings of cardiovascular devices based on natural polymers such as polysaccharides.

4.08 Cationic Ring-Opening Polymerization of Cyclic Ethers

P Kubisa, Polish Academy of Sciences, Lodz, Poland

4.08.1 General Considerations

Cyclic ethers constitute an important class of heterocyclic monomers that polymerize by ionic mechanisms. Studies of the mechanism, kinetics, and thermodynamics of cyclic ether polymerization were essential in establishing basic principles of ionic ring-opening polymerization (ROP). There are several book chapters and reviews summarizing this field and although some of them date back to early 1980s, the main conclusions are still valid and provide a basis for more recent developments.[1–12]

Cyclic ethers are the class of heterocyclic monomers that provide suitable models for mechanistic studies. Polymerization of several monomers of this class leads to polymeric materials that are produced on an industrial scale. The most prominent examples are polymers of ethylene oxide (EO), propylene oxide (PO), epichlorohydrin (ECH), or tetrahydrofuran (THF). Cationic ring-opening polymerization (CROP) of cyclic ethers is thus interesting from both an academic and industrial point of view.

In this chapter, the basic features of CROP of cyclic ethers will be briefly outlined on the basis of published earlier chapters and reviews, mainly the first edition of *Comprehensive Polymer Science,*[6] and then more recent developments will be discussed based on the original literature.

4.08.1.1 Thermodynamic Polymerizability of Cyclic Ethers

Polymerizability in a thermodynamic sense is related to the Gibbs energy change (ΔG) associated with a conversion of monomer into polymer unit. More detailed analysis of the thermodynamics of polymerization is given in Chapter 4.02; in this section (4.08.1.1), the simplified description is provided to show the relationship between equilibrium monomer concentration ($[M]_e$), enthalpy of polymerization (ΔH) (closely related to the ring strain), and temperature. Gibbs energy of polymerization is a function of enthalpy (ΔH) and entropy (ΔS) of polymerization.

$$\Delta G_p = \Delta H_p - T\Delta S_p \qquad [1]$$

In the polymerization of heterocyclic monomers, the driving force of polymerization is provided by the release of the strain of the ring upon its opening.[13]

In the process of polymerization, many monomer molecules are incorporated into a polymer chain thus translational entropy decreases. This may be partly counterbalanced by the increase in rotational and vibrational entropy resulting from converting a rigid monomer molecule into a more flexible chain unit. Thus, the entropy of polymerization of heterocyclic monomers is typically lower than entropy of polymerization of vinyl monomers. Although entropy of polymerization depends on the ring size, $-\Delta S$ values for polymerization of cyclic ethers are typically not higher than 80 J (~20 cal)/ °C × mol.[13] Thus, at ambient temperatures (~300 K), the term $-T\Delta S$ usually does not exceed the value 25 kJ mol^{-1} (~6 kcal mol^{-1}). This sets a borderline between polymerization that is practically irreversible and polymerization that proceeds reversibly because in order to make polymerization possible from the thermodynamic point of view ($\Delta G < 0$), enthalpy (ΔH) must outweigh the entropy term ($T\Delta S$). Thus, the thermodynamic polymerizability is governed by the enthalpy of polymerization closely

Table 1 Ring strains of cycloalkanes[14]

Number of atoms in the ring	*Bond angle distortion*	*Strain energy (kJ mol^{-1})*
3	24°44′	115 (27.6 kcal mol^{-1})
4	9°44′	110 (26.2 kcal mol^{-1})
5	0°44′	26 (6.3 kcal mol^{-1})
6	–5°16′	1 (0.2 kcal mol^{-1})
7	–9°33′	27 (6.4 kcal mol^{-1})
8	–12°46′	42 (9.9 kcal mol^{-1})

related to the ring strain of the monomer. Polymerization of highly strained three- and four-membered cyclic ethers is practically irreversible while polymerization of five-membered THF is a typical example of reversible polymerization in which a significant amount of monomer remains in equilibrium with polymer.

Enthalpy of polymerization is related mainly (but not exclusively) to the ring strain. As the bond lengths and the bond angles for C–O and C–C bonds are similar, the ring strains of cycloalkanes provide a good approximation for ring strains of cyclic ethers. Ring strains of cycloalkanes are listed in **Table 1**.

For nonsubstituted cyclic ethers, the following values of ring strain are given in the literature (**Table 2**).[15] The geometry of cyclic ethers is governed mainly by the number of atoms in the ring. Ring strain is caused mainly by the difference between the angles resulting from orbital overlap and the angles imposed by the ring size. The additional strain may arise from the interactions of the nonbonded atoms located in close proximity.

Molecules of cyclic ethers, with the exception of EO, are not planar although the deviation from planarity in the four- and five-membered rings is small. The free electron pairs on the oxygen atoms behave sterically like medium-sized substituents.

As already mentioned, polymerization of highly strained three- and four-membered cyclic ethers is practically irreversible, while polymerization of five-membered THF is a typical example of reversible polymerization.

Reversibility of propagation in simplified form may be represented by eqn [2]:

$$\cdots - M_n^* + \mathrm{M} \rightleftharpoons \cdots - M_{n+1}^* \qquad [2]$$

Equilibrium constant for reversible propagation is equal to:

$$K = [\cdots - M_{n+1}^*]/[\cdots - M_n^*][\mathrm{M}]_e \text{ and assuming that } [\cdots - M_{n+1}^*] = [\cdots - M_n^*] \qquad [3]$$

$K = 1/[\mathrm{M}]_e$, where $[\mathrm{M}]_e$ denotes concentration of monomer at equilibrium.

There is the following relationship between Gibbs energy of polymerization and equilibrium constant K:

$$\Delta G^o = RT \ln K \qquad [4]$$

Thus,

$$RT \times \ln 1/[\mathrm{M}]_e = \Delta H - T\Delta S \quad \text{and} \quad \ln 1/[\mathrm{M}]_e = \Delta H/RT - \Delta S/R \qquad [5]$$

A more detailed description of thermodynamics of polymerization is given in Chapter 4.02; in this section, the simplified analysis is provided to show the relationship between equilibrium monomer concentration ($[\mathrm{M}]_e$), enthalpy of polymerization (ΔH) (closely related to the ring strain), andtemperature.

Table 2 Ring strains of cyclic ethers[15]

Cyclic ether	*Ring strain (kJ mol^{-1})*
Oxirane (three membered)	114
Oxetane (four membered)	107
Tetrahydrofuran (oxolane) (five membered)	23
Tetrahydropyran (oxane) (six membered)	5
Oxocane (eight membered)	42

In simple terms

1. the lower is the enthalpy of polymerization (ring strain) the higher is the equilibrium monomer concentration;
2. the higher the temperature the higher the equilibrium monomer concentration; and
3. for each initial concentration of monomer ($[\mathrm{M}]_0$), there is a temperature at which $[\mathrm{M}]_e$ becomes equal to $[\mathrm{M}]_0$ meaning that for a given $[\mathrm{M}]_0$ at this and higher temperatures polymerization is not possible. This temperature is denoted as a ceiling temperature for polymerization (T_c). Ceiling temperature is typically given in the literature either for standard conditions (i.e., for $[\mathrm{M}]_0 = 1\ \mathrm{mol\,l^{-1}}$) or for bulk polymerization. For practical purposes, the value of T_c for bulk polymerization is of interest because above this temperature the monomer will not polymerize under any conditions.

There are the following practical consequences that are important for understanding of behavior of cyclic ethers in ROP.

Gibbs energy of polymerization is strongly negative for the polymerization of strained three- and four-membered cyclic ethers; therefore, polymerization is practically irreversible, which means that there are no thermodynamic barriers for reaching quantitative conversions even at low $[\mathrm{M}]_0$ and higher temperatures. It should be remembered, however, that kinetic factors may prevent quantitative conversion if a termination reaction occurs.

In contrast, polymerization of weakly strained cyclic ethers containing five or more atoms in the ring is highly reversible, which means that there are thermodynamic limits on the ultimate conversion. The highest conversion that may be achieved is equal to:

$$\text{Ultimate conversion} = ([\mathrm{M}]_0 - [\mathrm{M}]_e)/[\mathrm{M}]_0 \times 100\% \qquad [6]$$

Thus, to reach the highest monomer conversion in reversible polymerization, polymerization should be conducted at high $[M]_0$ and low temperature (to reduce $[M]_e$ value). This latter requirement is in conflict with kinetic requirements. In the system with reversible propagation, polymerization is faster at higher temperatures but because of higher $[M]_e$, the highest attainable conversion is lower. Thus, it should be remembered that the term 'polymerizability' does not have an unequivocal meaning and one should clearly distinguish between kinetic and thermodynamic polymerizability. The former is governed by rate constants of elementary reactions while the latter by the equilibrium constant of propagation. Thus, typically, with increasing temperature kinetic polymerizability will be enhanced (higher rate of propagation) but thermodynamic polymerizability will be lowered (equilibrium position will be less favorable for the formation of polymer).

It should be pointed out that the presented picture applies to homopolymerization. Monomers that do not undergo homopolymerization at particular conditions may still be able to undergo copolymerization. It should also be remembered that thermodynamic parameters of polymerization are valid for the transformation of monomer into relatively high-molecular-weight polymer. Therefore, even at the conditions when monomer does not polymerize due to the thermodynamic restrictions, some low-molecular-weight oligomers may still be formed.

4.08.1.2 Nucleophilicity and Basicity of Cyclic Ethers

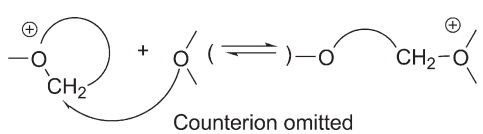
Propagation in the cationic polymerization of cyclic ethers proceeds as a nucleophilic attack of an oxygen atom on the carbon atom in α-position in an oxonium ion (Scheme 1).

If the oxygen atom (-O-) is a part of monomer molecule, this scheme represents chain propagation. If, however, it is a part of polymer unit, such a reaction is a chain transfer to polymer. Chain transfer to polymer (either intermolecular or intramolecular) is a typical feature in CROP of cyclic ethers. Its significance in particular cases will be discussed in subsequent sections (Section 4.08.1.5 and 4.08.2.1).

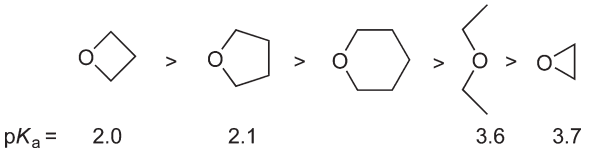
As the reaction shown in the scheme above is a nucleophilic substitution reaction, nucleophilicity of oxygen atoms in monomers and polymer units is an important factor governing the competition between chain propagation and chain transfer to polymer.

Nucleophilicity is often expressed in terms of basicity. Nucleophilicity and basicity reflect the same property, namely the ability to share the lone electron pair with an electron acceptor. Nucleophilicity is determined at kinetically controlled conditions whereas basicity is determined at the conditions controlled thermodynamically (from the studies of equilibria).

Linear and cyclic ethers belong to the group of weak organic bases.[16,17]



Scheme 1



Scheme 2

Basicity of cyclic ethers decreases in the order as shown in Scheme 2.

Knowledge of the order of basicities of cyclic and linear ethers is important for understanding certain phenomena in cyclic ether polymerization. As indicated earlier, chain transfer to polymer is a general feature of the cationic polymerization of cyclic ethers because the nucleophilic site of the monomer molecule (oxygen atom) is transferred to the polymer unit. To what extent chain transfer to polymer competes with propagation depends on the relative nucleophilicity of monomer and polymer unit. Thus, for five-membered THF, the polymer unit is a weaker base than the monomer. This makes the polymer less reactive than the monomer in nucleophilic substitution type reactions. Consequently, for this monomer, chain transfer to polymer is slow as compared to propagation. In contrast, in the polymerization of three-membered EO, the polymer unit is more basic than monomer. Therefore, reactions involving the polymer chain are important in this system. Practical consequences will be discussed in the subsequent sections devoted to polymerization of different classes of cyclic ethers.

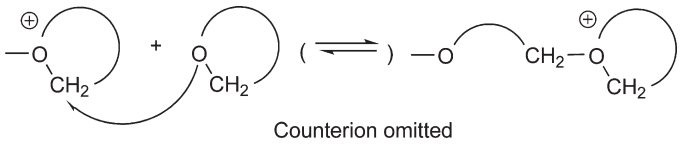
4.08.1.3 Mechanism of Cationic Polymerization of Cyclic Ethers

Cyclic ethers polymerize by ionic mechanism. Three-membered cyclic ethers (oxiranes) polymerize by both cationic and anionic mechanisms. Four-membered and higher cyclic ethers polymerize by cationic mechanism only (although examples of anionic polymerization are occasionally mentioned in the literature). Thus, cationic mechanism is a general mechanism of cyclic ether polymerization.

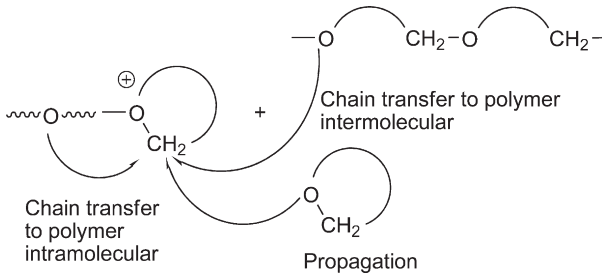
The growing species on which propagation occurs are typically tertiary oxonium ions (although the mechanism involving secondary oxonium ions, the activated monomer (AM) mechanism may also operate as it will be discussed in the following sections). Those tertiary oxonium ions are located at the growing chain end; thus, the typical mechanism of cyclic ethers polymerization is called the active chain end (ACE) mechanism.

Propagation by the ACE mechanism is represented in Scheme 3.

Propagation proceeds by nucleophilic attack of an oxygen atom in a monomer molecule on a carbon atom in α-position to an oxygen atom bearing formally the positive charge in a tertiary oxonium ion located at the chain end. Even such a simplified scheme indicates the possibility of a side reaction that is a typical feature of cationic polymerization of cyclic ethers. A nucleophilic center (oxygen atom) is present not only in monomers but also in polymer chains. Therefore, the attack of an oxygen atom from the chain on a carbon atom in a



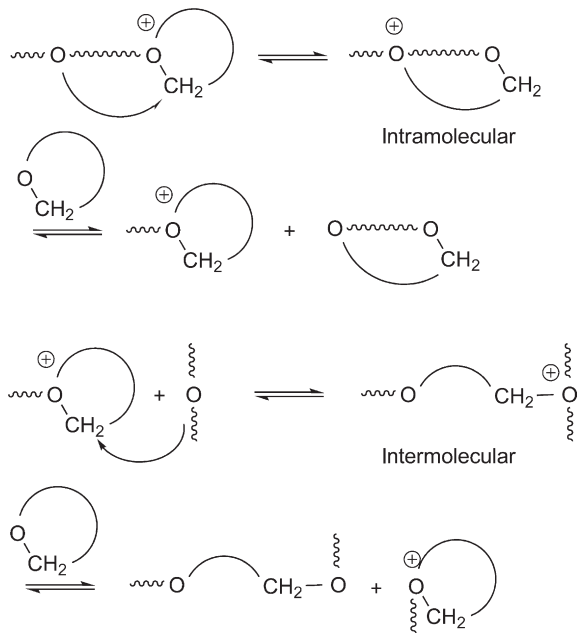
Scheme 3



Scheme 4

growing center may occur and compete with propagation, as shown in Scheme 4.

It should be stressed that the fact that the monomer molecule is strained while the polymer chain is essentially strainless is not relevant from the point of view of competition between both the processes. In both the cases, it is the ring in the growing center that is opened while the attacking molecule remains intact. Thus, the competition is governed mainly by nucleophilicity of an oxygen atom in cyclic and linear structures (with a possible contribution of steric effects). Therefore, chain transfer to polymer is a typical feature in CROP of cyclic ethers. Intermolecular reaction leads to segmental exchange (so-called scrambling), while intramolecular reaction leads to cyclization as shown in Scheme 5.



Scheme 5

As a result of intramolecular chain transfer to polymer, a certain number of cyclic oligomers may be formed in addition to linear polymers. This is a serious limitation for synthetic applications of CROP of cyclic ethers because a fraction of the polymer may have a distinctly different molecular weight (thus broadening molecular weight distribution) and will not contain end-groups (which is especially disadvantageous for the synthesis of reactive, telechelic polymers). In some systems (as in the cationic polymerization of THF), chain transfer to polymer is slow as compared to propagation and polymerization may be terminated before cyclic oligomers start to form. In other systems, however, especially in the cationic polymerization of oxiranes, cyclization in polymerization proceeding by the ACE mechanism cannot be avoided. As will be discussed, cyclization may be eliminated if polymerization is conducted at conditions where the AM mechanism of propagation dominates.

Intermolecular chain transfer to polymer is less harmful because the number of macromolecules does not change and the number-average degree of polymerization (DP) is not affected. Segmental exchange leads, however, to a broadening of molecular weight distribution. Another effect may be disproportionation of polymer end-groups as shown in Scheme 6.

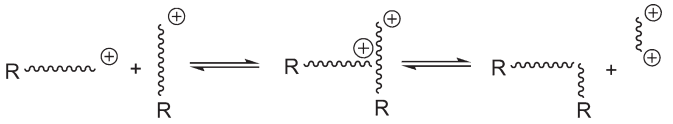
Chain transfer to polymer is the major side reaction in CROP of cyclic ethers. If it could be avoided, the system would approach conditions required for living polymerization. According to the recent IUPAC definition, living polymerization is: "A chain polymerization from which irreversible chain transfer and irreversible chain termination (deactivation) are absent."[18]

Tertiary oxonium ions that are active species in CROP of cyclic ethers are inherently stable (trialkyloxonium salts with stable counterions are commercially available and may be stored without special precautions for prolonged periods of time). Thus, if basic impurities are avoided in CROP of cyclic ethers, there is essentially no irreversible termination. Those polymerization are, however, not classified as living because reversibility of propagation and reversible chain transfer to polymer cause deviations from the ideal situation observed for, for example, anionic vinyl polymerization in which $DP_n = [M]_0/[I]_0$, molecular weight distribution is close to Poisson distribution and the nature of end-groups may be strictly controlled. As will be discussed in subsequent sections, conditions of living polymerization may be more closely approached if polymerization proceeds by the AM mechanism.

4.08.1.4 Elementary Reactions in Cationic Polymerization of Cyclic Ethers

4.08.1.4.1 Initiation

There are three possible routes of initiation of cyclic ether polymerization, by:



Scheme 6

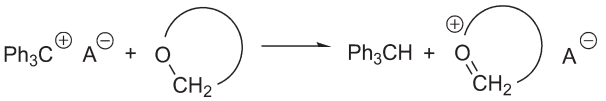
1. direct addition of initiator to monomer molecule;
2. abstraction of hydride ion (H^-) from monomer molecule; and
3. formation of zwitterions between monomer and initiator.

Most commonly initiation proceeds as direct addition of initiator to monomer molecule (route 1). Cationic polymerization of cyclic ethers may be initiated by both Bronsted and Lewis acids. Most commonly used initiators include strong protic acids such as trifluoromethanesulfonic (triflic) acid (also its anhydride or esters), fluorosulfonic acid, perchloric acid, or heteropolyacids, oxonium salts such as triethyloxonium (e.g., $Et_3O^+A^-$), carbenium (e.g., $Ph_3C^+A^-$), or carboxonium (e.g., $C_6H_5CO^+A^-$) salts where A^- should be stable, weakly nucleophilic counterion (e.g., BF_4^-, PF_6^-, and SbF_6^-) or Lewis acids (most commonly used is $BF_3 \cdot Et_2O$). Several other initiation systems have been used (e.g., rare earth triflates) but the advantages over typically used simple and easily available initiators have not always been shown.

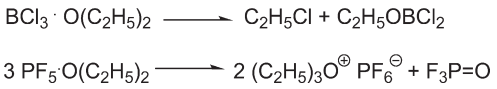
The mechanism of initiation is relatively simple in the case of initiation by protic acids. There is a fast protonation of monomer molecule with formation of secondary oxonium ion followed by reaction of this ion with another monomer molecule forming tertiary oxonium ion. This step may be slower than subsequent propagation steps because reactivity of secondary oxonium ions is generally lower than that of tertiary oxonium ions (Scheme 7).

Oxonium, carbenium, or oxocarbenium salts generate tertiary oxonium ions in single step, as shown in Scheme 8 for initiation with triethyloxonium salt.

Some carbenium salts that form sterically hindered addition product, that is, triphenylmethylium (trityl) salts may initiate through hydride ion abstraction as shown in Scheme 9 (route b).[19,20] Oxocarbenium ions thus formed serve as actual



Scheme 9



Scheme 10

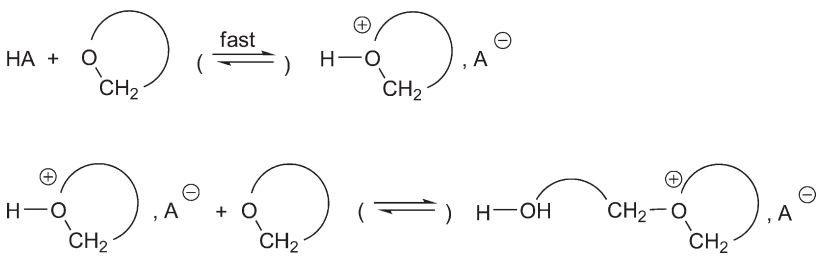
initiator (although proton expulsion and formation of double bonds is also possible).

Less obvious is the mechanism of initiation in the case of Lewis acid initiators. First of all, the behavior of different Lewis acids in similar systems may be different. Thus, complexes of BF_3 with ethers are stable while BCl_3 may react with ethers[21] and complexes of PF_5 with ethers may undergo disproportionation (Scheme 10).[22]

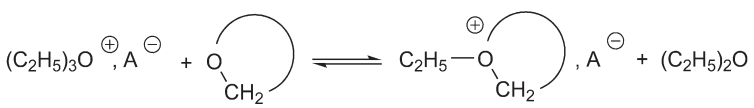
There is no evidence supporting the view that the most commonly used Lewis acid, that is, BF_3 (typically as a complex with Et_2O) may generate ionic species directly. Thus, it is generally accepted that the presence of coinitiator is necessary and (unless coinitiator is purposely added) this role is most often played by adventitious water. In a related system, that is, in the cationic polymerization of cyclic acetals, it was conclusively proved that if water is rigorously excluded, BF_3 does not initiate polymerization.[23] In less thoroughly dried systems, addition of a proton trap effectively prevented initiation by BF_3.[24]

It has been claimed, however, that some of the cyclic ethers, particularly the strained ones, may directly produce a zwitterion with a tertiary oxonium ion at one of its ends, when initiated with BF_3, as shown in Scheme 11.[25]

It has also been claimed that PF_5 may directly initiate polymerization of THF and, on the basis of ^1H and ^{31}P NMR



Scheme 7



Scheme 8

Scheme 11

spectra, formation of transient zwitterions has been postulated.[26] On the other hand, BF_3 forms a complex with THF which does not initiate the polymerization of THF in the absence of coinitiator.[27]

4.08.1.4.2 Propagation

As already discussed, propagation in cationic polymerization of cyclic ethers by the ACE mechanism proceeds on tertiary oxonium ion active species. Ionic species in general may exist in the form of ion-pairs (contact or solvent separated) and free ions. The fraction of each form is governed by a corresponding equilibrium constant that depends on the polarity of the medium. The knowledge of the fraction of different ionic forms, which is essential for the proper analysis of kinetics of anionic vinyl polymerization in which different forms show different reactivity, is less crucial in analyzing the kinetics of cationic polymerization of cyclic ethers because available data point out to equal reactivity of ion-pairs and free ions in propagation.

This has been shown for cationic polymerization of five-membered THF[28,29] and seven-membered oxepane.[30] The difference between situations encountered in anionic vinyl polymerization and cationic polymerization of cyclic ethers stems from the solvating ability of the latter class of monomers. Cyclic ethers solvate cationic centers and solvation of free oxonium cation is much stronger than solvation of ion-pairs, which provides a counterbalance for the inherent differences in reactivity of different ionic species.

Analysis of polymerization kinetics and the determination of the true values of propagation rate constants require the knowledge of the concentration of growing species. If it can be proved that initiation is fast and quantitative (e.g., by showing that $DP_n = ([M]_0 - [M]_t)/[I]_0$), the concentration of active species may be simply taken as equal to the starting concentration of the initiator. The concentration of active species can also be measured. It should be noted that propagation rate constants in the cationic polymerization of cyclic ethers are relatively low (in the range 10^{-4} to $1\,mol^{-1}\,l\,s^{-1}$); thus, to achieve reasonable rates of polymerization, the concentration of active species is typically much higher (at the level 10^{-4}–$10^{-2}\,mol\,l^{-1}$) than that in the cationic vinyl polymerization.

In the cationic polymerization of THF, the concentration of active species was measured by capping the growing chain with sodium phenoxide and the determination of phenoxy groups in polymers by UV spectroscopy.[31] More general methods have been developed in the Lodz group.[32,33] Active species of cationic polymerization of cyclic ethers (and other heterocyclic monomers) were trapped by reaction with tertiary phosphine. It was shown that oxonium ions are fast and irreversibly converted to corresponding phosphonium ions that could be quantitatively analyzed by ^{31}P NMR using a known excess of phosphine as an internal standard without the need for polymer isolation. The principle of the method, which allows determination not only of concentration but also of the structure of active species, is outlined in Scheme 12.

Concentration: integration of signal of R-$P^+(Ph)_3$ vs $P(Ph)_3$
Structure: ^{31}P NMR chemical shift of R-$P^+(Ph)_3$

Scheme 12

For several monomers, propagation rate constants have been determined (the extensive list can be found in Reference 3). For polymerization of THF, the values between 3×10^{-3} and $1 \times 10^{-2}\,mol^{-1}\,l\,s^{-1}$ are given by different authors for different conditions for polymerization of oxepanes values between 10^{-4} and $10^{-5}\,mol^{-1}\,l\,s^{-1}$ and for polymerization of oxetanes values between 10^{-1} and $1\,mol^{-1}\,l\,s^{-1}$ (at 0 °C in different solvents at different monomer and initiator concentrations).

4.08.1.4.3 Termination

Due to the lower reactivity of oxonium ions and the basic character of monomers, chain transfer (other than chain transfer to polymer) and/or termination is less critical in CROP of cyclic ethers than in vinyl polymerization (either cationic or anionic). The best documented system not involving any termination is polymerization of five-membered THF in the presence of stable counterions (SbF_6^-, AsF_6^-, and PF_6^-) or noncomplex anions like $CF_3SO_3^-$ for which recombination occurs but is fully reversible. For these systems, the DP is equal to the calculated value up to the high DP_n values.[29,34]

$$DP_n = ([THF]_0 - [THF]_e)/[I]_0 \qquad [7]$$

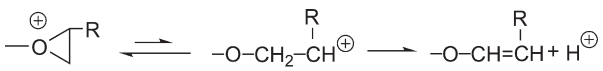
The H^+ transfer, that is a typical route of transfer in cationic vinyl polymerization, is not important in the polymerizations proceeding with the participation of tertiary oxonium ions as active species. This type of transfer may, however, occur in special cases where the presence of carbenium ions cannot be excluded. Such situations may appear in the cationic polymerization of suitably substituted oxiranes when the presence of low concentration of carbenium ions in equilibrium with oxonium ions has been postulated (Scheme 13).

Unsaturated end-groups were indeed observed in cationic copolymerization of nitroglycidyl ether or ECH with THF.[35]

4.08.1.5 Macrocyclization in the CROP of Cyclic Ethers

In CROP, electrophilic active centers can react with heteroatoms in their own chains. This reaction, called 'backbiting', leads to the formation of cyclic oligomers. Formation of cyclic oligomers is a reversible process; monomers and macrocycles react with active centers in a similar way.

Competition between backbiting and propagation depends on the relative nucleophilicity of oxygen atoms in monomer and polymer units. In the polymerization of EO, the basicity of the polymer unit is higher than that of the monomer (cf. Section 4.08.1.2); thus, macrocyclization proceeds concurrently with propagation, and formation of cyclic oligomers cannot be avoided in the polymerization



Scheme 13

proceeding by the ACE mechanism. On the other hand, in the cationic polymerization of THF, the basicity of oxygen in polymer units is considerably lower than that of oxygen in monomer molecules. Therefore, cyclization by backbiting is relatively slow as compared to propagation. Thus, in cationic polymerization of THF, there is a kind of window when high conversion is already attained but the concentration of macrocyclics is still negligible. If polymerization is terminated at this stage, a linear polymer free of cyclic fractions may be obtained. If, however, the system is kept nonterminated for a prolonged period of time, a build-up of cyclic fractions is gradually observed until a final equilibrium distribution of cyclic and linear polymer is attained.[36] Thus, this system provides a good example of the distinction between the kinetic and thermodynamic distribution of cyclic and linear fraction in CROP. Unfortunately, cationic polymerization of THF is rather an exception. In the polymerization of oxiranes or oxetanes, the kinetic factor does not disfavor backbiting and cyclic oligomers are formed parallel to the formation of linear polymer.

What factor governs the distribution of cyclic and linear fractions? Distribution of unstrained cyclic oligomers in equilibrium is described by the dependence

$$[M_n] = A \times n^{-5/2} \qquad [8]$$

(where n is a polymerization degree and A is preexponencial factor) derived theoretically by Jacobson and Stockmayer (JS theory) for polymers with unperturbed chain conformation.[37] The JS theory describes an idealized situation because it assumes that all macrocycles are strainless and that polymer chain conformation is described by Gaussian statistics. For some systems in CROP, distribution of cyclic oligomers close to that predicted by the JS theory was indeed observed. This is the case of cationic polymerization of cyclic siloxanes[38] and cyclic acetals[39] because in those systems, due to the flexibility of polymer chains, deviations from the assumptions of the JS theory are relatively small.

In most systems, however, more complicated situations are encountered. Due to different strains of rings in cyclic oligomers, their distribution is different from that predicted by the JS theory and those oligomers that may assume conformation minimizing the strain are preferentially formed. This is the case of cationic polymerization of oxiranes. In the polymerization of oxirane (EO), predominantly six-membered cyclic dimer (1,4-dioxane) is formed.[40,41] Polymerization of substituted oxiranes yields products containing not only the cyclic dimers but also higher cyclic oligomers. This was observed for polymerization of methyloxirane (propylene oxide),[42,43] (chloromethyl)oxirane (ECH),[42,44] 2,2-dimethyloxirane (isobutylene oxide),[45] or phenyloxirane (styrene oxide)[46] where mainly cyclic trimers or tetramers were observed.

4.08.2 CROP of Oxiranes

4.08.2.1 Mechanism of Polymerization

The mechanism of cationic polymerization of three-membered cyclic ethers (oxiranes) was studied mostly in the 1960s and 1970s and the major findings have been summarized in several monographs and reviews published since then.[1–12] Thus, in this chapter, the basic features of CROP of oxiranes will be outlined only briefly and then the recent developments, mainly related to various synthetic applications, will be presented.

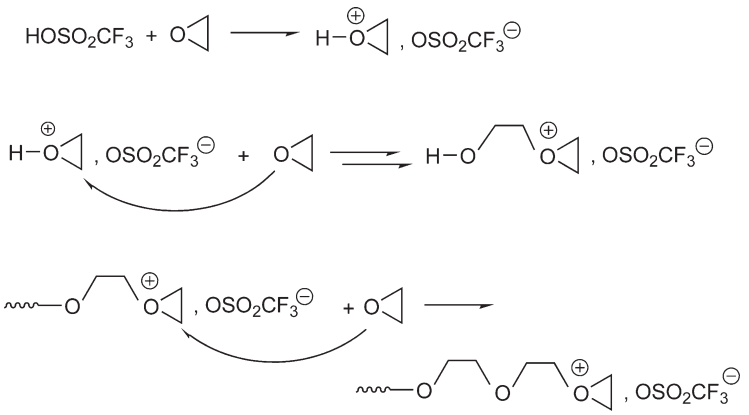
Three-membered rings are highly strained; ring strain arises because it is not possible for the atom orbitals to overlap at their optimum angles in rings composed of only three atoms. Thus, ring strain for EO is equal to 26.8 kcal mol^{-1}.[47–49] Due to relatively large ring strain, the enthalpy factor significantly outweighs the entropy factor in the equation $\Delta G = \Delta H - T\Delta S$ and polymerization of oxiranes is practically irreversible.

CROP of oxiranes may be initiated by typical cationic initiators including strong protic acids (e.g., $HOSO_2CF_3$), Lewis acids (e.g., BF_3 and its complexes), or oxonium salts (e.g., R_3O^+, A^-).

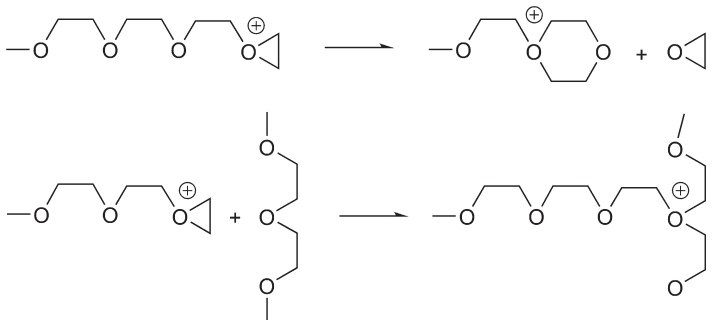
Of practical importance is photoinitiated cationic polymerization of oxiranes, this subject will be discussed in more detail later on in this section.

Secondary or tertiary oxonium ions formed upon initiation react with another monomer molecule generating tertiary oxonium ions as growing species as shown schematically for polymerization of EO initiated by $HOSO_2CF_3$ (**Scheme 14**).

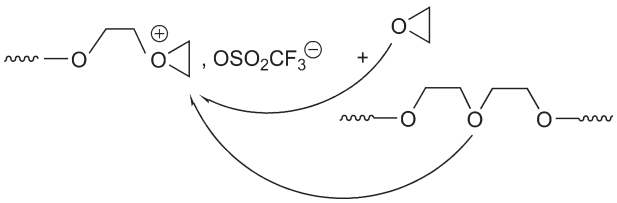
Propagation proceeds by nucleophilic attack of an oxygen atom in a monomer molecule on a carbon atom in α-position to an oxygen atom bearing formally the positive charge in tertiary oxonium ion located at the chain end. Such a mechanism is known thus as ACE mechanism.



Scheme 14



Scheme 15



Scheme 16

The oxiranium cation has not been observed directly. It has been shown, however, on the basis of ^{1}H and ^{13}C NMR spectra that the strained oxonium ion is partly converted into a less strained oxonium ion involving a six-membered ring and to a strainless branched oxonium ion (**Scheme 15**).[50]

In CROP of cyclic ethers, a nucleophilic center (oxygen atom) is also present in a polymer chain. Therefore, the attack of this oxygen on the carbon atom in the growing center may occur and compete with propagation, as shown in **Scheme 16**.

As discussed in the previous section, the competition between propagation and chain transfer to polymer is governed mainly by the nucleophilicity of oxygen atoms in cyclic and linear structures (with a possible contribution of steric effects). Thus, chain transfer to polymer is important in the case of CROP of cyclic ethers. The intermolecular reaction leads to segmental exchange ('scrambling') while the intramolecular reaction leads to cyclization. The intramolecular reaction is especially pronounced in CROP of three-membered cyclic ethers because the basicity of the polymer unit is higher than that of the cyclic oxirane monomers (cf. Section 4.08.1.2). Cyclization of oxirane may occur at the stage when the product is a strainless cyclic dimer (1,4-dioxane). Cationic polymerization of unsubstituted oxirane (EO) leads to a mixture of rather low-molecular-weight linear polymer and cyclic oligomers (predominantly cyclic dimer, i.e., 1,4-dioxane).[40,41] Similar behavior was observed for monosubstituted oxiranes such as PO[42] or ECH,[44] although in those cases cyclic trimers or tetramers were the main components of cyclic fraction. Therefore, CROP of oxiranes proceeding by the ACE mechanism is of little synthetic value for the synthesis of high-molecular-weight polymers, although the tendency to cyclization has been ingeniously applied in the synthesis of crown ethers. CROP of EO in the presence of suitable cations, due to the template effect, leads to crown ethers of a given ring size in good yields. Thus, in the presence of large Rb^{+} and Cs^{+} cations, the cyclic fraction contains almost exclusively 18-crown-6 (cyclic hexamer), while in the presence of small lithium cation a mixture containing 30% of cyclic tetramer and 70% of cyclic pentamer is formed.[51]

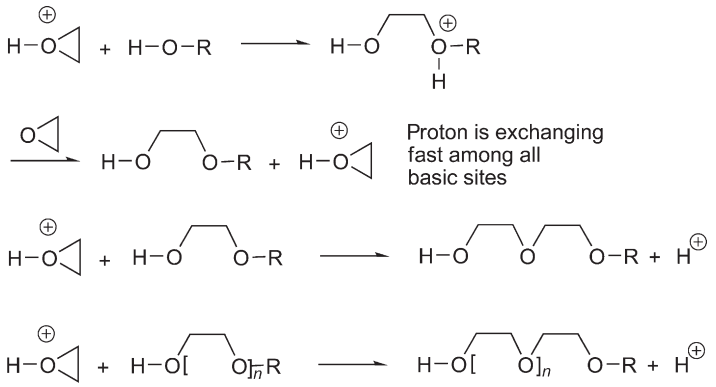
Cyclization by backbiting cannot be avoided if active species of propagation are tertiary oxonium ions located at the chain end. Several years ago, we proposed that if acid-catalyzed polymerization of oxiranes is conducted in the presence of hydroxyl-group-containing compounds, the other mechanism competes with the ACE mechanism. This mechanism is based on the established mechanism of acid-catalyzed hydrolysis of oxiranes.[52] In analogy to the hydrolysis mechanism, if an excess of oxirane (e.g., EO) is present, successive reactions of protonated monomer molecules with hydroxyl groups lead to extension of the chain as shown in **Scheme 17**.[53]

According to this mechanism, charged species are protonated (activated) monomer molecules, thus the term 'activated monomer mechanism' has been applied in analogy to the term introduced by Szwarc and Bamford for anionic polymerization of *N*-carboxyanhydrides (NCA).[54] It should be noted that in polymerization proceeding by the AM mechanism, hydroxyl-group-containing compounds act as initiators, being incorporated into polymer chains as end-groups, while strong protic acids are catalysts. It should also be stressed that introduction of hydroxyl-group-containing compounds does not simply shift the mechanism of polymerization from ACE mechanism to AM mechanism. In the absence of intentionally added hydroxyl-group-containing compounds, the only propagation reaction possible is reaction of protonated monomer with another monomer molecule leading to the formation of tertiary oxonium ion on which further propagation proceeds by ACE mechanism (in fact, some hydroxyl end-groups are formed as a result of initiation, but their concentration is low as compared to concentration of monomer).

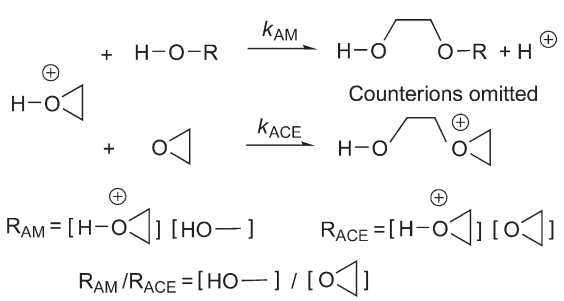
When a hydroxyl-group-containing compound is introduced into the system, protonated monomer may react either with monomer or with hydroxyl group as shown in **Scheme 18** for polymerization of EO.

Competition between ACE and AM mechanisms in CROP of oxiranes was discussed in a series of original papers[55,56] and reviews;[9,53,57] therefore, in this chapter, only a general picture will be presented.

The contribution of two competing reaction pathways depends on the ratio of corresponding rate coefficients and the ratio of concentrations. Rate coefficients depend on nucleophilicity of both competing nucleophiles, that is, hydroxyl groups and cyclic ether. Although the pK_B values reported in the literature differ depending on the measurement method, it



Scheme 17



Scheme 18

may be estimated that basicities of hydroxyl groups and cyclic ethers are not much different. Indeed for CROP of ECH, the ratio of k_{AM}/k_{ACE} was found to be close to 5.[58] Because in AM polymerization, hydroxyl-group-containing compound (R–OH) is an initiator, the DP (if side reactions were excluded) should be equal to $DP_n = [M]_0/[I]_0$ (where M denotes cyclic ether and I denotes R–OH). At the conditions when $[M] \gg [I]$ required for the formation of polymer, the AM-type of propagation may play only a minor role considering that k_{AM} is not very much higher than k_{ACE}.

Suitable conditions for AM-type polymerization may be created, however, by applying the overall ratio of [M]/[I] high enough to allow the formation of polymer chain with desired length, but at the same time keeping instantaneous concentration of monomer low to ensure low instantaneous ratio of [M]/[I]. Thus, polymerization should be conducted by slow feeding of monomer to reaction mixture, that is, at monomer-starved conditions.

What are the advantages of conducting CROP of oxiranes by AM mechanism? First of all, because there is no charged species at the growing chain ends, chain transfer to polymer is eliminated and linear polymers free of cyclic fraction may be formed. This was shown conclusively for polymerization of EO, PO, and ECH. In **Table 3**, the dependence of content of cyclic dimer on [EO]/[HO^-] ratio is shown.[59] The same effect was observed for polymerization of PO (**Table 4**).[60]

Secondly, hydroxyl-group-containing compounds, acting as initiator, are incorporated into chain ends. As shown in **Scheme 19**, depending on the nature of initiator, different types of functional polymers can be obtained.

Table 3 Yield of 1,4-dioxane formed in the oligomerization of ethylene oxide (EO) in the presence of CH_3OH

Telechelic oligodiols and macromonomers with M_n close to calculated values, narrow-molecular-weight distribution, and required functionality were prepared by AM CROP of PO and ECH.[59–62]

Block or star copolymers can be obtained by AM polymerization if polymers containing hydroxyl groups are used as macroinitiators. Application of poly(ethylene glycol) as initiator in cationic AM polymerization of glycidyl methacrylate (GM) led to block copolymers containing hydrophilic poly(oxyethylene) block and poly(GM) block in which methacrylic double bonds were fully preserved. The resulting amphiphilic block copolymers formed core-shell micelles in water that could be stabilized by cross-linking involving double bonds of poly(GM) block.[63]

Cationic AM polymerization of EO initiated by a multihydroxy core obtained by cationic polymerization of 3-ethyl-3-(hydroxymethyl)oxetane (as described in Section 4.08.3.3) in the presence of acid catalyst allowed preparation of star polymers.[64]

Although polymerization of oxiranes by the AM mechanism offers several advantages, there are also some limitations. Instantaneous [M]/[HO] ratio should be kept low thus monomer should be fed slowly into reaction mixture. The reaction is, therefore, slow and to achieve higher molecular weights, long reaction times are required. Moreover, the proton from a catalyst is exchanged quickly between all basic sites and only its fraction participates in the activation of the monomer. At the

Table 4 Influence of instantaneous monomer concentration (PO) on the amount of cyclic tetramer formed.

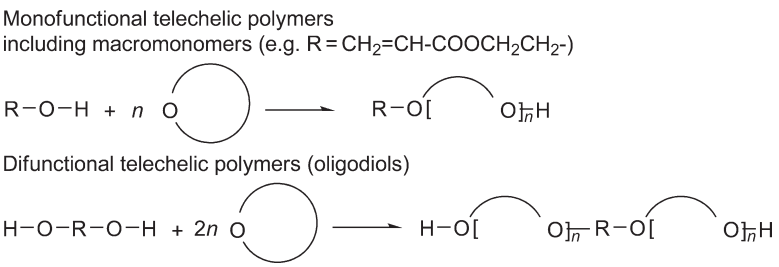


Scheme 19

early stages, proton is involved in protonation of HO groups and oxygen atoms in monomer molecule, while in the later stages an increasing fraction of protons is involved in protonation of oxygen atoms in the polymer chain thus the fraction of protons activating monomer decreases in the course of polymerization. For these reasons, AM CROP of oxiranes is a suitable method of synthesis of medium-molecular-weight telechelic polymers (M_n up to $\sim$5000) rather than high-molecular-weight polymers.

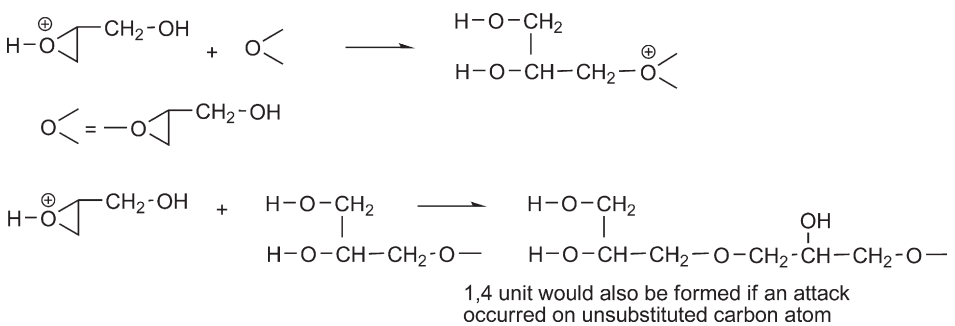
If both functions, that is, oxirane group and hydroxyl group, are present in the same molecule than propagation by AM mechanism leads to branched structures.[65] The simplest monomer of this class is (hydroxymethyl)oxirane (glycidol). Polymerization of glycidol by ACE mechanism should lead to polymers composed entirely of 1,3-units. Analysis of ^{13}C NMR spectra of the relatively high-molecular-weight polymers (M_n up to 10^4) prepared with $HPF_6 \cdot Et_2O$ as a catalyst in bulk revealed the presence of both 1–4 and branched units providing direct proof for the participation of the AM mechanism. It was not possible, however, to resolve sufficiently the ^1H and ^{13}C NMR spectra and to thus obtain quantitative information on the relative contributions of both the mechanisms.[66]

The formation of 1–4 units (containing secondary hydroxyl groups), resulting from AM propagation, was confirmed, however, by analysis of ^{29}Si NMR spectra of a silylated polymer (**Scheme 20**). In subsequent attempts to analyze the contributions of the AM and ACE mechanisms in the polymerization of glycidol, it was observed that the structure of the polymer formed depends to some extent on the nature of the catalyst.[67] The content of 1–3, 1–4, and branched units was measured by ^{13}C and ^{29}Si NMR, and on this basis the following contribution of the AM mechanism was estimated: $SnCl_4 \sim 80\%$, $BF_3 \cdot Et_2O \sim 50–70\%$, and $CF_3SO_3H \sim 50\%$.

Hyperbranched polyethers were also obtained by cationic copolymerization of glycidol with alkyl glycidyl ethers.[68]

Glycidol polymerizes also by anionic mechanism. Anionic polymerization leading to hyperbranched multihydroxyl polyethers has been studied extensively and possible applications of polymers obtained by anionic polymerization have been indicated.[69–71]

Properties of hyperbranched polyethers prepared by cationic polymerization of glycidol have also been studied. Cationically prepared polyglycidol after esterification of hydroxyl end-groups with palmitoyl chloride showed an interesting self-assembly behavior. Depending on the solvent and content



Scheme 20

of hydrophobic arms, regular unimolecular micelles or vesicles of different size were observed.[72] Block copolymers containing polystyrene (formed by atom transfer radical polymerization (ATRP)) and polyglycidol block (formed by cationic polymerization) in combination with lithium salts have been applied as polymer electrolytes.[73]

Although anionic polymerization of glycidol leading to hyperbranched multihydroxyl polyethers, as reviewed recently,[71] has been studied much more extensively than the cationic process, cationic polymerization of hydroxyl-group-containing cyclic ethers provides a more general approach to the synthesis of branched multifunctional polyethers because, as discussed in Sections 4.08.3.3 and 4.08.4.3, it may be extended to four- and five-membered cyclic ethers that polymerize only by cationic mechanism.

4.08.2.2 Cationic Photopolymerization of Oxiranes

Photopolymerization of various classes of monomers is covered in more detail in Chapter 4.37; therefore, in this section, only the major findings related specifically to oxirane photopolymerization are briefly outlined.

The advantage of photoinitiated cationic polymerization is its lack of sensitivity to atmospheric oxygen and substantial dark polymerization, that is, the chain reaction continues to proceed effectively after UV exposure is terminated, due to the fact that the propagating polymer cations, in contrast to radicals, do not mutually react. On the other hand, the rate of cationic photopolymerization of difunctional epoxides is by 1 order of magnitude lower than that of radical photopolymerization of diacrylate monomers, most probably because of a lower propagation rate constant.[74] Nevertheless, in recent years, cationic photopolymerization of oxiranes have found many applications, for example, in coatings, adhesives, and printing inks.[75]

Cationic photopolymerization is typically initiated by onium salts, for example, diaryliodonium salts $Ar_2I^+ MtX_n^-$ or triarylsulfonium salts Ar_3S^+, MtX_n^- ($MtX_n^- = PF_4^-$, BF_6^-, SbF_6^-, etc.). The irradiation of photoinitiator generates a number of reactive species that subsequently react with solvent or monomer to give protonic acid $HMtX_n$.

Although in photocurable formulations, difunctional oxirane derivatives are employed; for mechanistic studies, monofunctional oxiranes are used including cyclohexene oxide, styrene oxide, or phenyl glycidyl ether. These studies indicate that the cationic polymerizations proceeding as a result of photoinitiation by onium salts have typical characteristics of polymerizations initiated by strong protonic acids. Thus, initiation involves protonation of oxirane ring while propagation proceeds on tertiary oxonium ions as active species, that is, by the ACE mechanism.[76,77]

Photoinitiated cationic polymerization may also proceed by the AM mechanism if an HO-containing compound is present in the system. AM polymerization of cyclohexene oxide was used to prepare polymer/clay nanocomposite by photopolymerization of cyclohexene oxide in the presence of montmoryllonite modified with ammonium salts containing $-CH_2CH_2OH$ groups and $(Ph)_2I^+ PF_6^-$ as photoinitiator. Upon irradiation protic acid was formed that catalyzed AM propagation on HO groups. As a result, polymer chains were attached to clay surfaces and exfoliated structures were obtained.[78]

AM photopolymerization of epoxy monomers bearing hydroxyl groups has also been studied. In analogy to the earlier described AM polymerization of simplest monomer of this class, that is, glycidol, AM photopolymerization of cyclohexene oxide and norbornene oxide substituted with hydroxyl group led to highly branched polyethers containing several hydroxyl end-groups. The rates of photopolymerization of those monomers were significantly higher than the rates of photopolymerization of analogous epoxy monomers bearing methoxy groups, which was attributed to inherently more rapid kinetics of the AM mechanism that the former monomers undergo as compared to the conventional epoxide ROP for the latter compounds.[79]

4.08.3 CROP of Oxetanes

4.08.3.1 Mechanism of Polymerization

In contrast to three-membered cyclic ethers, oxiranes, and four-membered cyclic ethers, oxetanes polymerize only by cationic mechanism (although anionic polymerization of oxetanes has been occasionally reported[80]). Polymerization of oxetanes, due to the relatively high ring strain is practically irreversible.

First reports on the cationic polymerization of oxetanes appeared in the open literature in the 1950s,[81,82] but the process had been studied earlier because at that time Hercules Inc. had developed the industrial production of polymer of 3,3-bis (chloromethyl)oxetane (poly-BCMO) and had been marketing the polymer for about 15 years under the Trade Name Penton®.

On the basis of studies of the parent monomer of this class (unsubstituted oxetane), the basic features of cationic polymerization of oxetanes (including substituted oxetanes) have been established. Typically, polymerization was initiated by BF_3 (in the form of complex with, e.g., Et_2O) and the necessity of water cocatalysis was well documented.[81–86]

Another system especially suited for the synthesis of high-molecular-weight poly(BCMO) is the R_3Al/H_2O initiating system.[87–89] Kinetic studies revealed that for this system the rate of polymerization increases by increasing the ratio $[H_2O]/[R_3Al]$ up to 1/1. This indicates clearly that polymerization is initiated by protic acid generated by interaction of water with Lewis acid.

Cationic polymerization of oxetanes provided examples of the influence of the number and size of substituents on the tendency to cyclization. The steric hindrance caused by the presence of substituents can make it more difficult for the macromolecule to assume conformation suitable for the ring closure. Thus, in the cationic polymerization of unsubstituted oxetane, up to 50% of cyclic tetramer was formed (at 100 °C with $BF_3 \cdot Et_2O$ initiator). The content of cyclic fraction was lower at lower temperatures.[82] In the polymerization of 3,3-dimethyloxetane, the content of cyclic fraction was considerably lower (~20%).[90] In the polymerization of 3,3-bis-(chloromethyl)oxetane containing still larger substituents, only 2% of cyclic oligomers were formed in polymerization initiated with the R_3Al/H_2O system even at high temperature (180 °C).[91]

Cyclization occurs by intramolecular chain transfer to polymer. Intermolecular reaction leads to the formation of branched polymeric tertiary oxonium ion of low reactivity,

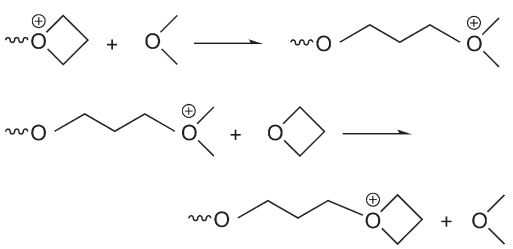
thus such a reaction leads to termination. Although the two possible modes of chain transfer to polymer (intra- or intermolecular reaction) are not necessarily related, in the cationic polymerization of oxetanes for those groups of monomers that have stronger tendency to cyclization, generally lower molecular weights of linear fraction were observed. Thus, in the polymerization of unsubstituted oxetane, polymers with M_n in the range $\sim 3.5 \times 10^4$ and broad-molecular-weight distribution were obtained at −20 °C[92] while in polymerization of 3-methyl-3-(chloromethyl)oxetane and BCMO initiated with a R_3Al/H_2O system polymers with M_n exceeding 5×10^5 and $M_w/M_n < 1.3$ could be prepared.[88,89]

More recently, cationic polymerization of oxetane has been studied in the presence of an ether additive that converts strained tertiary oxonium ion active species into strain-free tertiary oxonium ion (dormant species) that may be reactivated by monomer addition as shown in **Scheme 21**.[93–95]

The concept of polymerization involving reversible deactivation of growing species had been applied earlier to a number of systems in the field of radical as well as ionic polymerization. The authors stress that "unlike conventional quasi-living polymerization based on reversible end-capping reactions, the dormant species is reactivated by a monomer addition"[92–94] (the term 'quasi-living' is discouraged in IUPAC terminology). This, however, is not an entirely new concept. In the cationic polymerization of THF in the presence of $CF_3SO_3^-$ counterion, deactivation of growing species occurred by the formation of covalent macroester that could be reactivated mainly by reaction with monomer molecules (see Section 4.08.4.1). Cationic polymerization of oxetane in the presence of a suitable additive (1,4-dioxane, tetrahydropyran) indeed proceeds as a living/controlled process and side reactions resulting from chain transfer to polymer such as cyclization or chain segment redistribution may be eliminated. Polymers with M_n up to 1.6×10^5 and a narrow-molecular-weight distribution ($M_w/M_n = 1.18–1.28$) were obtained.[95]

Cationic polymerization of oxetanes has been more recently exploited to prepare a variety of functional polymer materials including functional polymer networks and energetic binders for solid rocket propellants. Polymerization of BCMO has been studied extensively in the past because of the industrial application of this process. After the production of Penton® was discontinued the interest in polymers of BCMO ensued from the fact that they may serve as a precursor for various functional polyoxetanes.

Polymers used as energetic binders should act not only as a binder but also as a real propellant component. Thus most frequently azido groups having a tendency to highly exothermic decomposition are introduced into a side chain. Oxetane



Scheme 21

polymers are used because by replacement of $-CH_2Cl$ groups in BCMO (or its polymer) two $-CH_2N_3$ groups may be introduced into each repeating unit, which results in a high nitrogen content (50 wt.%), considerably higher than in polymers derived from oxirane derivative, for example, glycidyl azide (42.5 wt.%). Two approaches are used to synthesize azido-group-containing oxetane polymers; azido groups are introduced by the reaction of suitable substituents ($-CH_2Cl$, $-CH_2Br$, and $-CH_2OTs$) in the monomer with NaN_3 (with subsequent cationic polymerization) or in polymer. The disadvantage of the former route is a necessity of handling and storage of azide-containing monomers that are considerably more shock sensitive than the corresponding polymers.[96] Frequently, to decrease crystallinity, other monomer units are introduced along the chain by copolymerization.[97–99]

Side-chain liquid-crystalline polyoxetanes showing smectic polymorphism were obtained by cationic polymerization of oxetanes substituted with two mesogenic groups connected by a flexible spacer.[100]

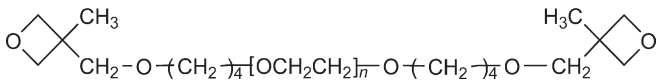
Oxetane polymers containing perfluorinated substituents are also studied. Cationic polymerization of 3,3-bis[(2,2,2-trifluoroethoxy)methyl]oxetane leads to polymers showing oleophobicity that compare favorably with that of more highly fluorinated acrylates.[101]

Telechelic oxetane polymers containing hydroxyl end-groups at both ends were synthesized by cationic polymerization of substituted oxetanes in the presence of diols.[102,103] Although the mechanism of polymerization was not discussed, it may be expected that polymerization proceeded by the AM mechanism. These telechelics containing fluorinated substituents after converting hydroxyl end-groups into ammonium salts showed unusually low surface tensions.[104] Telechelics containing fluorinated and alkylammonium substituents along the chain were also obtained by cationic copolymerization of suitably substituted oxetanes and were incorporated into polyurethanes in order to modify their surface properties.[105]

Oxetanes containing fluorinated substituents are employed for preparation of oligodiols, which may be used for the synthesis of polyurethanes having more hydrophobic surfaces.[106] Oxetanes containing pentafluoropropoxy or heptafluorobutoxy groups in position 3 were polymerized with $BF_3 \cdot Et_2O$ as initiator in the presence of a butandiol giving telechelic polymers with M_n in the range $4–12 \times 10^3$ and rather high polydispersity ($M_w/M_n \sim 2–3$). There was no simple relationship between the reported M_n values and [monomer]/[HO] ratio as observed for polymerization of oxiranes in the presence of HO-containing compounds and proceeds by the AM mechanism which may indicate that some chain transfer and/or termination reaction operate in this system.[103] Characterization of poly(perfluorooxetane)s by matrix-assisted laser desorption/ionization (MALDI) mass spectrometry, size exclusion chromatography, and NMR spectroscopy has been reported.[107]

Dioxetane monomers containing two oxetane rings coupled with short poly(oxyethylene) chains (as shown in **Scheme 22**) were polymerized with $BF_3 \cdot Et_2O$ to network polymers that showed activity as phase-transfer catalysts.[108]

Polymerization of such dioxetanes could be initiated by lithium salts (e.g., $LiN(SO_2CF_3)_2$) giving polyoxetane-lithium salt complexes that could be applied as solid polymer electrolytes.[109]



Scheme 22

4.08.3.2 Cationic Photopolymerization of Oxetanes

Photopolymerization of various classes of monomers is covered in more detail in Chapter 4.37; thus in this section, only the major findings related specifically to oxetane photopolymerization are briefly outlined.

In comparison with epoxides, the photoinitiated cationic polymerization of oxetane monomers is relatively slow and proceeds with an extended induction period.[110] The origin of the induction period is still a matter of discussion.[111] The induction period may be considerably shortened by conducting photopolymerization in the presence of more reactive epoxide monomers. Due to relatively low reactivity of propagating tertiary oxonium ions, photopolymerization of oxetane monomers is rather slow but the polymerization continues during the dark storage of a sample.[112] Cationic photopolymerization of di- and trifunctional oxetanes, including those containing mesogenic groups, proceeds with a low volume shrinkage.[113,114] The volume shrinkage can be further reduced by copolymerization with spiro orthocarbonates.[115] An oxetane monomer, 3-ethyl-3-[(methacryloyloxy)methyl]oxetane, was polymerized by ATRP on the surface of monodisperse silica particles. The polymeric layer thus obtained was cross-linked by cationic polymerization of oxetane groups and after removal of silica core, uniform polymeric hollow spheres were obtained.[116]

Fabrication of solution-processed multilayered organic light-emitting diodes (OLEDs) from oxetane-functionalized precursors, which are commonly photochemically cross-linked by UV radiation in the presence of a photoinitiator, has been reported recently.[117] The reaction proceeds via CROP. Insoluble cross-linked polymer networks were obtained using precursors that contain two or more oxetane units per molecule. This novel approach simplifies OLED fabrication, and is generally compatible with various deposition/printing techniques.

4.08.3.3 CROP of Oxetanes Leading to Hyperbranched Polyethers

Synthesis of highly branched polyethers by cationic polymerization of hydroxymethyl-substituted oxetanes is a relatively recent development, not covered by earlier reviews, therefore this subject will be discussed in more detail.

As discussed in previous section, cationic polymerization of cyclic ethers (e.g., glycidol) containing hydroxyl groups as substituents leads to highly branched multihydroxy polyethers by the process involving propagation by the ACE and AM mechanisms. Polymerization of three-membered glycidol (either cationic or anionic) leads to branched polyethers containing both primary and secondary hydroxyl groups. In contrast, polymerization of oxetane monomers substituted with CH_2OH groups leads to branched polyethers containing exclusively primary hydroxyl groups, irrespectively of contribution of ACE and AM mechanisms. Typical monomers of this class are shown in Scheme 23.

Vandenberg *et al.* reported that cationic polymerization of those monomers leads to branched polymers, but they did not investigate the process in more detail because their interest at that time was in the synthesis of linear polymers.[118] More recently, there has been an increasing interest in the synthesis of highly branched polymers, which in some applications may perform certain functions of dendrimers but being much easier to synthesize.

Studies of cationic polymerization of 3-ethyl-3-(hydroxymethyl)oxetane (EOX), conducted by us[119,120] and by other groups[121,122] showed that this monomer can be polymerized to medium-molecular-weight polymers (molecular weights amounts to few thousands). There seems to be a certain upper limit of molecular weights that can be achieved, although it has been reported that somewhat higher-molecular-weight polymers are formed at higher temperatures.[123]

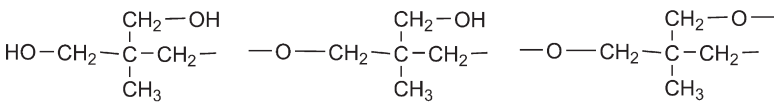
The polymers contain three types of units shown in Scheme 24.

The contents of terminal, linear, and branched units can be determined by ^{13}C NMR. The signals of quaternary carbon atoms in those units (after acetylation of HO groups) are well separated allowing integration. The number of branched units in poly(EOX) is limited. In polymers with DP_n of about 15, there are on an average about three branched units per macromolecule.[119,120] The degree of branching increases with increasing conversion[123] and with increasing temperature.[124] It was shown that in the cationic polymerizatization of 3-ethyl-3-(hydroxymethyl)oxetane

3-alkyl-3-(hydroxymethyl)oxetane

3,3-bis(hydroxymethyl)oxetane

Scheme 23



Terminal unit

Linear unit

Branched unit

Scheme 24

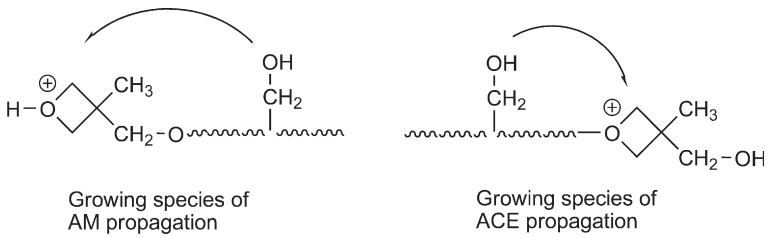
(EOX) M_n of the polymer is essentially independent of conversion. Analysis of MALDI time-of-flight (MALDI-TOF) spectra of polymers revealed that one kind of macromolecules is present and that the molar masses of macromolecules are exact multiples of molar mass of monomeric units.[120] This indicates that the macromolecules are cyclic or contain cyclic fragment. The cyclic fragment may be formed by the reaction of either a protonated oxetane ring or a tertiary oxonium ion with any HO group of the same macromolecule (**Scheme 25**).

Also, 3,3-bis(hydroxymethyl)oxetane (BHMO) polymerizes by cationic mechanism. Every unit in BHMO polymers contains two HO groups; therefore, the probability of branching should be enhanced. Poly(BHMO) is, however, insoluble in common organic solvents, thus the structure of polymer cannot be easily determined. Copolymerization of BHMO with EOX leads to soluble polymers with molecular weights similar to those of poly(EOX), that is, $2–3 \times 10^3$ with a considerably higher fraction of branched units as shown by ^{13}C NMR. MALDI-TOF analysis indicates that also in this system cyclic macromolecules are formed.[125]

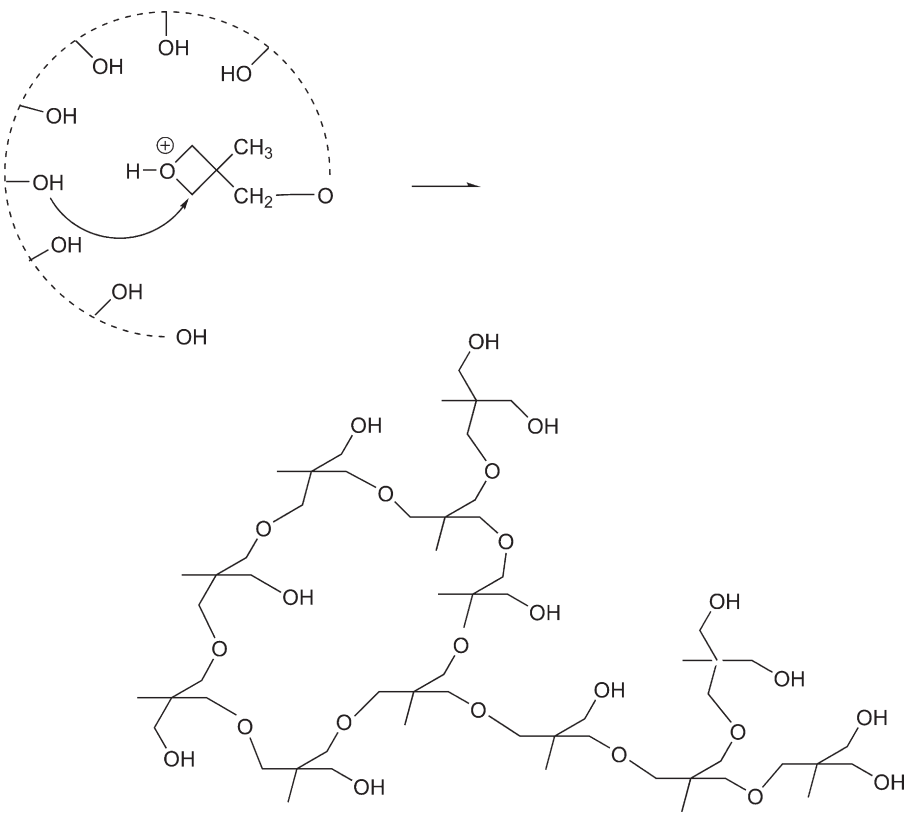
In view of the proposed polymerization mechanism, the fact that M_n is rather low and does not increase with conversion is a little unexpected. Branched units are formed by reactions involving HO groups. The question arises why at a certain stage of growth of macromolecules the HO groups are no longer able to participate in growth of the macromolecule (M_n does not change significantly with conversion).

Analysis of IR and NMR spectra of polymers provided indication of hydrogen bonding of HO groups.[65] Hydrogen bonding may strongly reduce the nucleophilic reactivity of HO groups.[126] With an increasing number of HO-containing units within the macromolecule, intramolecular hydrogen bonding may force the macromolecule into conformation facilitating intramolecular chain transfer to polymer (cyclization) as shown in **Scheme 26**.

Poly(EOX) and its copolymers with BHMO are either amorphous with $T_g \sim 40\ ^\circ C$ (at high degree of branching) or



Scheme 25



Scheme 26

semicrystalline with $T_m \sim 100–130$ °C (at low degree of branching).

Although these materials may find applications that are predicted for hyperbranched polymers, they are used rather as precursors allowing (either by using hydroxyl groups directly or after their transformation into required initiating groups) the synthesis of multiarm star polymers of different structures.[127,128] Star polymers containing poly(EOx) core may also be prepared by a one-pot procedure. Thus, in cationic copolymerization of EOX with THF, EOX polymerized first and, after it was essentially exhausted, the resulting hyperbranched species acted as a macroinitiator and initiated the cationic polymerization of THF.[129] More recently, dumb-bell polymers consisting of linear poly(EO) middle block and two outer branched poly(EOX) blocks were synthesized by bulk cationic polymerization via dropwise addition of EOX to poly (ethylene glycol) (PEG, $M_n \sim 1900$) in the presence of $BF_3 \cdot Et_2O$. Polymers containing up to ~ 14 EOX units per PEG chain were obtained (Scheme 27).[130]

Copolymerization of 3-(hydroxymethyl)-3-methyloxetane (MeOx) with oxetane containing in position 3 the $-[OCH_2CH_2]_3OCH_3$ substituent (MEMO) led to branched polymers with short oligo(ethylene oxide) chains. These materials were tested as potential solid polymer electrolytes.[131]

A one-pot procedure was developed for the synthesis of star polymers containing poly(EOx) core and poly(ethylene oxide),[132,133] poly(propylene oxide)[134] or poly(tetrahydrofuran) (PTHF) arms.[129]

EOX was polymerized first with $BF_3 \cdot Et_2O$ as initiator in CH_2Cl_2 solution. EO was then added dropwise at –20 °C. Star polymers with M_n in the range $1–2 \times 10^4$ and M_w/M_n between 1.5 and 1.9 were obtained. In acetone solution, these products underwent self-organization to multiwalled tubes with diameters of the order of millimeters and lengths of the order of centimeters. In water solution, large vesicles having a high (> 60%) hydrophilic fraction were formed. Star polymers containing poly(propylene oxide) arms also self-assembled into large spherical micelles (> 120 nm) with the size depending on the molar ratio of arms to core.[134] Multiarm star polymers containing poly(EOX) core with different degrees of branching (DB) and polyoxyethylene (POE) arms can self-assemble into vesicles, wormlike micelles, and spherical micelles depending on DB of the core.[135,136]

It was reported recently that hyperbranched multifunctional polyethers can be advantageously used as coatings of capillary columns for separation of proteins showing reduced adsorption of basic proteins and excellent separation efficiency.[137] EOX was also polymerized in the presence of solid materials containing hydroxyl groups on the surface. In this way, hyperbranched polyethers were attached to surfaces of carbon black,[138] carbon nanotubes,[139] or montmoryllonite.[140]

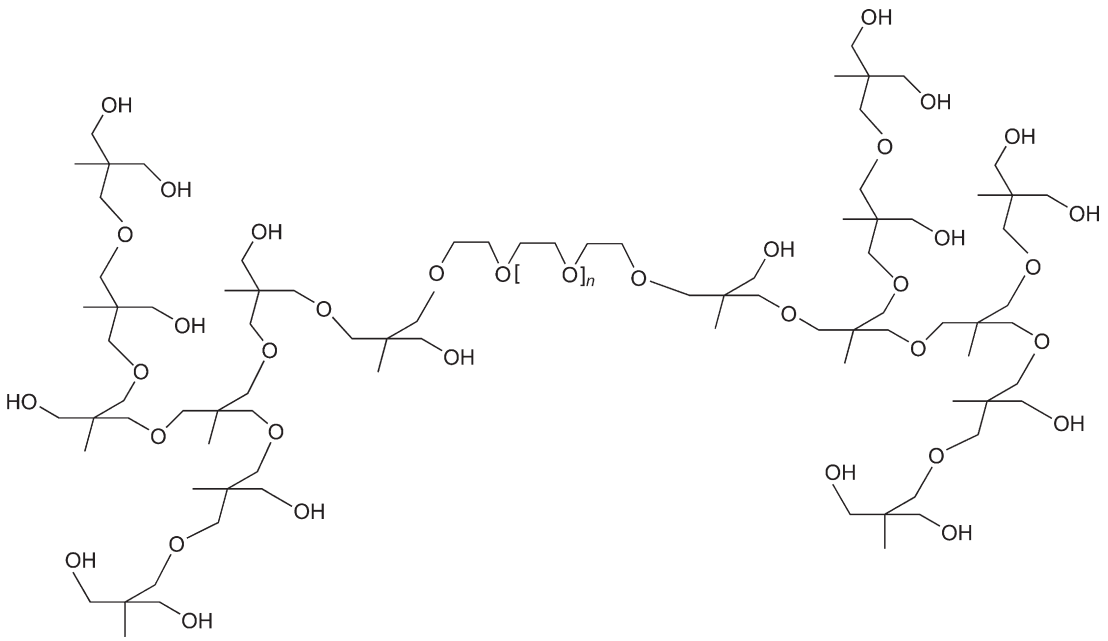
Cationic polymerization of oxetane-containing polymeric precursor obtained by anionic polymerization of 3-ethyl-3-[(oxiranylmethoxy)methyl]oxetane led to ladder polymers containing 15-crown-4 units as shown in Scheme 28.

Gel-free polymers showed the metal binding selectivity similar to 14-crown-4. Possible applications as polymer electrolytes were indicated.[141]

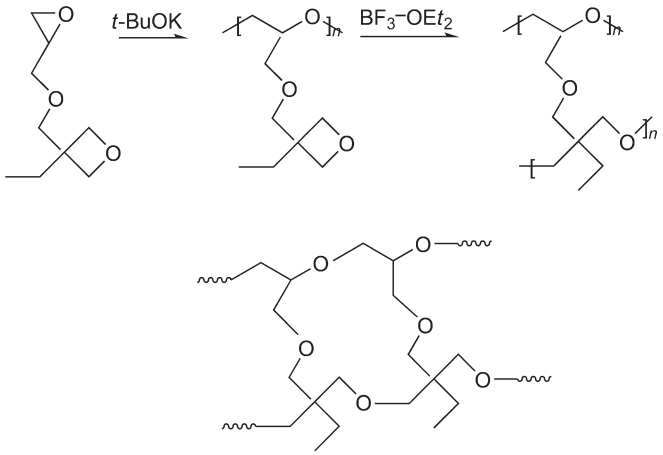
It should be noted that although generally oxetanes polymerize only by a cationic mechanism, there are a few reports on the anionic polymerization of (hydroxymethyl)oxetanes.[142,143]

4.08.4 CROP of THFs (Oxolanes)

Three- and four-membered cyclic ethers are highly strained (ring strain > 20 kcal mol^{-1}) thus their polymerization is practically irreversible. When there are five- and more atoms in the ring, the ring strain is considerably lower; thus polymerization of five- and seven-membered cyclic ethers is highly reversible while six-membered cyclic ethers do not polymerize.



Scheme 27



Scheme 28

Practical consequences of reversibility of propagation have been already discussed (cf. Section 4.08.1.1). They may be summarized as follows:

1. The highest conversion that can be achieved is equal to $([M]_0 - [M]_e)/[M]_0 \times 100\%$. Thus, to reach the highest monomer conversion in reversible polymerization, it should be conducted at high $[M]_0$ and low temperature ($[M]_e$ decreases with decreasing temperature).
2. Active centers of polymerization should be deactivated at the temperature at which polymerization is conducted. Otherwise changes of temperature or concentration in the course of polymer isolation and/or purification may cause depolymerization.

For polymerization of unsubstituted five-membered cyclic ether – THF – the ceiling temperature for bulk polymerization is ~80 °C (the values reported in the literature differ slightly, see Reference 13, p 168), which means that above this temperature THF cannot be polymerized even in bulk. The equilibrium monomer concentration $[M]_e$ at room temperature is close to 3.3 mol l^{-1},[144] but it may vary depending on the solvent. This means that the highest conversion allowed by thermodynamics for bulk polymerization at room temperature is close to 75%.

It should be remembered that the equilibrium constant of propagation is dependent on the chain length becoming constant only after reaching a certain DP_n value. Thus, short oligomers may be still formed at conditions when polymerization to a high-molecular-weight polymer is prohibited by thermodynamics. It should also be remembered that at the conditions when monomer cannot undergo homopolymerization, it may participate in copolymerization.

4.08.4.1 Mechanism of Cationic Polymerization of THF

The discoverer of living polymerization, M. Szwarc, discussed cationic polymerization of THF as an example of living polymerization.[145,146] Indeed, in early studies of this system, it had been pointed out that polymerization may proceed as a terminationless process.[147–150] Thus, cationic polymerization of THF has been studied in detail and many fundamental issues related to the kinetics and mechanism of polymerization of cyclic ethers in general have been resolved on the basis of studies of this system.

In the book *Cationic Ring Opening Polymerization* published in 1985,[5] a whole chapter was devoted to temporary (reversible) termination. Polymerizations proceeding with reversible deactivation of active species are now widely studied because they offer the possibility of controlling molecular weights, molecular weight distribution, and the structure of end-groups in a variety of radical and ionic polymerizations (living/controlled polymerizations).

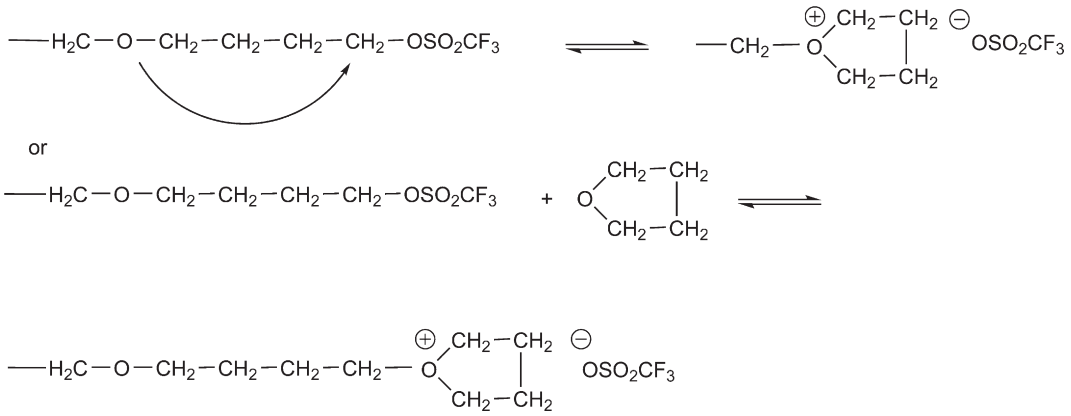
Cationic polymerization of THF provided the first thoroughly studied example of polymerization with reversible deactivation of active species. In the polymerization initiated by trifluoromethanesulfonic acid (or its derivatives such as anhydride or ester), the active species are involved in the following equilibria (**Scheme 29**).[151–156]

Ionic and covalent active species have been directly observed by ^{1}H NMR. Methylene groups in α-position to oxygen bearing a positive charge in ionic species give a triplet at 4.86 ppm (δ) while methylene groups in covalent species ($-CH_2OSO_2CF_3$) give a triplet at 4.58 ppm. Both signals can be independently observed in polymerizing mixture and their fractions depend on the polarity of solvent as shown in **Figure 1**.[151]

In highly polar nitromethane almost exclusively, ionic species are present in moderately polar methylene chloride, both types of species are observed in similar concentrations while in nonpolar tetrachloromethane covalent species predominate with only ~5% of ionic species.

In the original publications, these two routes of ionization were described as internal ionization and covalent propagation (although the latter could also be considered as external ionization).

The full kinetic scheme (**Scheme 30**) including rate constants of ionization and deactivation (temporary termination), rate constants of propagation and all involved equilibrium constants have been resolved, as discussed in detail in several reviews.[1–12]



Scheme 29

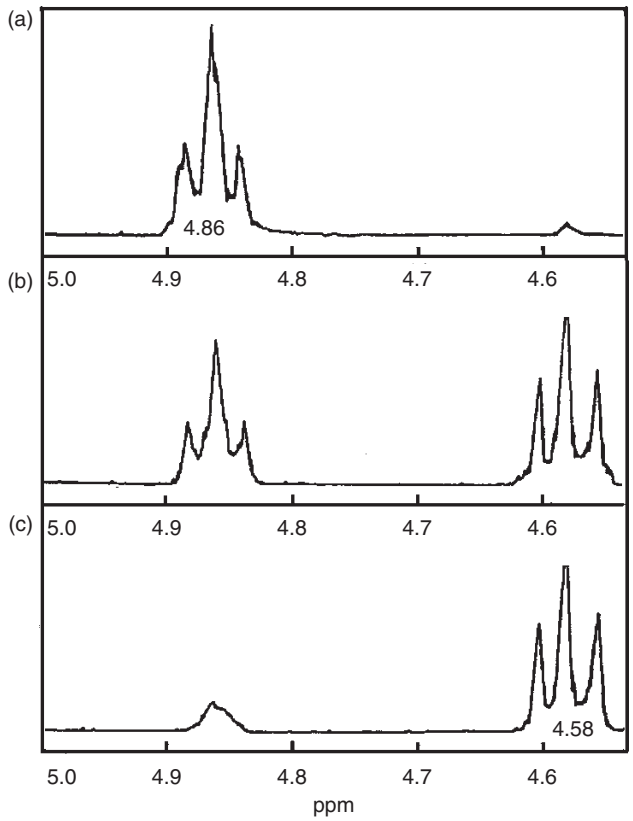


Figure 1 300 MHz ^{1}H NMR spectra (4.5–5.0 ppm region only) of living poly(THF) with $CF_3SO_3^-$ anion at 17 °C. $[M]_0 = 8.0\,mol\,l^{-1}$, $[initiator]_0 = 0.05\,mol\,l^{-1}$ in (a) CD_3NO_2, (b) CH_2Cl_2, and (c) CCl_4. Reprinted with permission from Matyjaszewski, K.; Penczek, S. *J. Polym. Sci. Polym. Chem. Ed.* **1974**, *12*, 1905.[151]

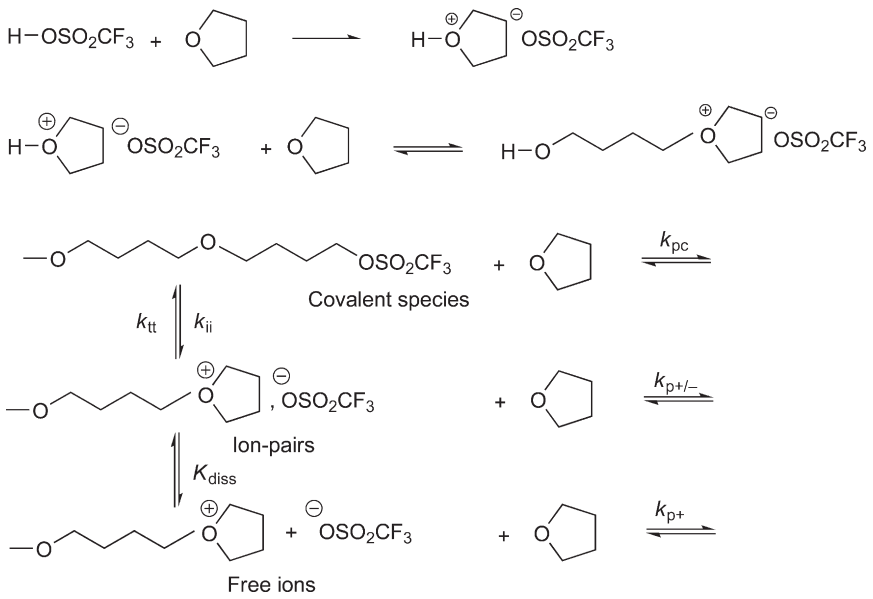
All involved rate constants (and also equilibrium constants) have been determined. For a $7\,mol\,l^{-1}$ solution of THF in CH_3NO_2 at 25 °C, the following values were obtained: $k_{pc} = 5 \times 10^{-4}\,mol^{-1}\,l\,s^{-1}$, $k_{p+/-} = k_{p+} = 2.4 \times 10^{-2}\,mol^{-1}\,l\,s^{-1}$, $k_{ii} = 12 \times 10^{-2}\,s^{-1}$, $k_{tt} = 0.3 \times 10^{-2}\,s^{-1}$.

The major findings can be summarized as follows:

- Ionization of covalent species proceeds predominantly by intramolecular ionization ($k_{ii} \gg k_{pc}$). Covalent species are essentially dormant (k_{pc} is very low) but may be reactivated by intramolecular ionization. Thus, formally the situation resembles that encountered in more recently studied processes of controlled radical polymerization (ATRP and nitroxide-mediated polymerization (NMP)) and the system can be described as polymerization with reversible deactivation of growing species.
- Propagation rate constants for ion-pairs and free ions are the same ($k_p^+ = k_p^{\pm}$); the reactivity of ion-pairs does not depend on the structure of counterion. This is a general feature of



Scheme 30

CROP, in contrast to anionic vinyl and anionic ROP polymerizations.[157,158] In anionic polymerization the charge is localized on the terminal atom while in CROP the charge is delocalized between the oxygen and neighboring carbon atoms in cyclic oxonium ion; thus the interaction of cation and anion is rather weak. Free cations may be more strongly solvated, which may counterbalance the interaction with anion in ion-pair. Additionally, according to the steric course of S_N2 reactions, propagation on ion-pair may not require complete separation of ion-pair. All these factors account for equal reactivity of free ions and ion-pairs in CROP of THF.[28,29] The same reactivity of ion-pairs and free ions was found also for CROP of seven-membered cyclic ethers – oxepanes.[30,159]

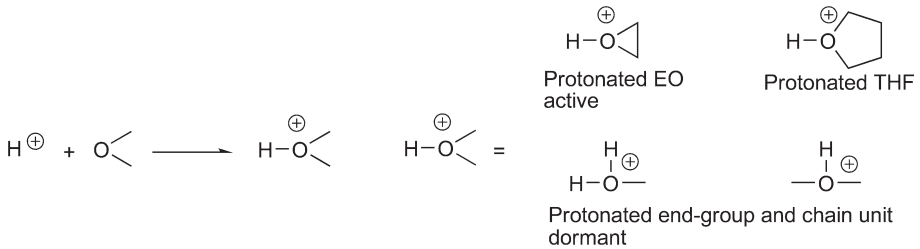
4.08.4.2 Synthetic Applications of Cationic Polymerization of THF

Cationic polymerization of THF proceeds without chain transfer or termination and in principle it can be considered as living polymerization (although it is highly reversible). Thus, this process is well suited for the synthesis of telechelic polymers. Tetrahydrofuran oligodiols (poly(butane-1,4-diol) known under the trivial name poly(tetramethylene glycol) (PTMEG)) are used for the preparation of polyurethanes and polyester thermoplastic elastomers with outstanding hydrolytic stability at elevated temperatures and desirable mechanical properties.[160] The world capacity for PTMEG amounted to $\sim 300\,000\,t\,yr^{-1}$ in 2001 and since then has increased further, mainly due to new production facilities in China (overall China PTMEG capacity has expanded to $230\,000\,t\,yr^{-1}$).[161]

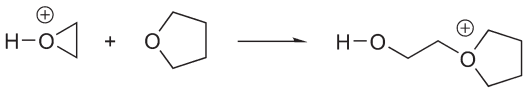
Earlier processes employed strong protic acids (e.g., fluorosulfonic acid) as initiators with subsequent hydrolysis of ester end-groups. Newer processes use catalytic amounts of immobilized acids. THF is polymerized over a heterogeneous catalyst in the presence of acetic anhydride to form polymer diacetate which is converted to PTMEG by transesterification with an excess of methanol in the presence of a basic catalyst. Such an approach reduces considerably the amount of waste. Unreacted THF (being in equilibrium with polymer) is recovered and recycled to the reactor.[162]

It should be pointed out that AM polymerization of THF would be the most straightforward route to poly(THF) diols (PTMEG used in polyurethane and polyester technology). THF, however, does not polymerize in the presence of hydroxyl-containing compounds (alcohols and diols) used in quantities required to obtain polymers with molecular weights in the range of few thousands. At first sight, this seems a little unexpected because strong protic acids (e.g., trifluoromethanesulfonic acid) initiate polymerization of THF, although the initiation is slow as compared to propagation. This may be related to lower reactivity of secondary oxonium ions as compared to tertiary oxonium ion. Initiation with strong protic acids generates HO head groups and further polymerization proceeds in the presence of those hydroxyl groups. It should be pointed out, however, that PTMEG used to introduce soft blocks into polyurethanes or block copolyesters has M_n in the range $1–2 \times 10^3$. To obtain such polymers by AM polymerization, the ratio [THF]/[diol] should not exceed 40 (considering limited conversion of THF due to reversibility of propagation). Thus, the ratio [THF]/[HO] should not be higher than 20, which corresponds to 5 mol.% with respect to THF. In the polymerization initiated by acids, concentration of initiator (and thus concentration of HO head groups) is considerably lower. Thus, cationic polymerization of THF is possible in the presence of minute amounts of HO groups but is prohibited if the concentration of HO groups is in the range that would be needed for AM polymerization giving PTMEG in the required range of molecular weights.

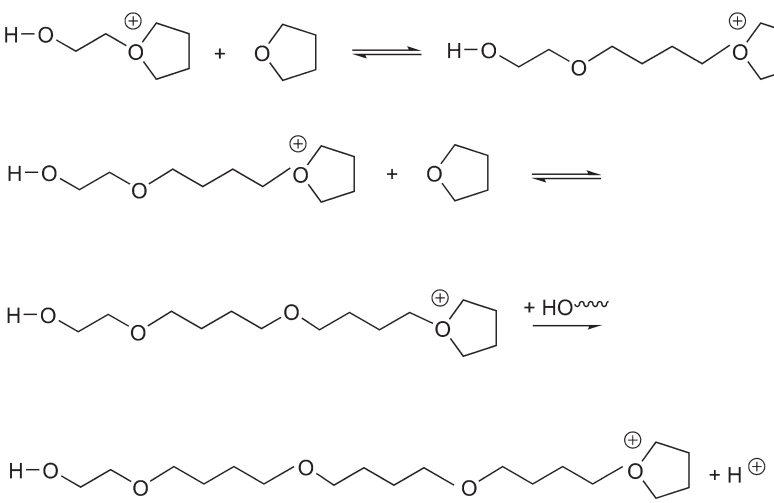
THF may be incorporated into oligodiols by the process involving both the AM and ACE mechanisms if a highly strained cyclic ether (e.g., EO or ECH) is continuously fed into the reaction mixture containing THF and the diol as



If [THF] >>[EO], [HO-] then protonated EO reacts preferentially with THF



A few propagation steps by ACE mechanism may occur before the whole segment is incorporated into the growing macromolecule by reaction with HO- group.



Scheme 31

reagent and strong protic acid as catalyst. The reaction proceeds by the mechanism outlined in **Scheme 31**.[163,164]

Although PTMEG is by far the most important commercial product (and one of the prominent examples of industrial application of CROP), there is a considerable research activity concerning other synthetic applications of CROP of THF.

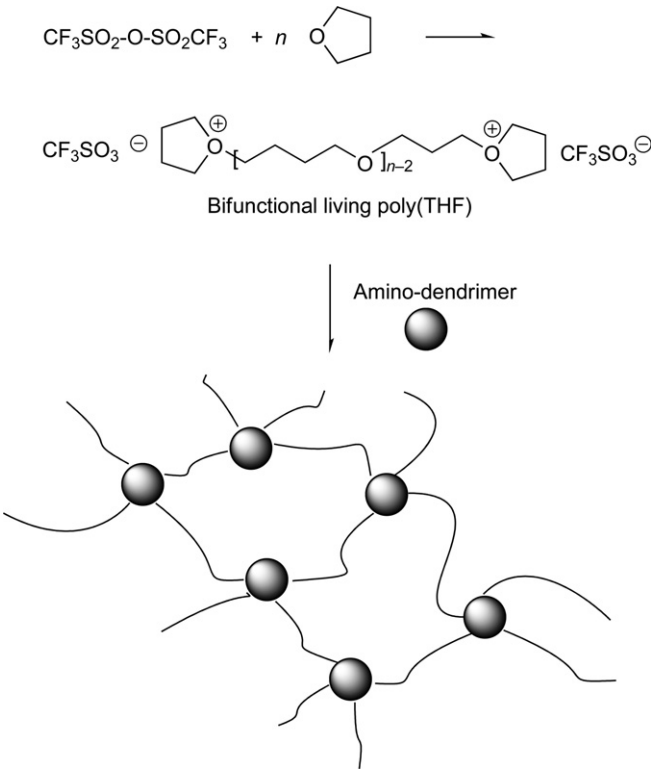
Active species of CROP of THF are long-living, which makes possible their quantitative conversion to a variety of functional polymers that may be used for synthesis of polymers with complex architectures, such as star polymers or block copolymers.[165]

Star polymers of THF were prepared by the reaction of living poly(THF) with multifunctional amines. Stars containing up to seven arms were prepared using this approach.[166,167]

A similar approach was based on the coupling of bifunctional living poly(THF) and dendrimers containing iminopropane-2,3-diyl units or grafting of living poly(THF) onto an amino dendrimer to form a star, acrylate-terminated poly(THF) multimacromonomer with the dendrimer as core. Subsequent addition of unreacted amino groups of the dendrimer onto acrylate end-groups led to the formation of a segmented polymer network containing amino dendrimers (**Scheme 32**).[168]

Cationic polymerization of THF followed by termination of living chain ends with 2,2′-bipyridine led to ionene elastomers.[169] Another approach to the synthesis of poly(THF) ionenes was based on the chain extension reaction of living poly(THF) chains with (dimethylamino)trimethylsilane.[170] Hydrolysis of block copolymers containing 2-methyl-4,5-dihydroimidazole (2-methyl-2-oxazoline) and THF blocks gave block copolymers containing linear poly(ethylenimine) blocks. Addition of $CuCl_2$ to these block copolymers led to the formation of the corresponding complexes, which resulted in dramatic changes in their physical properties. Depending on the relative length of each block, the complexed polymers were soft and ductile materials or tough thermoplastic elastomers.[171]

Developments in controlled radical polymerization led to novel block copolymers involving poly(THF) blocks.[172] ATRP was used to polymerize radically polymerizable monomers to polymers containing reactive chain ends (e.g., halogen end-groups in the case of ATRP) and, after transforming end-groups into groups that can initiate cationic polymerization of THF, a second block was obtained by CROP. In this way, block copolymers containing polystyrene and poly(THF) blocks,[173–175] poly(methyl methacrylate) (PMMA), and poly



Scheme 32

(THF) blocks,[176,177] or polacrylate and poly(THF) blocks[178] as well as star block copolymers with PTHF core and poly(*tert*-butyl acrylate) (PtBA) shell[178] were obtained.

Reversible addition-fragmentation chain transfer polymerization (RAFT) polymerization of methyl acrylate was combined with cationic polymerization of THF to synthesize comb copolymers.[179] Asymmetric star block copolymers based on polystyrene (PS), PTHF, and PMMA were synthesized by a combination of CROP and redox polymerization methods.[180] Miktoarm star polymers containing poly(THF) and polystyrene arms were also obtained by combining CROP and ATRP methods.[181] Another approach for the synthesis of block copolymers involving poly(THF) blocks is based on transformation of cationic active species of THF polymerization into species initiating anionic[182] or radical polymerization.[183] Copolymerization of poly(THF) macromonomers with *N*-isopropylacrylamide (NIPAA) led to segmented polymer networks acting as polymer membranes with thermoresponsive permeability.[184] Conducting THF copolymers were obtained by capping living poly(THF) with a thiophene or pyrrole derivative and subsequent electropolymerization.[185,186]

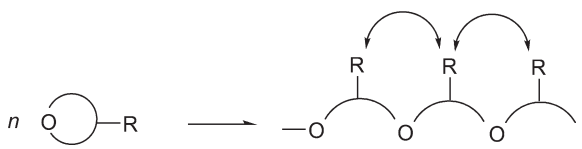
By applying cationic polymerization of tetrahydrofuran starting from the carbonyl chloride group-functionalized multiwalled carbon nanotubes (MWNT)[187] with silver perchlorate as a catalyst poly-THF was chemically anchored to MWNT surfaces affecting their properties.[126]

4.08.4.3 CROP of Substituted THFs

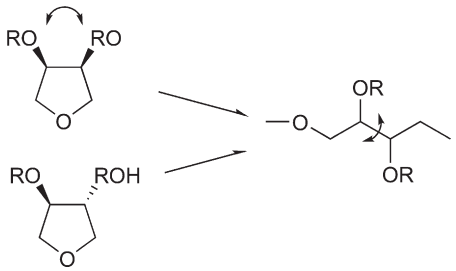
THF as a five-membered cyclic ether is only weakly strained. Substitution decreases thermodynamic polymerizability of heterocyclic monomers; thus substituted THFs do not polymerize (although their oligomerization to low-molecular-weight products is possible).[188] It should be remembered, however, that the enthalpy of polymerization (ΔH) is not exclusively related to ring strain (although ring strain provides a major contribution to the ΔH value). If the ring is substituted, it does not affect significantly the ring strain in the monomer but steric repulsion between substituents may introduce strain into the polymer chain as shown in **Scheme 33**.

An interesting example of the influence of the number and positions of substituents on the thermodynamic polymerizability was provided by studies of cationic polymerization of 3,4-dialkoxy-THF.[189] When two substituents were in *cis*-position, polymers with DP_n up to ~ 35 could be obtained while *trans*-monomer essentially did not polymerize. As shown in **Scheme 34**, if substituents in cyclic monomer are in *cis*-position, there is a considerable additional strain due to their steric repulsion; this strain is partly released when a rigid cyclic monomer is converted to a polymer chain in which, due to free rotation around carbon–carbon and carbon–oxygen bonds, the strain can be minimized. In *trans*-monomers, steric repulsion is considerably lower; thus the gain in enthalpy is less significant.

More recently, it has been shown that disubstituted THF derivatives containing two hydroxymethyl groups



Scheme 33



Scheme 34

Scheme 35

(anhydrosugars) can be polymerized to medium-molecular-weight highly branched polymers in analogy to hydroxymethyl-substituted three- and four-membered cyclic ethers (cf. Section 4.08.3.3) and an AM mechanism of propagation was suggested.[190–193] It was shown, however, that in addition to ROP, dehydration reaction occurs; thus the structure of polymers is more complex than suggested.[194]

Although this chapter deals with ROP of cyclic ethers, it should be mentioned that 2,3-dihydrofurans and their derivatives (cyclic vinyl ethers) polymerize cationically through opening of the double bond as shown in Scheme 35.[195–198]

4.08.5 Outlook

Cyclic ethers constitute an important class of heterocyclic monomers that polymerize by ionic mechanism. Studies of the mechanism, kinetics, and thermodynamics of cyclic ether polymerization were essential in establishing basic principles of ionic ROP. Cyclic ethers are the class of heterocyclic monomers that provide suitable models for mechanistic studies. On the other hand, polymerization of several monomers of this class leads to polymeric materials that are produced on an industrial scale. The most prominent examples are polymers of EO, PO, ECH, or THF. CROP of cyclic ethers is thus interesting from both the academic and industrial point of view.

Investigations of CROP of cyclic ethers (mainly THF) provided the first thoroughly studied examples of polymerization with reversible deactivation of growing species involving equilibria between ionic and covalent (dormant) species. Studies of polymerization kinetics led to determination of rate constants of elementary reactions and in several cases equal reactivity of ions and ion-pairs in propagation was observed, which seems to be a general phenomenon in CROP of heterocyclic monomers.

More recent developments of cationic polymerization proceeding by the AM mechanism have opened new horizons for the synthetic application of ROP of cyclic ethers. By using this approach, main side reaction (intramolecular chain transfer to polymer leading to the formation of cyclic fraction) can be minimized and control over molecular weight, molecular weight distribution, and the structure of end-groups can be achieved under kinetic control. AM polymerization is especially suited for the synthesis of telechelic (functional) oligomers such as oligodiols or macromonomers and several examples of successful application of AM polymerization to the synthesis of such materials can be found in recent literature. AM polymerization of cyclic ethers containing hydroxyl functionality offers also a convenient synthetic route to hyperbranched multihydroxy polyethers and this area was also explored recently.

Thus, there is steady, although not very intensive, progress in the field of CROP of cyclic ethers. It can be expected that this trend will continue and new specialty polymers or oligomers will be created by combining the knowledge accumulated over several decades with new developments such as the AM polymerization mechanism.

Acknowledgment

This chapter is based on the chapter *Cationic Ring-Opening Polymerization: Ethers* coauthored by S. Penczek and P. Kubisa from the first edition of *Comprehensive Polymer Science*, Vol. 3, Part I. The author wishes to express his gratitude to Professor Stanislaw Penczek for the permission to use large parts of the text from the first edition.

Biographical Sketch

Przemyslaw Kubisa received his MSc degree in 1963 from Warsaw University of Technology. From 1963 until 1969, he was employed in the Institute of Plastics in Warsaw as a research associate and in 1969, he joined the Center of Molecular and Macromolecular Studies (CMMS) of the Polish Academy of Sciences in Lodz. In 1972, he received his PhD (under the guidance of Prof. S. Penczek) and in 1978 his habilitation from the Technical University in Lodz. P. Kubisa was a postdoc in the University of Masschussetts (group of Prof. Otto Vogl) (1974) and a visiting scientist in the University of Masschussetts (6 months in 1979) and the Institut Ch. Sadron in Strasbourg (1 year in 1984).

The research interests of P. Kubisa cover various aspects of ionic (mostly cationic) ring-opening polymerization of oxygen-containing heterocyclic monomers. He is an author or coauthor of 140 original papers and 40 book chapters or review papers. From 1991 until 2007, he held a position of the Deputy Director of CMMS and in 2005, he succeeded Prof. S. Penczek as the Head of Polymer Chemistry Department (until 2009). He is presently a Titular Member of IUPAC Polymer Division.

4.09 Stereoselective Ring-Opening Polymerization of Epoxides

H Ajiro, PCB Widger, SM Ahmed, SD Allen, and GW Coates, Cornell University, Ithaca, NY, USA

4.09.1 Introduction

4.09.1.1 Background

In the 1950s, Baggett and Pruitt[1–4] reported that iron (III) chloride was capable of polymerizing racemic propylene oxide to give a polymeric material that could be separated into amorphous as well as crystalline materials using solvent fractionation. Shortly thereafter, Natta *et al.*[5] and Price *et al.*[6,7] provided evidence that the crystalline material was isotactic poly(propylene oxide), in which the main-chain stereogenic centers were of the same relative configuration. This finding marked the first discovery of a stereoselective catalyst for epoxide polymerization. This chapter highlights the significant advances made in the field of stereoselective epoxide polymerization and copolymerization using discrete catalysts.

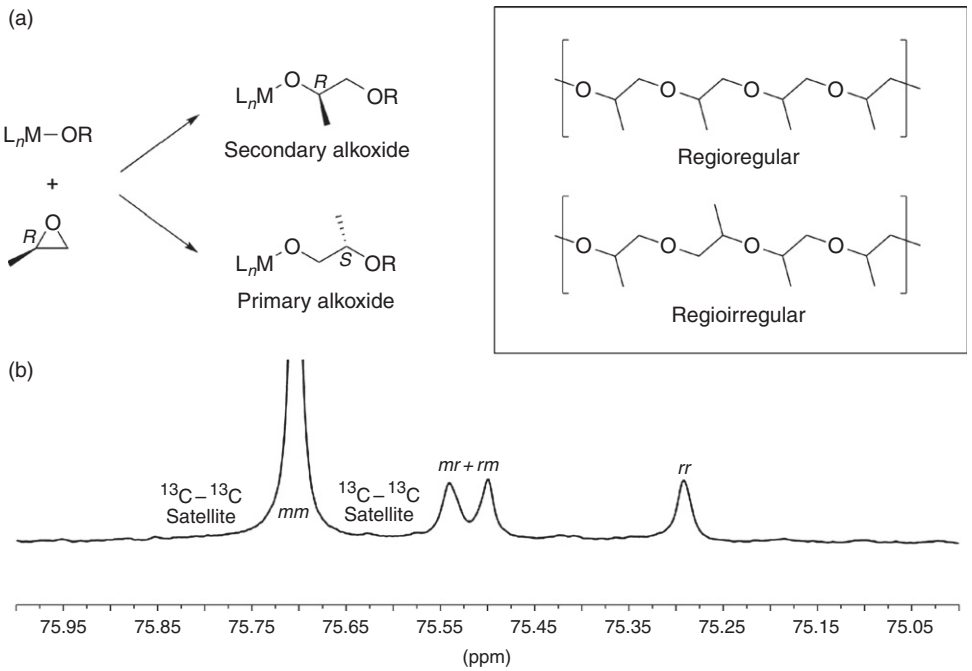
4.09.1.2 Scope

Many of the important contributors to the field of stereoselective epoxide polymerization have written accounts of their research;[8–20] we have recently written a comprehensive review which forms the basis for this review.[21] This chapter focuses on discrete catalysts for the stereoselective polymerization of racemic (chiral) and meso (prochiral) epoxides. Due to space limitations, catalysts bearing at least one ancillary ligand that is not likely to react with epoxides are discussed; catalysts only bearing ligands that are well known to react with epoxides are not covered. A discussion of strategies for controlling the relative configuration of main-chain stereogenic centers of epoxide polymers is included. The polymerization of optically active epoxides[6] is not covered as the emphasis of this chapter is on stereochemical control of polymerization by the catalyst or initiator.

4.09.2 Basic Concepts in Stereoselective Epoxide Polymerization

4.09.2.1 Regiochemistry

Both the ancillary ligands (L_n) surrounding the active metal center (M) and the growing polymer chain (OR) influence the regiochemistry and stereochemistry of epoxide polymerization (**Scheme 1**(a)).[22] When the epoxide is unsymmetrically substituted (i.e., propylene oxide), enchainment commonly can occur in two ways: (1) S_N2 attack by the polymer's alkoxide chain-end at the less-substituted methylene with retention of the configuration of the substituted carbon to give a secondary metal alkoxide; or (2) S_N2 attack at the substituted methine with inversion of configuration to give a primary metal alkoxide (**Scheme 1**). The polymer is regioregular when only one



Scheme 1 Methine region of the ^{13}C NMR spectrum of partially isotactic poly(propylene oxide) showing triad stereoerrors.

process dominates; the polymer is regioirregular when both processes occur. The regiochemistry of a polyether (such as poly(propylene oxide)) can be readily determined by ^{13}C NMR spectroscopy.[23–25]

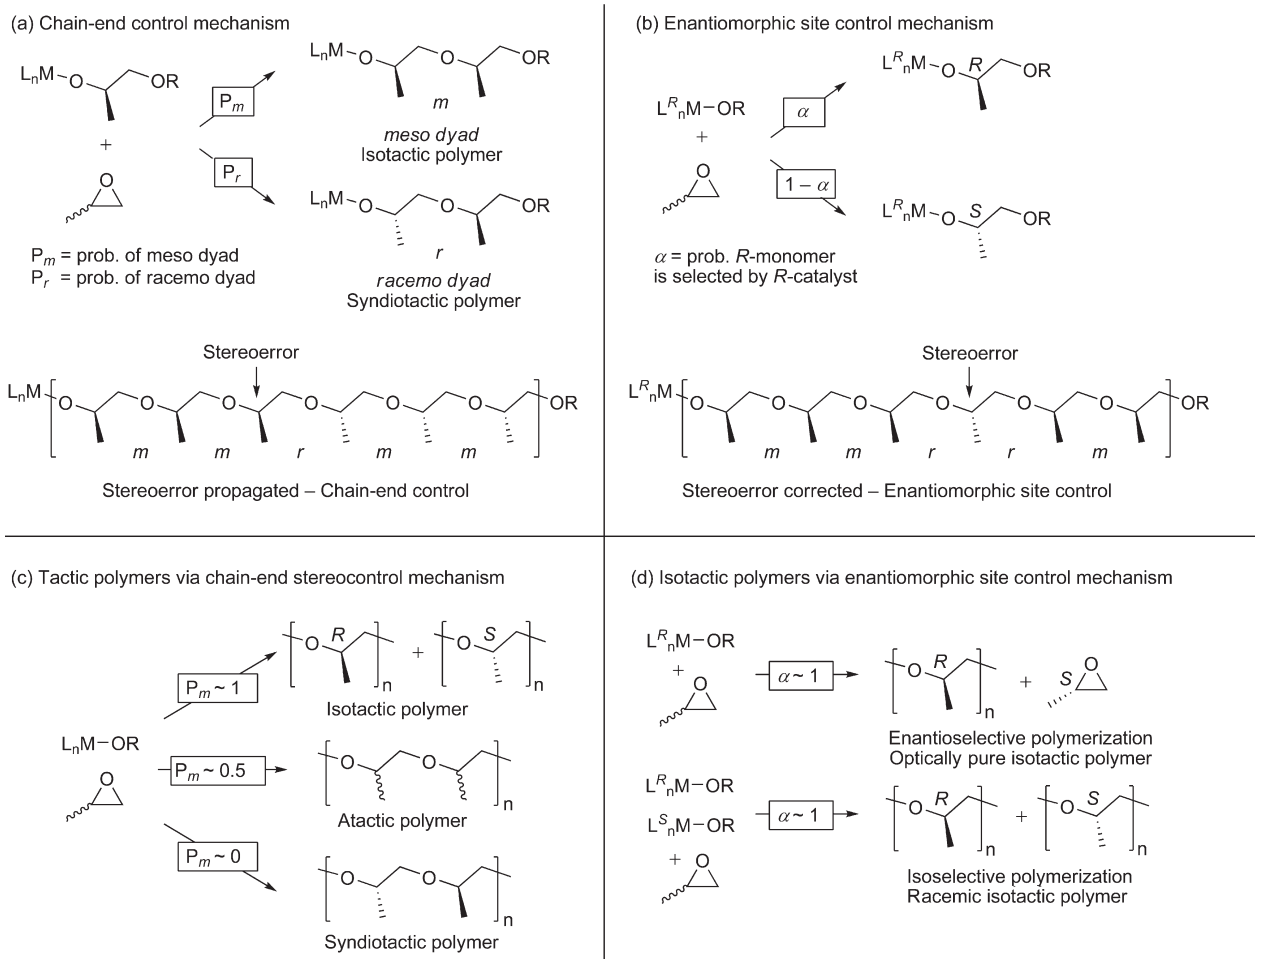
4.09.2.2 Analysis of Polymer Stereochemistry

NMR spectroscopy is the most useful method for determining polymer tacticity.[26,27] In many cases, the chemical shifts for the various polymer nuclei are sensitive to adjacent stereogenic centers, resulting in fine structure that can provide quantitative information about the polymer microstructure once the shift identities are assigned. For example, the methyl, methylene, and methine regions of a high-resolution ^{13}C NMR spectrum of regioregular atactic poly(propylene oxide) display several resonances, each of which represents a different set of consecutive stereocenters. As each resonance in the spectrum has been assigned (**Scheme 1(b)**),[23,24,28] a routine ^{13}C NMR experiment can reveal both the tacticity and the degree of stereoregularity of a sample of poly(propylene oxide).

4.09.2.3 Chain-End Control and Enantiomorphic Site Control of Stereochemistry

In a chain-growth polymerization reaction, one end of the polymer chain remains at the active metal center during monomer enchainment. Thus, the stereogenic center in the polymer chain from the last enchained monomer unit will have an influence on the stereochemistry of monomer enchainment. If this influence is significant, the mode of stereochemical regulation is referred to as 'polymer chain-end control' (**Scheme 2(a)**). If the active site is chiral and overrides the influence of the polymer chain end, the mechanism of stereochemical direction is termed 'enantiomorphic site control' (**Scheme 2(b)**).[9–11] The Bovey formalism is a convenient way to describe polymer tacticity, where an '*m*' for *meso* (same configuration), or an '*r*' for *racemic* (opposite configuration) describes relationships between adjacent stereogenic centers (dyads). These dyads are seen as unique signals in ^{13}C NMR. The monomer enchainment mechanism can be easily identified by observing the stereochemical errors propagated in a polymer chain. The ratio of the signals in a ^{13}C NMR spectrum can be used to determine the mechanism of stereocontrol. In the case of an isotactic polymer, a 'chain-end control' mechanism produces polymers in which stereoerrors are propagated (i.e., would display primarily *mm*, *mr*, and *rm* triads, **Scheme 2(a)**). In the 'enantiomorphic site control' mechanism, correction of stereoerrors occurs because the ligands direct the stereochemical events, leading to an isolated error (i.e., produces a polymer which would display primarily *mm*, *mr*, *rm*, and *rr* triads, **Scheme 2(b)**).

Optically active catalysts can kinetically resolve racemic monomers (**Scheme 2**) via enantioselective polymerization producing optically active polymers as well as enantiomerically enriched monomers. The nonpreferred enantiomer remains unreacted in the reaction mixture after the preferred enantiomer of monomer has been enchained as a polymer. The quantitative measure of stereocontrol in such a system is given by the selectivity factor (s-factor, *s*), which is the ratio of the rate constants for the polymerization of the fast enantiomer converted to polymer with respect to the slow enantiomer enchained [$s = k_{fast}/k_{slow} = \alpha/(1-\alpha)$] ($\alpha$ is the probability that the preferred enantiomer will be selected by the catalyst).[29] A racemic enantioselective catalyst can polymerize both enantiomers of racemic monomer via isoselective polymerization to give racemic isotactic polymer.



Scheme 2 (a) Chain-end stereocontrol mechanism. (b) Enantiomorphic site stereocontrol mechanism. (c) Tactic polymers via chain-end control mechanism. (d) Isotactic polymers via enantiomorphic site control mechanism. L^R_nM–OR is an enantiomerically pure metal alkoxide complex that prefers *R*-monomer; L^R_n is an enantiomerically pure, chiral ligand.

4.09.3 Stereoselective Epoxide Polymerization

The vast majority of papers reporting stereoselective epoxide polymerization focus on the isoselective polymerization of propylene oxide using different metal-based catalysts. Thus, this chapter is organized based on the metal of the active center of the catalyst. Aluminum, zinc, cobalt, tin, and chromium are the most commonly used metals for discrete stereoselective epoxide polymerization catalysts and their use in this field of research forms the foundation of this review.

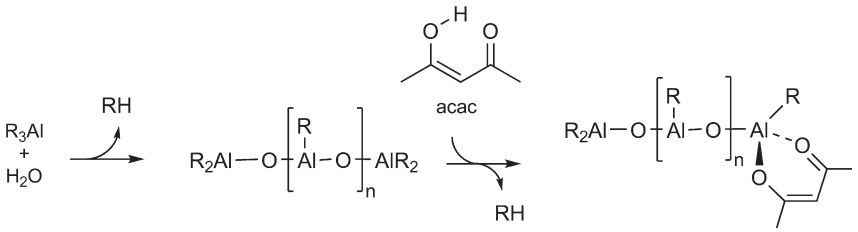
4.09.3.1 Aluminum-Based Catalysts

Although aluminum alkoxide- and aluminoxane-based catalysts have shown promise for the isoselective polymerization of epoxides, the poorly defined nature of these species has significantly hampered their use in such polymerizations due to the formation of large amounts of atactic polyether.[30] Some examples of discrete aluminum complexes have been reported herein.

4.09.3.1.1 Aluminum–acetylacetonate complexes

The prevailing theory for the mechanism of epoxide polymerization has been that epoxide coordination to the metal center precedes insertion. To support this mechanism, Vandenberg proposed that the addition of chelating agents such as acetylacetonate (acac) to an R_3Al/H_2O (R = alkyl) polymerization system would block potential coordination sites on the metal center, thus hindering the reaction. Instead, these additives enhanced the polymerization rate and ushered in a new class of versatile and highly active catalysts.[12,31–33] The presumed structure of the active aluminum–acac catalyst is shown in Scheme 3. Although the precise structure of the active catalyst is unknown, a few structural features have been determined: (1) an oxygen atom bridges two aluminum centers (although the presence of multiple linkages, such as those in oligomeric aluminoxanes, cannot be ruled out); (2) alkyl groups are present on the aluminum atoms; and (3) the acac ligand is chelated to the aluminum center.[20]

Tuning the AlR_3/H_2O/acac catalyst (R = alkyl) composition by varying the R groups and the ratio of components creates systems that conduct epoxide polymerizations to give high conversions, in many instances achieving >90% conversion to give high-molecular-weight, acetone-insoluble polyethers. The fraction of acetone-insoluble, isotactic polymer produced varies according to the exact composition of the catalyst system used, and is ~30% of the total mass of the ether-insoluble material, while the remaining 70% is acetone-soluble atactic polymer.[32,33]

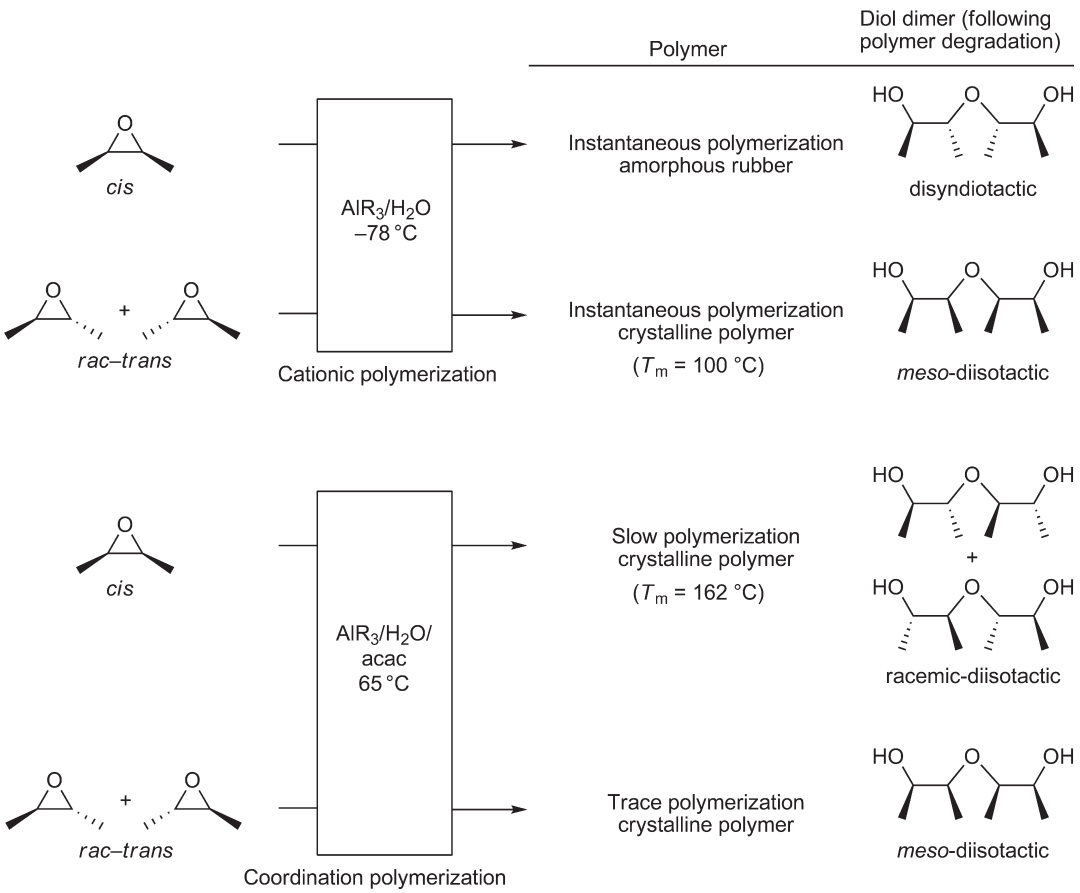


Scheme 3 Synthesis of AlR_3/H_2O/acac epoxide polymerization catalysts (R = alkyl).

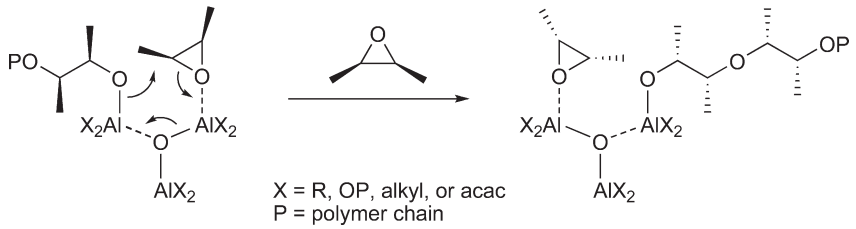
In work investigating the mechanism of this system, Vandenberg used AlR_3/H_2O catalysts to polymerize *cis*- and *trans*-2,3-epoxybutane. Mechanistic information for the polymerization was obtained from the properties of the resultant polymers and the examination of the diol decomposition products. These results are summarized in Scheme 4.[12,20,34–36]

The AlR_3/H_2O catalysts polymerize both *cis*- and *trans*-2,3-epoxy butane instantaneously at −78 °C, consistent with a cationic process for monomer enchainment. The polymer isolated from the *cis* isomer is an amorphous rubber, whereas the polymer isolated from the *trans* isomer is crystalline with a melting temperature (T_m) of 100 °C. This finding is in contrast to the AlR_3/H_2O/acac system, which only slowly polymerizes the same monomers at 65 °C, presumably through a much slower coordination–insertion mechanism. The coordination polymerization of the *cis* isomer yields a crystalline polymer with a T_m of 162 °C, whereas the *trans* isomer polymerizes extremely slowly, producing only trace amounts of a crystalline polymer with a T_m similar to that obtained with the cationic polymerization. Vandenberg attributes the extremely slow polymerization of the *trans* isomer to its increased steric bulk compared to the *cis* isomer at the metal coordination site. The steric bulk hinders the required precoordination to the metal center for monomer insertion.

Through the controlled degradation of the polyethers to diol dimers using *n*-butyllithium, the stereochemistry of the monomer units in the polymer chain was determined.[34] The decomposition of all four polymers showed that inversion of configuration at the site of attack on the epoxide ring occurred in both cationic and coordination–insertion polymerization mechanisms. The *cis* epoxides (*RS* stereocenters) produce monomeric units in the polymer chain with *RR* and *SS* stereocenters, and the *trans* epoxides (either *RR* or *SS*) produce monomeric units in the polymer chain with only *RS* units.



Scheme 4 Stereoselectivity of polymerization of *cis*- and *trans*-2,3-epoxybutane using AlR_3/H_2O catalysts (R = alkyl).



Scheme 5 Proposed bimetallic enchainment of epoxides using (acac)Al complexes. acac, acetylacetonate; P, polymeryl.

This observation shows that both polymerizations are stereospecific, with inversion of configuration occurring at the site of attack, regardless of the polymerization mechanism.

In order to obtain the geometry required for an S_N2 attack in a coordination–insertion mechanism, Vandenberg proposed the transition-state structure shown in Scheme 5. In this scheme, an epoxide is activated by coordination to an aluminum center, while the adjacent aluminum center delivers the growing polymer chain. During this process, coordination bonds are exchanged to keep the charges balanced. Although a bimetallic mechanism for epoxide ring opening is claimed, there is scant evidence for this proposal.[37–39]

4.09.3.1.2 Aluminum systems featuring chiral alkoxides

Haubenstock and co-workers[40] synthesized chiral aluminum alkoxides for the stereoselective polymerization of propylene oxide. Addition of 1.5 equiv. of (−)-(*R*)-3,3-dimethylbutane-1,2-diol ((*R*-dmbd)H_2) to AlH_3 generated the active complex $[(R\text{-dmbd})_{1.5}/Al]_n$. Alone, $[(R\text{-dmbd})_{1.5}/Al]_n$ displayed very low activity for the polymerization of propylene oxide, achieving 85% conversion in 3 weeks with negligible optical activity in the unreacted monomer. The addition of $ZnCl_2$ (Al:Zn = 1:1) to the $[(R\text{-dmbd})_{1.5}/Al]_n$ initiator generated a much more active catalyst, as shown in Scheme 6. Furthermore, the optical activity of the unreacted propylene oxide was observed to increase with increasing conversion to polymer, and based on the optical rotation of the unreacted monomer, Haubenstock and co-workers[40] determined that the catalyst system preferentially reacted with (*R*)-propylene oxide because the reaction solution became enriched in the (*S*) enantiomer, although with modest selectivity ($s = 1.05$). On fractionation, 10% of the total mass of the isolated polymer was acetone insoluble and highly isotactic (>99% *m*-dyads), whereas the remainder of the polymer was acetone soluble and atactic. Although a slight enantiomeric enrichment of monomer was achieved, this system did not significantly improve the yield of isotactic poly(propylene oxide) compared to similar systems,[41–43] and it is unclear whether the selective enchainment of the *R*-enantiomer was contributing to the formation of the 10% of crystalline polymer as opposed to it arising from a different mechanism.

4.09.3.1.3 Aluminum–porphyrin complexes

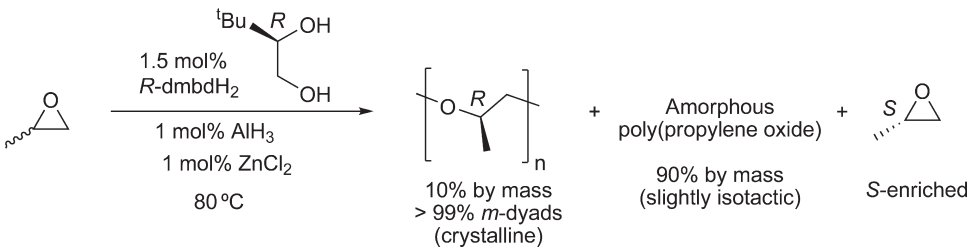
Inoue[44–46] first reported that 5, 10, 15, 20-tetraphenylporphyrin (tpp) aluminum chloride (Figure 1, **1**) was active for the living polymerization of propylene oxide. Although the polymer microstructure was not studied in great detail, ^{13}C NMR spectra showed the polymers to be highly regioregular and slightly isotactic.[44,45] The activity of (tpp)AlCl was relatively low, requiring 6 days to achieve 100% conversion. The addition of Cl or OMe substituents on the porphyrin ligand, as in (*p*-Cl-tpp)AlCl (**2**) and (*p*-OMe-tpp)AlCl (**3**), increased the activity by a factor of 2, but the tacticity of the resulting polymers was not discussed.[45] More detailed ^{13}C NMR analyses by Le Borgne and co-workers[24] showed that the poly(propylene oxide) derived from **1** was slightly isotactic, with an *m*-dyad content of 69% and an *mm*-triad content of 45%, confirming the initial results reported by Inoue.

4.09.3.1.4 Aluminum–Schiff base complexes

Well-defined [*N*,*N*′-bis-(2-hydroxybenzylidene)-(1*R*,2*R*)cyclohexane-1,2-diamine] (*R*,*R*-salcy) aluminum complexes (Figure 1, **4**) have been used as enantioselective epoxide polymerization catalysts.[47–49] Polymerization of racemic propylene oxide in the presence of 5 mol.% **4** yields ~70% conversion to poly(propylene oxide) after 62 h. The remaining unreacted monomer exhibits an optical rotation of +1.85°, which corresponds to an *ee* of 15% (Scheme 7). The modest s-factor of 1.3 obtained in this system is slightly higher than that observed for the previously discussed heterogeneous aluminum systems.[50] Examination of the isolated polymer reveals both chloro and hydroxyl end groups, suggesting that each metal center produces a single polymer chain since each chain bears a Cl atom from initiation and a hydroxyl group from terminiation.[48]

4.09.3.1.5 Aluminum–calixarene complexes

Kuran and co-workers synthesized a dimethylcalixarene-based system (Figure 1, **5**) that exhibited low activity for propylene



Scheme 6 Polymerization of propylene oxide with $[(R\text{-dmbd})_{1.5}Al]_n/ZnCl_2$ catalysts. dmbd, 3,3-dimethyl-1,2-butanediolate.

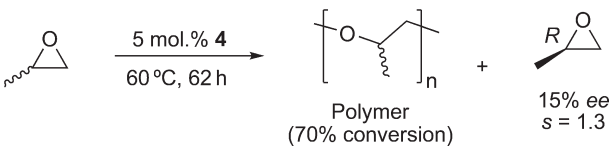


Scheme 7 Attempted enantioselective polymerization of racemic propylene oxide using **4**.

oxide polymerization (TOF = 0.06 h^{-1}).[51] The polymerization of propylene oxide produced predominantly isotactic poly(propylene oxide) with an *m*-dyad content of ~74%.

4.09.3.1.6 Other well-defined aluminum systems

N,*N*′,*N*″-Tris(trimethylsilyl)diethylenetriamine complexes of aluminum have been shown to be active oligomerization catalysts for propylene oxide.[52] Over the course of 2 days, catalyst **6** (**Figure 1**) produces low-molecular-weight poly(propylene oxide) (M_n < 500 g mol^{-1}) with predominantly head-to-tail linkages and an *m*-dyad content of 60%.

4.09.3.2 Zinc-Based Catalysts

During research on aluminum catalysts for the stereoselective polymerization of epoxides, it was discovered that the addition of zinc cocatalysts to these systems greatly enhanced catalyst activity.[41] These enhancements prompted a number of studies focusing on the design of zinc-based catalyst systems.

4.09.3.2.1 Zinc alkoxide catalysts

Furukawa and co-workers[53] explored catalysts derived from the addition of methanol or ethanol to diethylzinc as epoxide polymerization systems, and found that both the yield and crystallinity of the resulting polymers were inferior to those for polymers synthesized with the $ZnEt_2/H_2O$ system. The use of achiral alcohols as cocatalysts was revisited in 1994 when Kuran and Listos[54] reported the polymerization of propylene oxide and cyclohexene oxide (a *meso* substrate) with $ZnEt_2$/polyhydric phenol (such as 4-*tert*-butylcatechol), phenol, or 1-phenoxypropan-2-ol. The poly(propylene oxide) formed from these systems contained mostly isotactic dyads (72% *m*), while the poly(cyclohexene oxide) contained mostly syndiotactic dyads (80% *r*) (**Scheme 8**).

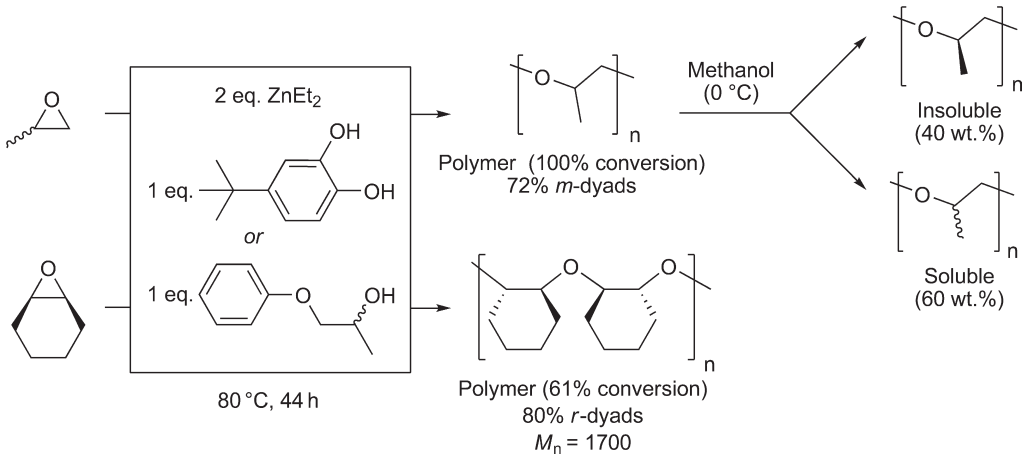
4.09.3.2.2 Chiral zinc alkoxide catalysts

Sigwalt and co-workers noted higher stereoselectivity during the polymerization of propylene sulfide using a (*R*)-3,3-dimethylbutane-1,2-diol/$ZnEt_2$ system when compared with a similar chiral alcohol/$ZnEt_2$ system. Based on these results, they applied this system to propylene oxide, but noticed that stereoselectivity was actually lower than that for the polymerization of propylene sulfide.[16,55,56] This lower stereoselectivity was attributed to the weaker coordination of the 'harder' epoxide oxygen atom to zinc, as compared to the 'softer' coordination of the episulfide sulfur atom.

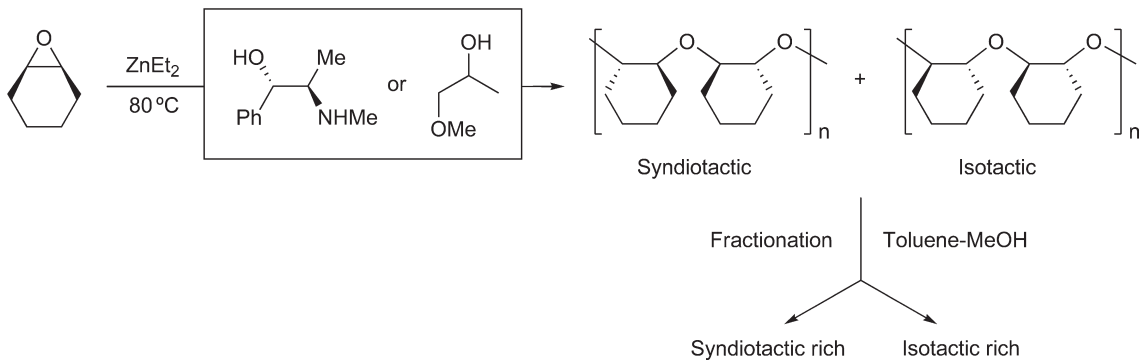
Sepulchre and co-workers investigated the polymerization of cyclohexene oxide using $ZnEt_2$ activated with water, alcohols, and chiral alcohols. In their study, a mixture of $ZnEt_2$ and 1-methoxypropan-2-ol or (1*S*,2*R*)-ephedrine simultaneously afforded a mixture of isotactic and syndiotactic poly(cyclohexene oxide) that was characterized using ^1H and ^{13}C NMR spectroscopies (**Scheme 9**).[57,58] They proposed a 'flip-flop' mechanism (similar to that proposed by Vandenberg[20] as shown in **Scheme 5**) involving neighboring zinc centers to explain this observation.

4.09.3.2.3 Zinc alkoxide clusters

Tsuruta and co-workers[59–68] synthesized and investigated the epoxide polymerization activity of several well-defined zinc clusters (**Figure 2**). Complexes $[Zn(OMe)_2 \bullet (EtZnOMe)_6]$ (**7**), $[Zn(OCH_2CH_2OMe)_2 \bullet (EtZnOCH_2CH_2OMe)_6]$ (**8**), and



Scheme 8 Polymerization of epoxides with $ZnEt_2$/1-phenoxy-2-propanol or 4-*tert*-butylcatechol.



Scheme 9 Preparation of a mixture of isotactic and syndiotactic poly(cyclohexene oxide) using chiral zinc alkoxide catalysts.

$[\{CH_3OCH_2CH(Me)OZnOCH(Me)CH_2OCH_3\}_2 \bullet \{EtZnOCH(Me)CH_2OCH_3\}_2]$ (**9**), were synthesized by the dropwise addition of 1.1 equiv. of the corresponding alkoxyalcohols to $ZnEt_2$ in heptanes at 5 °C. Each complex was crystalline, and its molecular structure was determined using X-ray crystallography (**Figure 2**).[59,62,68]

The polymerization activity for each complex is shown in **Scheme 10**. Surprisingly, isostructural complexes **7** and **8** had significantly different polymerization activities; **7** achieved 91% conversion in 216 h, while **8** attained only 22% conversion in 240 h. Catalyst **9**, however, was twice as active as complex **7**. This catalyst has a different molecular structure, as shown in **Figure 2**. Complex **9** bears six 1-methoxypropan-2-yl groups in a chair-like structure in three different coordination environments; the methoxy groups are either endo- and exo-coordinated to the central zinc atoms, or noncoordinated.

Studies using a deuterated version of **9** revealed that the non-coordinating 1-methoxypropan-2-olate groups initiated the polymerization by attack on the propylene oxide monomer, whereas the coordinated 1-methoxypropan-2-olate groups provided the chiral structure, which remained unchanged during the polymerization.[63] When these

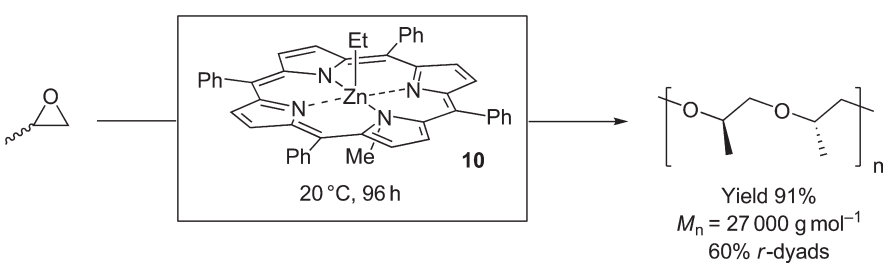
complexes were screened for cyclohexene oxide polymerization, only 9 was found to be active.[69,70] Through ^{1}H NMR analysis of polymer decomposition products (using Vandenberg's[34] method), Tsuruta and co-workers determined that the poly(cyclohexene oxide) obtained was predominantly syndiotactic (Scheme 11).

4.09.3.2.4 Zinc porphyrin-based catalysts

Inoue and co-workers reported that the polymerization of propylene oxide at 20 °C with the zinc porphyrin catalyst (Et_2Zn/*N*-methyl-5, 10, 15, 20-tetraphenylporphyrin, **10**) produced syndiotactic poly(propylene oxide) (M_w = 31 000, 60% *r*) (Scheme 12). This result was in contrast to those seen for all other zinc-based systems, which afford isotactic poly (propylene oxide). The authors attributed the unexpected syndiotactic microstructure of the polymer to the planar ligand and the isolated nature of the zinc center, which is different from that present in most other zinc aggregate systems.[44]

4.09.3.2.5 Zinc catalysts for asymmetric cyclohexene oxide/CO_2 copolymerization

There is significant interest in controlling the absolute stereochemistry of ring opening in epoxide/CO_2 copolymerization. Cyclohexene oxide, a *meso* molecule, is an ideal substrate for desymmetrization using chiral catalysts. In 1999, Nozaki *et al.*[71] reported that a 1:1 mixture of $ZnEt_2$ and (*S*)-diphenyl (pyrrolidine-2-yl)methanol (**11**) (Scheme 13) was active for stereoselective cyclohexene oxide/CO_2 copolymerization at 40 °C and 30 atm. CO_2 (Scheme 14). The resultant polycarbonate contained 100% carbonate linkages, had an M_n of



Scheme 12 Syndioselective polymerization of propylene oxide with **10**.

14

Figure 3 Chiral zinc catalyst **14** for the asymmetric, alternating copolymerization of cycloalkene oxides and CO_2.

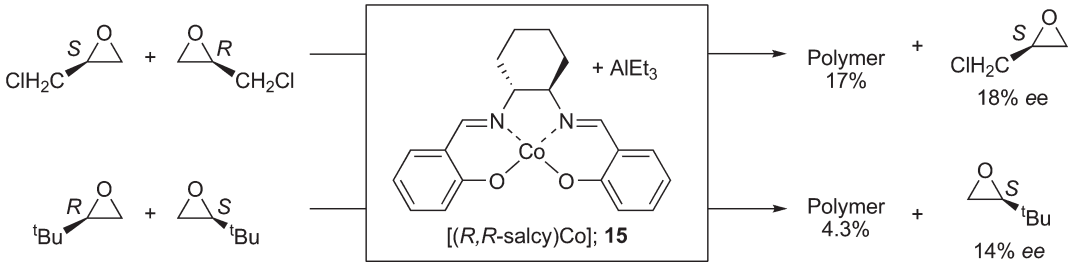
8400 g mol^{-1}, and had a M_w/M_n of 2.2. Hydrolysis of this poly(cyclohexane-1,2-diyl carbonate) with base produced the corresponding *trans*-cyclohexane-1,2-diol with 73% *ee*. ^{13}C NMR spectroscopy studies of model polycarbonate oligomers afforded spectral assignments for the isotactic (153.7 ppm) and syndiotactic dyads (153.3–153.1 ppm) of poly(cyclohexene oxide),[72] which agreed with those proposed by Cheng *et al.*[73] Finally, the ring-opening polymerization proceeded stereospecifically via complete inversion of configuration (S_N2 mechanism) of one carbon of each repeat unit; hence, no *cis*-cyclohexane-1,2-diol was observed after base-catalyzed degradation of the polycarbonate.

In a 2003 report, Nozaki and co-workers[74] isolated presumed intermediates in the asymmetric alternating copolymerization of cyclohexene oxide with CO_2. Reaction of a 1:1 mixture of $ZnEt_2$ and (*S*)-α,α-diphenylpyrrolidine-2-yl-methanol (**11**, **Scheme 13**) yielded dimeric **12**, which was structurally characterized by X-ray diffraction studies. At 40 °C and 30 atm. CO_2, **12** catalyzed the formation of isotactic poly(cyclohexane-1,2-diyl carbonate) (M_n = 11 800 g mol^{-1}, M_w/M_n = 15.7) with a turnover frequency of 0.6 h^{-1}. Hydrolysis of the resulting poly(cyclohexene carbonate) yielded the *trans*-cyclohexane-1,2-diol of 49% *ee*, which was lower than that seen with catalyst **11**. When copolymerization was attempted using a catalyst system consisting of **12** and 0.2–1.0 equiv. EtOH (**12**/EtOH), the *ee* of the hydrolyzed cyclohexane diol increased up to 80%. The catalyst and EtOH combination resulted in better control of polymer molecular weights and molecular weight distributions in comparison to polymerization using only **12**. Compound **13** (**Scheme 13**) was proposed to be the active initiating species in this polymerization. End-group analysis of the poly(cyclohexane-1,2-diyl carbonate)s prepared with **12** and **12**/0.2 EtOH by matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry revealed that in the absence of ethanol or in the presence of 0.2 equiv. ethanol end-group signals assignable to an aminoalcohol-initiated polymerization were identified. However, as EtOH addition was increased from 0.2 to 1.0 equiv., signals corresponding to the aminoalcohol-initiated polycarbonate disappeared as signals corresponding to end-group structures for EtOH-initiated poly(cyclohexane-1,2-diyl carbonate) emerged. This result was further confirmed by end-group analysis using ^{1}H NMR spectroscopy. Finally, mechanistic studies suggested that the dimeric form of the catalyst, **13**, was in fact the active species.

In 2000, Cheng and co-workers[73] developed C_1-symmetric imine-oxazoline ligated zinc compounds (**Figure 3**, **14**) for the isoselective, alternating copolymerization of cyclohexene oxide and CO_2 (**Scheme 14**). Through multiple electronic and steric manipulations of the imine-oxazoline ligand framework, compound **14** was found to exhibit the highest enantioselectivity for polymerization (*RR*:*SS* ratio in polymer was 86:14; 72% *ee*). Poly(cyclohexane-1,2-diyl carbonate) prepared with this catalyst possessed 100% carbonate linkages, an M_n of 14 700 g mol^{-1}, and an M_w/M_n of 1.35. This poly(cyclohexane-1,2-diyl carbonate) was crystalline with a glass transition temperature (T_g) of 120 °C, and a melting temperature (T_m) of 220 °C. Furthermore, stereocontrol was also achieved in the alternating copolymerization of cyclopentene oxide and CO_2, producing poly(cyclopentane-1,2-diyl carbonate) with an *RR*:*SS* ratio of 88:12 (76% *ee*). As revealed by ^{13}C NMR spectroscopy, the experimental carbonyl tetrad concentrations of this material matched the predicted tetrad concentrations for an enantiomorphic site control mechanism.[73]

4.09.3.3 Cobalt-Based Catalysts

Tsuruta found that the optically pure complex [(*R*,*R*-salcy)Co] (**15**) was active for epoxide polymerization (**Scheme 15**) when activated with $AlEt_3$. Although the system exhibited no enantioselectivity for the polymerization of propylene oxide, it was moderately selective ($s \sim 1.5$) for the enantioselective polymerization of *tert*-butyl ethylene oxide and epichlorohydrin (**Scheme 15**).[75]



Scheme 15 Enantioselective polymerization of racemic *tert*-butyl ethylene oxide and epichlorohydrin using **15**/$AlEt_3$.

4.09.3.3.1 Epoxide-carbon dioxide copolymerization systems

Qin and co-workers[76] reported that [(*R*,*R*-salcy-^{t}Bu)CoOAc] (**16**) copolymerizes propylene oxide and CO_2 (**Scheme 16**). Novel features of the catalyst are high regioregularity and alternation, coupled with high selectivity for polycarbonate formation (cyclic propylene carbonate is not formed). (*S*)-Propylene oxide is consumed faster than (*R*)-propylene oxide with a modest s-factor of 2.8. Given the same absolute monomer configuration and similar s-factor observed by Tokunaga *et al.*[39] for the cobalt-catalyzed ring opening of aliphatic epoxides with benzoic acid, a related mechanism was proposed to occur for polymerization with [(*R*,*R*-salcy-^{t}Bu)CoOAc], giving a cobalt-alkoxide catalyst resting state to produce the regioregular structure shown in **Scheme 16**.

Lu and co-workers[77] found that the addition of quaternary ammonium salts increased the s-factor to 3.5. The use of cobalt–salen complexes (in conjunction with an ionic organic ammonium salt or a sterically hindered strong organic base) allowed for the stereoselective alternating copolymerization of CO_2 and racemic aliphatic epoxides. By using a 7-methyl-1,5,7-triazabicyclo[4.4.0]dec-5-ene (MTBD) cocatalyst with the cobalt catalyst, it was possible to produce poly(propylene carbonates) with a s-factor of 5.6, with >95% head-to-tail units and >99% carbonate linkages. The same catalytic system was also used for the copolymerization of cyclohexene oxide and CO_2 to produce polycarbonates with an *ee* of 36.6% and greater than 99% carbonate linkages.[78] More recently, Cohen and Coates[79] have reported that a combination of complex **17** and bis(triphenylphosphine)iminium chloride ([PPN]Cl) exhibits an s-factor of 9.7 for the copolymerization of propylene oxide and CO_2 at −20 °C (**Scheme 16**).

Cohen and co-workers[80] also reported the first syndioselective copolymerization of cyclohexene oxide and CO_2 (**Scheme 17**). Using complex [*rac*-(salpr-^{t}Bu)CoBr] (**18**), poly(cyclohexane-1,2-diyl carbonate) was formed with 80% *r*-dyads, as determined by ^{13}C NMR spectroscopy. The carbonyl

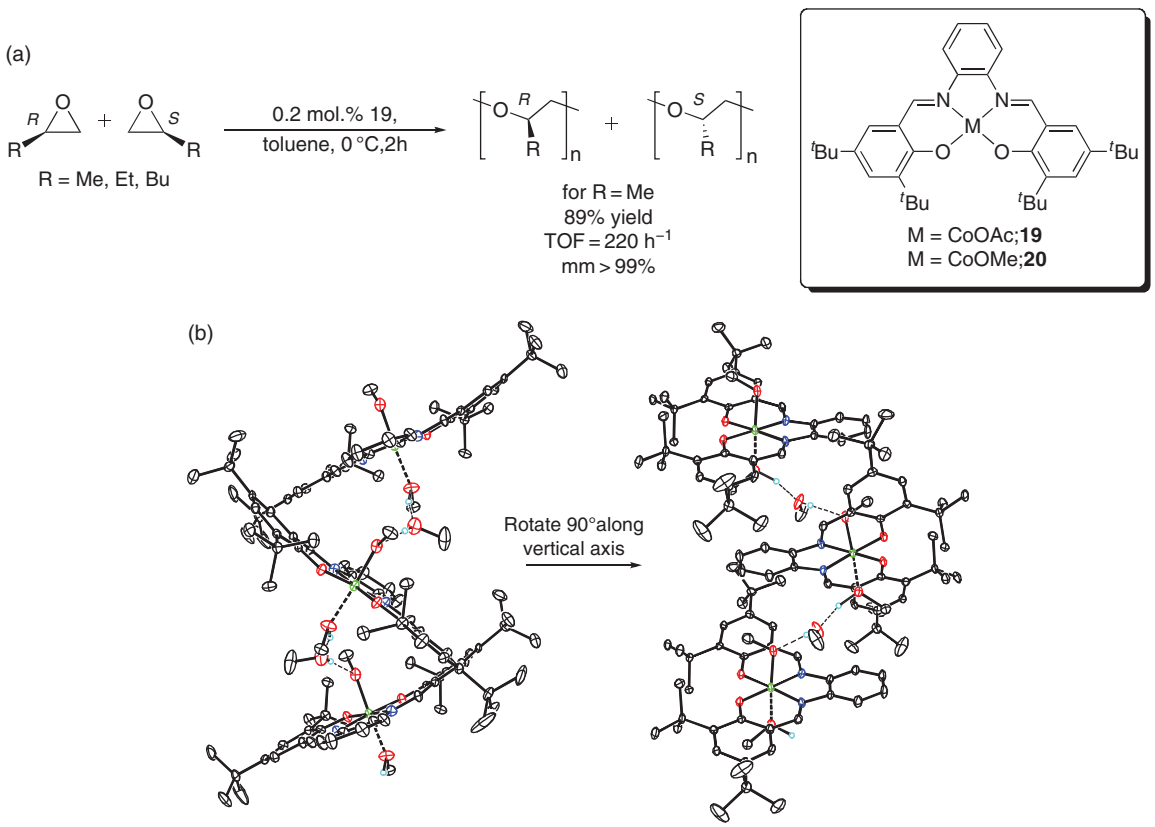
and methylene regions were best simulated using Bernoullian statistical methods, supporting a chain-end stereochemical control mechanism.

4.09.3.3.2 Recent stereoselective epoxide homopolymerization systems

In 2005, Peretti and co-workers[81] reported a highly active and isoselective (TOF = 220 h^{-1}, *mm* > 99%) cobalt complex, [(salph-^{t}Bu)CoOAc] **19** (**Scheme 18(a)**) for the polymerization of racemic propylene oxide. This is the first example of highly isotactic poly(propylene oxide) generation from racemic propylene oxide without concomitant atactic byproduct. 1-Butene oxide and 1-hexene oxide, though structurally similar to propylene oxide, displayed only trace activity with **19**, while all other substituted epoxides screened showed no activity. Though suitable crystals of **19** were not obtained, the crystal structure of the methoxide analog **20**, revealed the formation of chiral clefts that are proposed to facilitate its isoselective nature. Adjacent cobalt atoms were separated by 7.13 Å with the salen planes oriented 52° to each other, as shown in **Scheme 18(b)**.[82] Studies found that samples of crystalline **20** that had been ground mechanically displayed significantly higher activity than unground **20**. This large increase in polymerization activity of **20** with increased surface area supports that polymerization occurs on



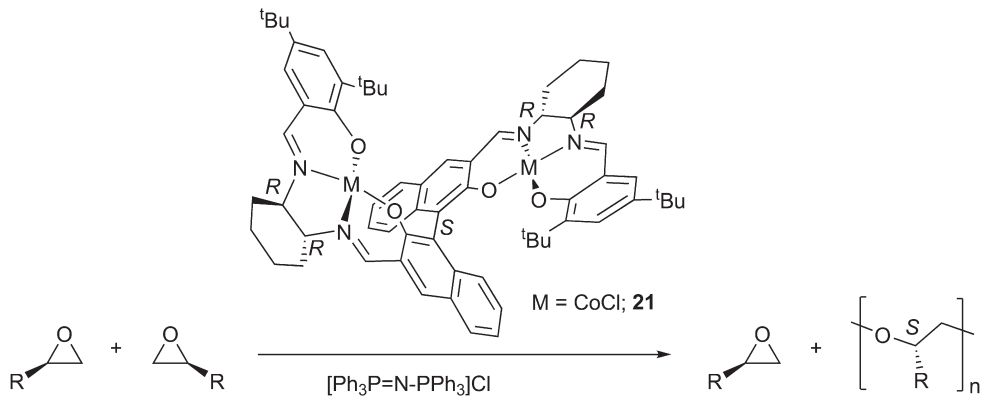
Scheme 18 (a) Isoselective polymerization of propylene oxide using **19**; (b) Molecular structure of methoxide analog **20**.

the surface of crystalline **19** and crystalline **20**. The supramolecular structure of **19** and **20** limits any attempts at catalyst optimization through substituent modification due to the inability to accurately predict structural packing, leading to desire for a soluble modular system to synthesize isotactic polyethers.

Mechanistic studies of **19** and **20** lead to the design of the complex **21**, which was reported by Coates and co-workers[83,84] in 2008. An axially chiral binaphthol linker covalently oriented the cobalt centers in the appropriate geometry and maintained the ideal distance between metal centers for epoxide polymerization (**Scheme 19**). The catalytic system consisting of **21** and a cocatalyst, [PPN]OAc, can enantioselectively polymerize propylene oxide with s-factor greater than 300 and TOF of 5400 h^{-1}. The system displayed enantiomorphic site control as determined by ^{13}C NMR. A variety of monosubstituted racemic monomers including alkyl, glycidyl, vinyl, styrenic, and fluorinated epoxides were shown to be enantioselectively polymerized to form highly isotactic enantiopure polyethers. This left valuable enantiopure epoxides in the starting material with s-factors ranging from 20 to 300. Racemic catalyst was shown to isoselectively polymerize epoxides in quantitative yield at low (0.1 mol.%) catalyst loading. Many of the isotactic polyethers synthesized were crystalline unlike their atactic analogs and nearly all had high M_n values.

Subsequent work developed a simplified isoselective variant of the catalyst (**22**) by substituting the cyclohexanediamine bridge for ethylenediamine and using a racemic binapthol linker (**Scheme 20**).[85] This complex displayed low activity and selectivity for TOF when combined with [PPN]OAc. The identity of the cocatalyst was found to dramatically affect reactivity, the bulkier [PPN]OPiv cocatalyst gave the highest rates and isoselectivities for a broad range of epoxides. This system displays the highest rate reported for isoselective TOF (=1000 h^{-1}) and high tacticity (*mm* = 97%).

Studies of these bimetallic systems have shown that the axial chirality of the binapthol linker determines the enantiopreference for epoxide enchainment,[85] rather than the stereochemistry of the diamine, unlike related cobalt salen systems.[39,79] Complexes **21** and **22** are currently believed to exist as mixtures of exo/endo chloride diastereomers. Addition of cocatalyst leads to an active anionic complex as shown in



Epoxide	TOF (min^{-1})	M_n (kg mol^{-1})	*s*-Factor	Epoxide	TOF (min^{-1})	M_n (kg mol^{-1})	*s*-Factor

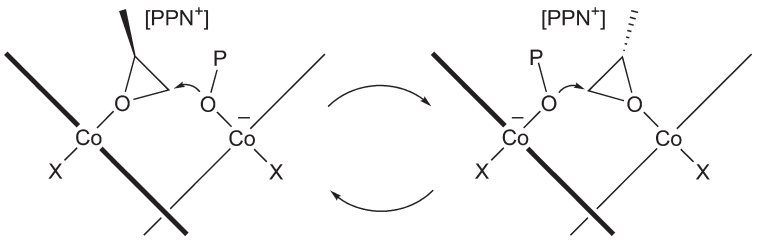

Scheme 21 Proposed mechanism of polymerization for **21** and **22**.

Scheme 21 where X can be either a chloride or a carboxylate. These bimetallic cobalt catalysts display induction periods and poor agreement between theoretical and experimental M_n values likely due to slow initiation relative to propagation. Polydispersities (M_w/M_n) were ~2, consistent with a single-site mechanism.[84]

4.09.3.4 Tin-Based Catalysts

In 1993, Miura and co-workers[86] studied the use of organotin-alkyl phosphate condensates derived from dibutyltin oxide and tributyl phosphate to catalyze the polymerization of propylene oxide (Figure 4). They observed that the polymeric product could be fractionated into benzene–hexane soluble and insoluble fractions. On studying the stereoerrors of the product by ^{13}C NMR, they determined that the insoluble fraction was isotactic poly(propylene oxide) with 94% *m*-dyads (91% *mm*-triads). A direct correlation was found between increasing the molecular weights of the tin condensate initiators with increasing molecular weight and stereoregularity of the polyethers synthesized. Schütz and co-workers[87] later demonstrated the further use of organotin phosphate coordination polymers to synthesize isotactic poly(propylene oxide). The tin phospate polymers were made by the condensation of tributyl phosphate and butyl tin trichloride. Propylene oxide was polymerized with high activity (TOF = 100 h^{-1}). After fractionation of the polymeric product, 10% was found to be insoluble in acetone and highly isotactic with 88% *m*-dyads. No allyl end groups were detected; these polymerizations have been proposed to undergo a bimetallic mechanism for enchainment.

4.09.3.5 Chromium-Based Catalysts

A significant contribution toward developing regioregular polycarbonates has been made by the Lu research group, including developing a saturated salicylaldimine chromium(III) catalyst ([SalanCr(III)], Figure 5), which in conjunction with

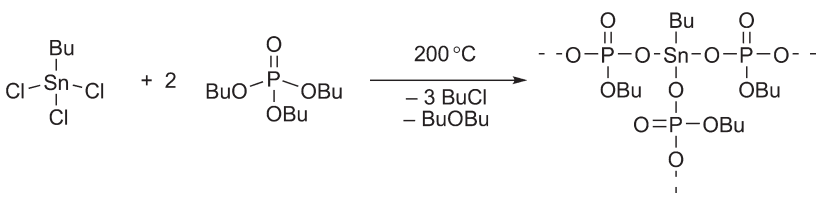

Figure 4 Preparation of organotin phosphate condensates.

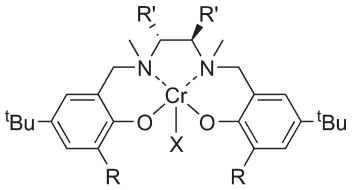

(Salan)Cr(III)

Figure 5 Structure of Salan Cr(III) complex.

quaternary ammonium salts can produce high-molecular-weight poly(propylene carbonate) with regiochemical control (>95% head-to-tail linkages) while also displaying moderate enantioselectivity ($2 < s < 8$) depending on the quaternary ammonium cocatalyst used.[88]

4.09.4 Conclusion/Outlook

Although significant advances in stereoselective epoxide polymerization have been achieved over the last half-century, only recently have catalysts been developed that are capable of high levels of stereocontrol. Historically, most catalysts for stereoselective epoxide polymerization have been heterogeneous and have exhibited poor selectivity. Current work in the development of well-defined, homogeneous, multimetallic catalysts with controlled spatial orientation of the active catalyst centers could lead to new generations of improved stereoselective epoxide polymerization catalysts. Major frontiers in stereoselective epoxide polymerization have yet to be explored – these include the development of new systems that are highly stereoselective for epoxide/CO_2 copolymerization, highly selective for polymerization of polysubstituted epoxides, as well as living and stereoselective, allowing for the formation of block copolymers. New catalysts are still needed to accomplish the challenge of synthesizing precisely defined highly tactic polyethers and polycarbonates.

Biographical Sketches

Hiroharu Ajiro received his Bachelor's degree in 1999, Master's degree in 2001, and PhD degree in 2004 from Nagoya University under the direction of Professor Yoshio Okamoto. He received a Research Fellowship for Young Scientists of the Japan Society for the Promotion of Scientists (2003–04). In 2004–05, he was a Postdoctoral Associate with Prof. Geoffrey W. Coates at Cornell University. He joined Osaka University, the Center for Advanced Medical Engineering and Informatics, as a specially appointed lecturer in 2006. He received the CSJ Presentation Award 2010 and the Award for Encouragement of Research in Polymer Science from SPSJ in 2010.

Peter C. B. Widger received his BS degree in chemistry from the University of New Hampshire in 2006. He then went on to study polymer chemistry at Cornell University with Professor Geoffrey Coates and received his PhD degree in 2011. He is currently a researcher at E Ink Corporation.

Syud Momtaz Ahmed received his BA degree in chemistry and mathematics from Wabash College in 2007, and is currently pursuing his PhD degree in organic materials at Cornell University. His research, conducted under the supervision of Professor Geoffrey W. Coates, focuses on the development of catalysts to synthesize polyethers and polycarbonates with controlled stereo- and regiochemistry. Ahmed has been recognized with multiple awards for academic excellence, was inducted to Phi Lambda Upsilon, the national chemistry honors society, and also received an award for excellence in teaching. Aside from chemistry, he has also established himself as a respectable musician and released commercial albums under reputable music labels in his home country of Bangladesh.

Scott Allen obtained his BS degree in chemistry from Virginia Commonwealth University in 1999 and moved to Cornell University to pursue his PhD degree on the design of catalysts for epoxide/CO_2 copolymerization under the supervision of Geoffrey Coates. After receiving his PhD degree in 2004, he cofounded Novomer to commercialize catalyst technology discovered at Cornell. Currently, he is the Vice President of Catalyst Development at Novomer.

Geoffrey W. Coates received his PhD degree in organic chemistry with Robert Waymouth at Stanford University in 1994 and was an NSF Postdoctoral Fellow with Robert Grubbs at the California Institute of Technology. He joined the Cornell University faculty in 1997, where he is now the Tisch University Professor. Professor Coates has received many awards, including the A. C. Cope Scholar Award, ACS Affordable Green Chemistry Award, and the Carl S. Marvel Creative Polymer Chemistry Award. In 2011, he was identified by Thomson Reuters as one of the world's top 100 chemists on the basis of the impact of his scientific research and was inducted into the American Academy of Arts & Sciences. He is the scientific cofounder of Novomer Inc., is a member of the Editorial Board of *Dalton Transactions*, and is an Associate Editor for *Macromolecules*.

4.10 Ring-Opening Polymerization of Cyclic Acetals

P Kubisa, Polish Academy of Sciences, Lodz, Poland
JP Vairon, Université Pierre et Marie Curie, Paris, France

4.10.1 Introduction

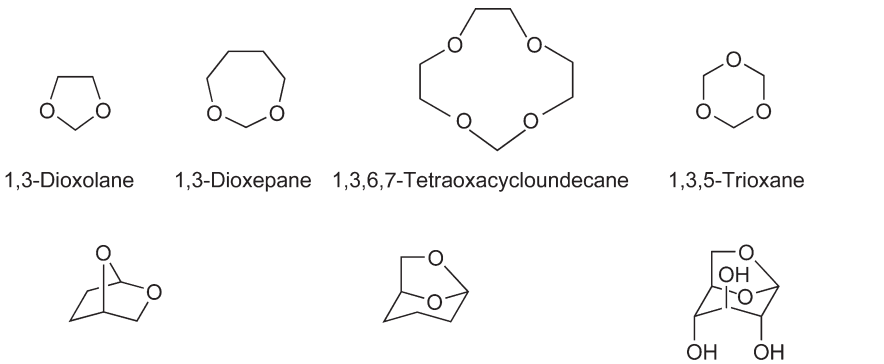
Homogeneous polymerization of cyclic acetals had been studied mostly before the first edition of *Comprehensive Polymer Science* was published and since then there has been limited activity in this area. Therefore, the first part of this chapter is based (sometimes *in extenso*) on the chapter 'Cationic Ring-Opening Polymerization: Acetals' from the first edition.[1] There are several reviews and book chapters in which cationic polymerization of cyclic acetals (including bicyclic acetals) has been discussed.[2–12]

Important progress has been made only in the field of heterogeneous polymerization of 1,3,5-trioxane (TOX) and this subject will be treated more extensively on the basis of more recent data in the second part of this chapter.

Cyclic acetals are five- and higher-membered monomers with at least one unit in which two oxygen atoms flank an unsubstituted or substituted methylene group. The bridge connecting two acetal oxygen atoms may be either an all-carbon chain (e.g., $-(CR^1R^2)_n-$) or may contain additional heteroatoms (e.g., $-(CR^1R^2)_nX(CR^1R^2)_m-$, where X is oxygen). Some typical monomers belonging to this class are shown in **Scheme 1**.

TOX, the six-membered cyclic trimer of formaldehyde, belongs to this group but its polymerization shows several distinct features and, therefore, it will be discussed separately in the last section of this chapter.

Polyacetals were among the first synthetic polymers studied by Staudinger[13] in the 1920s. Polyformaldehydes prepared by both anionic polymerization of formaldehyde and cationic polymerization of TOX were, however, thermally unstable. Thus, they were not commercialized until the late 1950s when the reasons for the thermal instability were better understood and the stabilization methods were developed. The DuPont process, based on anionic formaldehyde polymerization, involves esterification of unstable hemiacetal end groups from which degradation starts, while in the Celanese-Hoechst process TOX is copolymerized with a few percent of



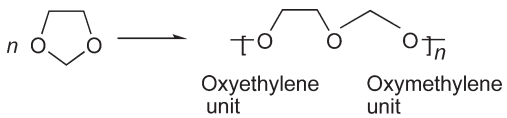
Scheme 1 Typical cyclic acetals.

comonomer, for example, ethylene oxide (EO) or 1,3-dioxolane (DXL). Randomly distributed -OCH_2CH_2- units interrupt the sequences of -OCH_2- units, which prevents depolymerization (unzipping). Polyformaldehyde (also called polytrioxane) is the only polyacetal made on an industrial scale (over 500×10^3 tons a year worldwide at the end of twentieth century).[14]

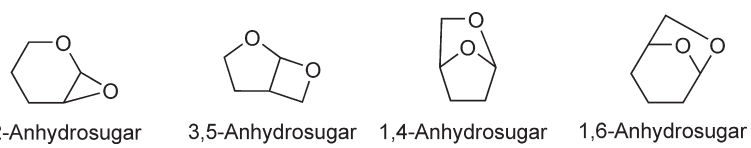
It should be noted that ring-opening polymerization of cyclic acetals is not the only route to polyacetals. Polyacetals are also formed by ionic polymerization of aldehydes,[15] by polycondensation of aldehydes and diols,[16] or by polyaddition of divinyl ethers to diols.[17–19] In this chapter, however, only cationic ring-opening polymerization of cyclic acetals will be discussed.

Cationic polymerization of cyclic acetals yields polyacetals, that is, polymers containing acetal bonds -OCR^1R^2O- in the main chain (the class name polyacetals should not be confused with the name poly(vinyl acetal)s, which is the class name for a group of polymers that are products of the reaction between poly(vinyl alcohol) and an aldehyde). Homopolymers of cyclic acetals are at the same time perfectly alternating copolymers composed of oxymethylene and oxyalkylene units, as shown for DXL polymerization in Scheme 2.

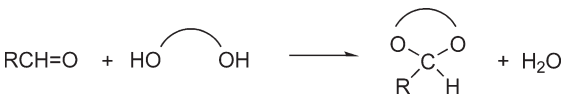
Acetal bonds appears also in some anhydrosugars. Anhydrosugars are monosaccharide derivatives that in addition to five-membered furanose ring or six-membered pyranose ring contain another oxygen-containing ring formed through elimination of water from two hydroxy groups of sugar. Anhydrosugars containing acetal bonds may have skeletons shown in Scheme 3.



Scheme 2 Structure of the repeating unit of polyDXL.



Scheme 3 Skeletons of typical anhydrosugars.



Scheme 4 Synthesis of acetals by condensation of diols with aldehydes.

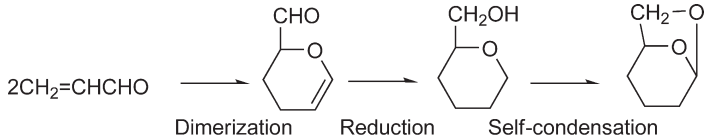
The remaining hydroxy groups in anhydrosugars have to be blocked prior to polymerization.[20] Synthetic polysaccharides prepared by polymerization of the acetal ring in anhydrosugars cannot compete with inexpensive products isolated from natural sources for use on a large scale such as food additives, paper additives, adhesives, and coatings. Thus, research on synthetic polysaccharides is stimulated mainly by their potential biomedical applications. It is expected that it will be easier to meet the high requirements for standardization with synthetic products than with natural ones.

4.10.1.1 Monomers

Cyclic acetals are usually prepared by condensation of formaldehyde (conveniently in the form of paraformaldehyde or TOX) or higher aldehydes with diols in the presence of 1–2 wt.% of an acid catalyst; *p*-toluenesulfonic acid or ion-exchange resins are most frequently used for this purpose (Scheme 4).[21]

TOX, the cyclic trimer of formaldehyde, is prepared by heating aqueous solutions of formaldehyde in the presence of strong acids. Water/TOX azeotrope (~ 70% TOX) is distilled off and pure TOX is isolated. The simplest purification method involves fractionation (b.p. 115 °C), often in the presence of a solvent that forms azeotrope with water, for example, *n*-heptane.

Synthesis of bicyclic acetals is more complex; thus, for example, 6,8-dioxabicyclo[3.2.1]octane (6,8-DBO) is prepared in three steps from acrolein as shown in Scheme 5.



Scheme 5 Synthesis of bicyclic acetal: 6,8-dioxabicyclo[3.2.1]octane.

4.10.1.2 Polymerizability of Cyclic Acetals

Polymers are formed from the corresponding monomer when

1. polymerization is thermodynamically possible,
2. a suitable mechanism exists.

The smallest ring of a cyclic acetal contains five atoms. Ring-opening polymerization of cyclic monomers with rings composed of more than four atoms is a reversible process due to a relatively low negative ΔH_p (enthalpy of polymerization) value (Table 1) (*see* Chapter 4.02). Thus, monomer–polymer equilibrium is established, and if the equilibrium monomer concentration $[M]_e$ is higher than its starting concentration, polymerization is not possible. This is the case with the six-membered cyclic acetal 1,3-dioxane.

Cyclic acetals are weak bases and require strong acids to initiate polymerization. The acetal bond is highly reactive and is easily opened in the presence of acid catalyst; thus, cationic polymerization provides a suitable mechanism for converting a cyclic acetal into a linear polymer.

4.10.1.3 Thermodynamics of Polymerization

For reversible polymerization, two interrelated parameters characterize the system: equilibrium monomer concentration $[M]_e$ (at a given temperature) and ceiling temperature T_c (for a given initial monomer concentration $[M]_0$, usually equal to 1 mol l^{-1} or in bulk concentration). The smaller the negative ΔG° (Gibbs free energy) value, the higher the $[M]_e$ value and the lower the T_c value:

$$\Delta G^\circ = \Delta H - T\Delta S \qquad [1]$$

$$\ln\left(\frac{1}{[M]_e}\right) = \frac{-\Delta G^\circ}{RT} \qquad [2]$$

where H is enthalpy, T is temperature, S is entropy, and R is gas constant. Selected thermodynamic parameters for polymerization of cyclic acetals are listed in Table 1.

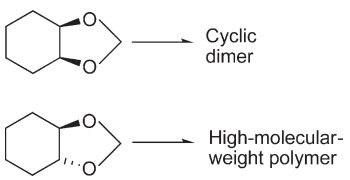
It was not always recognized in the past that in order to make polymerization of some cyclic acetals feasible, the highest possible $[M]_0$ and the lowest possible temperature should be used. This led to some unsuccessful attempts to prepare high polymers from substituted cyclic acetals. However, when suitable conditions were used, substituted cyclic acetals such as 4-phenyl-1,3-dioxolane[25] or 2-butyl-1,3,6-trioxocane[26] gave reasonably high yields of high-molecular-weight polymers.

For bicyclic (i.e., disubstituted) acetals, the thermodynamic polymerizability is usually enhanced due to additional strain introduced by the presence of the second ring; thus, for example, 6,8-DBO at concentrations of ca. 2.5 mol l^{-1} can be polymerized up to 95% conversion at −78 °C in CH_2Cl_2, which means that $[M]_e < 1.25 \times 10^{-1}$ mol l^{-1} under these conditions.[27]

The influence of the additional strain on the thermodynamic polymerizability may be illustrated by the polymerization of 7,9-dioxabicyclo[4.3.0]nonane. *Trans*-monomer gives high-molecular-weight polymer in high yield while under the same conditions *cis*-monomer gives only a cyclic dimer (Scheme 6).[28]

In some instances, the excess strain can even lead to the opening of the six-membered ring instead of the five-membered one. Thus, 2,7-dioxabicyclo[2.2.1]heptane, in which the six-membered ring is forced into an unfavorable boat conformation, gives polymers containing both five- and six-membered rings (Scheme 7).[10]

The thermodynamics of TOX polymerization, studied extensively by Enikolopyan and reviewed recently in a book by Berlin *et al.*[29] entitled *Polyoxymethylenes* (in Russian), is more complex. This is due to the fact that propagation proceeds simultaneously with phase transition; phase transition of the monomer molecule from liquid phase to crystalline phase occurs simultaneously with its incorporation into a polymer chain. Thus, the overall Gibbs free energy (ΔG°) for the propagation step is the sum of the energy changes associated with chemical reaction and phase transition. Consequently, equilibrium is shifted more toward polymer and TOX



Scheme 6 Polymerization of cis- and trans-7,9-dioxabicyclo[4.3.0] nonane.

Table 1 Thermodynamic parameters of homogeneous polymerization of unsubstituted cyclic acetals in CH_2Cl_2 solution

Monomer	ΔH^o (kJ mol^{-1})	ΔS^o (J mol^{-1} K^{-1})	T_c (°C) for $[M]_0$ = 1 mol l^{-1}	*References*

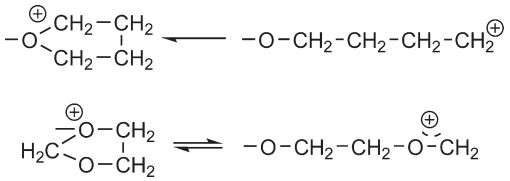
(six-membered ring of low strain) can be polymerized with high conversions.

The thermodynamics of trioxane polymerization is discussed in more detail in the chapter on Thermodynamic and Kinetic Polymerizability (Chapter 4.02) (by S. Penczek and K. Kałużyński).



Scheme 9 Unimolecular opening of oxonium ion in the cationic polymerization of cyclic ether (THF) and cyclic acetal (DXL).

4.10.2 Mechanism of Homogeneous Polymerization of Cyclic Acetals

4.10.2.1 General Considerations

Although the chemistry of acetal and ether bonds is quite different, cyclic acetals bear some resemblance to cyclic ethers; thus the polymerization of both groups of monomers shows some similarities. Essentially the same groups of initiators that initiate cationic polymerization of cyclic ethers (i.e., strong protonic acids, Lewis acids, or oxonium, carbenium, or oxocarbenium salts) are also effective in the polymerization of cyclic acetals. On the other hand, there are distinct differences.

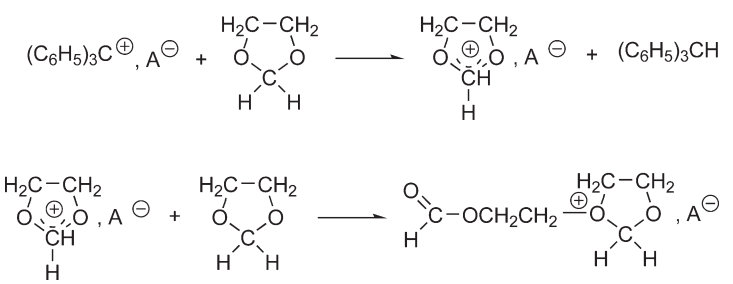
An acetal group readily participates in hydride transfer reactions because the resulting carboxonium ion is stabilized by electron pairs of the two neighboring oxygen atoms. Thus if compounds capable of acting as hydride ion acceptors, such as (triphenylmethyl)carbenium ions, are used as initiators, initiation of DXL polymerization proceeds through intermediate 1,3-dioxolan-2-ylium ion, which is a real initiator, as shown in Scheme 8.[30,31]

The presence of two oxygen atoms in an acetal bond raises also the question of the nature of active species and the mechanism of propagation. It is generally accepted that active species in the cationic polymerization of cyclic ethers are oxonium ions and propagation proceeds by S_N2 mechanism as an attack of oxygen atom of monomer molecule on α-carbon atom in cyclic oxonium ion (for active chain end (ACE)-type polymerization). An alternative pathway involving unimolecular opening of oxonium ion ring with formation of carbenium ion and subsequent reaction of this ion with monomer is excluded because conversion of relatively stable oxonium ion to highly reactive primary carbenium ion would be energetically very unfavorable. However, the situation is different in the cationic polymerization of cyclic acetals because unimolecular opening of oxonium ion ring generates stabilized carboxonium ion as shown in Scheme 9.

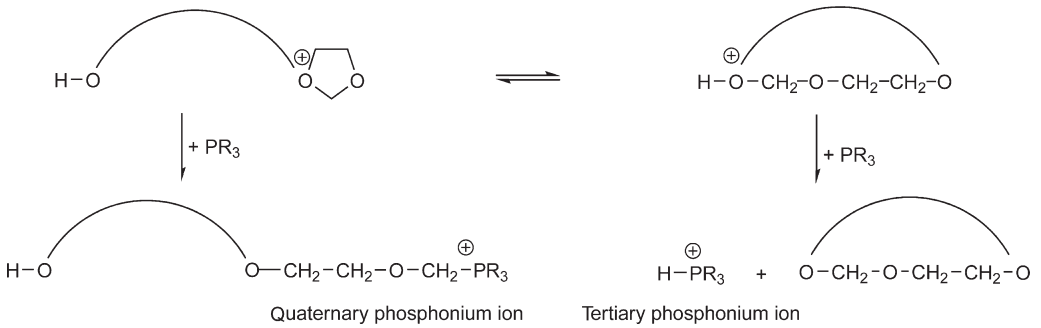
There was a long-lasting controversy concerning the participation of both types of ions in propagation. By studying a suitable model system it was eventually shown that carboxonium ions do exist in equilibrium although at typical polymerization conditions their fraction is low (< 0.1% of all ionic species, depending however on conditions such as temperature and solvent). In spite of low concentration of carboxonium ions their role in propagation is not negligible because the rate constant of propagation on carboxonium species is 2 orders of magnitude higher than the rate constant of propagation on an oxonium ion active species.[32]

In contrast to tetrahydrofuran (THF) polymerization, where chain transfer to polymer is slow compared to propagation, in the polymerization of cyclic acetals chain transfer to polymer is fast compared to propagation. Intramolecular chain transfer to polymer leads to the formation of a cyclic fraction. It was shown that cyclic oligomers are always formed in the cationic polymerization of DXL and this observation even led to the hypothesis that polymerization proceeds by ring-expansion mechanism and polymers are exclusively cyclic.[33] Detailed studies of this system revealed, however, that in the polymerization initiated with Lewis acids the content and distribution of the cyclic oligomer fraction agree well with those predicted by the Jacobson–Stockmayer (J-S) theory based on equilibrium between linear and cyclic macromolecules.[34]

In the polymerization initiated with protic acids, cyclic oligomers may be formed not only by random backbiting (i.e., according to the J-S theory) but also by end-to-end coupling. This type of initiation introduces the HO- head group,



Scheme 8 Initiation of DXL polymerization via intermediate formation of 1,3-dioxolan-2-ylium cation.



Scheme 10 Phosphine ion-trapping in the cationic polymerization of DXL.

which is considerably more nucleophilic than acetal oxygen atoms along the chain. Thus especially at the early stages, when relatively short chains can easily assume conformation in which HO- head group and tertiary oxonium ion at the end of a macromolecule are in close proximity, end-to-end closure may be favored over random backbiting, leading to kinetic enhancement in macrocycles. With increasing chain length this effect disappears as shown for cationic polymerization of 1,3,6,9-tetraoxacycloundecane (triethylene glycol formal).[35]

In the polymerization of DXL, using the phosphine end-capping method (the principle of the method is outlined in Scheme 10), it was shown that secondary oxonium ions exist in equilibrium with tertiary ones and the position of equilibrium is shifted toward tertiary oxonium ions with increasing chain length.[36]

The major conclusions stemming from these studies are the following:

- both tertiary oxonium ions and secondary oxonium ions (i.e., 'protons') are present in the system; therefore, propagation can take place on the linear active macromolecules (this is not excluding propagation on the cyclic ones);
- the proportion of tertiary oxonium ions on linear macromolecules is higher for longer chains, as can be expected.

4.10.2.2 Initiation

Cyclic acetals polymerize almost exclusively by a cationic mechanism. Most typical cationic initiators will initiate polymerization of cyclic acetals. Examples are (1) strong protonic acids, for example, $HClO_4$ and CF_3SO_2OH and their derivatives, esters (CF_3SO_2OR), anhydrides [$(CF_3SO_2)_2O$] but also tungsten or molybdenum heteropolyacids, for example, $H_3PMo_{12}O_{40}$; (2) organic salts: carbenium, for example, $Ph_3C^+A^-$, oxonium, for example, $Et_3O^+A^-$, or oxycarbenium, for example, $PhCO^+A^-$; and (3) Lewis acids (Friedel–Crafts catalysts), for example, BF_3, $SbCl_5$, and PF_5, and their complexes with, for example, ethers.

The (co)polymerization of TOX can also be mediated by transition metal complexes, for example, molybdenum or palladium.[37,38]

4.10.2.2.1 Influence of the counterion structure

Organic cations (carbenium, carboxonium, oxycarbenium, and oxonium) are coupled with complex counterions of MX^-_{n+1} type, for example, SbF_6^-, $SbCl_6^-$, or BF_4^-, or with noncomplex counterions, for example, ClO_4^- or $CF_3SO_2O^-$. It has been shown for DXL polymerization that only those initiators that contain the most stable and the least nucleophilic counterions, such as SbF_6^- and AsF_6^-, lead to the quantitative formation of stable active species.[39–41]

The unstable $SbCl_6^-$ and BF_4^- counterions, due to their fragmentation, give rise to side reactions, resulting in incomplete initiation and a decrease in active species concentration.

The fragmentation of counterions and the resulting decay of active species have been studied in detail for DXL polymerization in the presence of $SbCl_6^-$.[31]

Noncomplex counterions, derived from protonic acids (e.g., ClO_4^- or $CF_3SO_2O^-$), react with active species, forming covalent esters. However, this reaction being reversible does not lead to irreversible termination of the polymer chain:

$$-OCH_2^+ + CF_3SO_2O^- \rightleftharpoons CF_3SO_2OCH_2O- \qquad [3]$$

In eqn [5] and subsequent reaction schemes, ionic active species are shown for simplicity in the form of alkoxycarbenium (carboxonium) ions, although in reality a large majority of active species exist in the form of oxonium ions. There are several types of oxonium ions coexisting in the system (see Section 4.10.2.3.1) and, due to their multiplicity, schematic representation is difficult.

For DXL and 1,3-dioxepane (DXP) polymerizations initiated with $(CF_3SO_2)_2O$, the degree of polymerization is given by

$$DP_n = \frac{[M]_0 - [M]_e}{[(CF_3SO_2)_2O]_0} \qquad [4]$$

Equation [4] indicates that the number of growing macromolecules is equal to the number of initiator molecules used. Some representative data are given in Table 2.[42]

The overall rates of polymerization are ca. 10^2 times lower than the polymerization rates initiated with $PhCO^+SbF_6^-$. This indicates that active species exist predominantly in the form of

Table 2 Calculated and measured molecular weights in the polymerization of DXL and DXP initiated with $(CF_3SO_2)_2O$[42]

Monomer	M_n *calculated*	M_n *found (membrane osmometry)*
DXL	19 350	18 250
	21 300	21 100
	35 000	44 500
DXP	13 250	10 700
	55 600	57 100
	76 500	78 000

$[M]_0 = 1–3$ mol l^{-1}, $[(CF_3SO_2)_2O]_0 = 10^{-3}–10^{-2}$ mol l^{-1}, CH_2Cl_2, –50 to –78 °C.

less reactive covalent species. However, the agreement between the observed and calculated molecular weights clearly shows that there is an efficient exchange between covalent (dormant) and active ionic species.

4.10.2.2.2 Addition versus hydride transfer

The first fast step in initiation is the protonation or alkylation (acylation) of the monomer molecules. This leads to the formation of secondary or tertiary oxonium ions, as shown for DXL in Scheme 11.

The subsequent slower step involves nucleophilic attack of another monomer molecule, leading to the ring opening and formation of active species (Scheme 12).

Initiation proceeds according to Scheme 12 for the majority of initiators used, although the rate of initiation depends on the nature of R. In the polymerization of DXL initiated with $Et_3O^+SbF_6^-$ and $PhCO^+SbF_6^-$, the corresponding initiator fragments are incorporated quantitatively as the end groups.[40]

For some initiators, however, an alternative route of initiation is possible. For triphenylmethylium (tritylium) salts, the preinitiation step is highly reversible (Scheme 13).[43]

The equilibrium constant of this reaction is equal to $K = 3.2 \times 10^{-2}\,mol^{-1}\,l$ (CH_2Cl_2, 25 °C).[43] Thus, under typical polymerization conditions, a significant amount of carbenium ions exists in equilibrium and they participate in hydride transfer reactions. Carbenium ions are efficient hydride ion (H^-) acceptors. This reaction is relatively fast ($k = 8.3 \times 10^{-3}\,mol^{-1}\,l\,s^{-1}$, CH_2Cl_2, 25 °C), while an attack of another monomer molecule on an oxonium ion is apparently slow. Thus, instead of simple initiation by addition, as shown in Scheme 13, hydride transfer takes place and 1,3-dioxolan-2-ylium salt and triphenylmethane are formed quantitatively as shown in Scheme 8. 1,3-Dioxolan-2-ylium salts, which are relatively stable and can be isolated as pure crystalline compounds, are thus the true initiators, formed *in situ* in the DXL-$Ph_3C^+A^-$ system.

4.10.2.2.3 Friedel–Crafts-type initiators: Direct initiation versus coinitiation

The mechanism of initiation with Friedel–Crafts-type initiators is generally obscure. For BF_3, the most commonly used initiator of this type, two mechanisms, namely direct initiation and initiation by coinitiator (e.g., water present as impurity), have been proposed (Scheme 14).[44]

For polymerization of TOX in media of low polarity, it has been shown that in a rigorously dried system BF_3 alone is not able to initiate polymerization. There are, however, some indirect indications that in polar solvents such as nitrobenzene, which facilitate charge separation and formation of zwitterions, initiation may proceed even in the absence of a coinitiator.[45]

A mechanism of direct initiation, involving the formation of a zwitterion, has been proposed for polymerization of the bicyclic monomer 1,6-anhydro-2,3,4-tri-*O*-benzyl-β-D-glucopyranose initiated with PF_5. All the proposed species, for

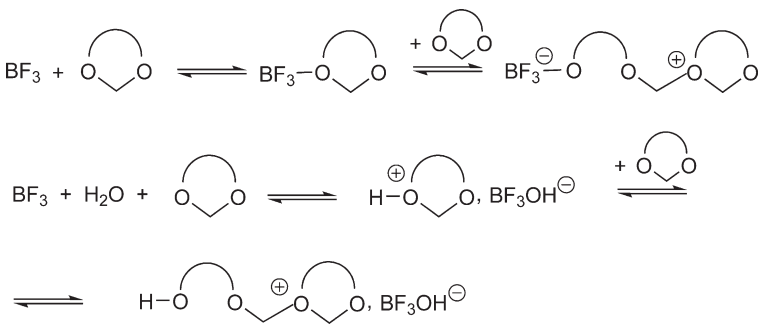


Scheme 14 Two possible mechanisms of initiation of cationic polymerization of cyclic acetals by BF_3.

example, $PF_5{}^-O<$, PF_4O^-, and PF_6^-, were identified on the basis of ^{31}P and ^{19}F nuclear magnetic resonance (NMR) spectra. In addition, formation of POF_3 was observed, indicating that terminal $-CH_2-OPF_4$ groups undergo decomposition to $-CH_2F$ and POF_3.[46] This reaction path is similar to the one observed for the THF/PF_5 system.[47]

It may be concluded that unlike protonic acids and organic salts, which under suitable conditions give clean quantitative initiation, Friedel–Crafts-type initiators lead to poorly defined systems. The efficiency of initiation, structure of counterions, and the structure of end groups are generally not known with any certainty for these initiators. The overall polymerization rates are usually lower than with other initiators, indicating the low efficiency of initiation.

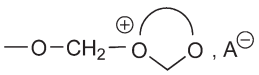
4.10.2.3 Propagation

4.10.2.3.1 Structure of active species

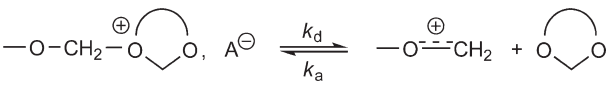
4.10.2.3.1(i) Oxonium–alkoxycarbenium ion equilibria

The simplest structure of active species in the polymerization of cyclic acetals, by analogy with the polymerization of other heterocyclic monomers, is an oxonium ion holding the monomer molecule (Scheme 15).

Already in the 1960s–1970s it was assumed, but not proven, that these species may coexist in equilibrium with carbenium (carboxonium) ion species.[48–51] Later studies of the model systems have revealed that indeed oxonium ions coexist in equilibrium with their alkoxycarbenium counterparts, in which the positive charge is delocalized between the carbon and α-oxygen atoms (Scheme 16).[32]



Scheme 15 Structure of oxonium ion in the cationic polymerization of cyclic acetals.



Scheme 16 Oxonium-carboxonium ion equilibrium in the cationic polymerization of cyclic acetals.

Equilibrium constants for the model reaction between methoxymethylium cation and dimethoxymethane (simple linear model of acetal) have been determined by dynamic ^1H NMR studies and were found to be $K_{ea} = k_a/k_d = 3 \times 10^3\ mol\,l^{-1}$ (SO_2, −70 °C).[32] This value indicates that active species in cyclic acetal polymerization exist predominantly in the form of oxonium ions, although a small proportion exist in the form of alkoxycarbenium ions.

4.10.2.3.1(ii) Structure of oxonium active species

The rate constants for formation (k_a) and dissociation (k_d) of oxonium ions are high: $k_a = 2 \times 10^6\ mol^{-1}\,l\,s^{-1}$ and $k_d = 6.7 \times 10^2\ s^{-1}$ (SO_2, −70 °C). Thus, the system is in a fast dynamic equilibrium. This leads to very fast isomerization of oxonium active species, proceeding via alkoxycarbenium ions.

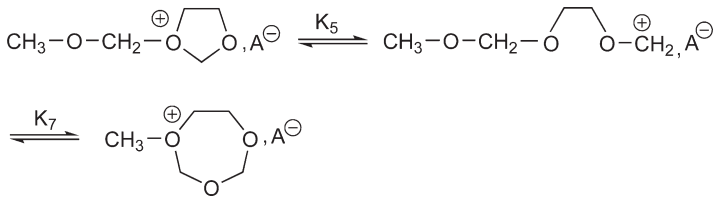
When DXL was used instead of dimethoxymethane in the studies of equilibria, it was observed by ^1H NMR that the predominant structure was not the five-membered ring oxonium ion but the corresponding cyclic ion involving the seven-membered ring (Scheme 17).

The ratio of equilibrium constants K_7 and K_5, corresponding to the ratio of concentrations of seven-membered oxonium ions to five-membered ones, is equal to 3×10^2.

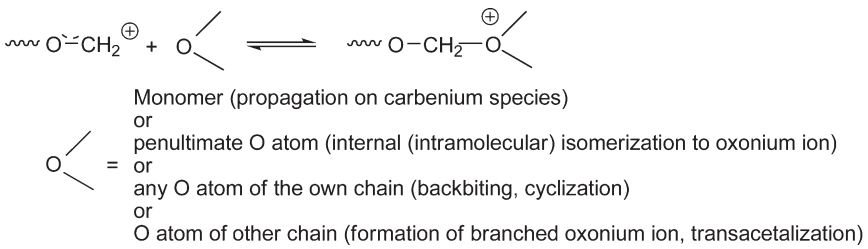
When the six-membered (1,3-dioxane) or the seven-membered (DXP) cyclic acetals were used in the studies of related equilibria, isomerization to the expanded ring structures (eight- or nine-membered, respectively) was negligible because the starting rings were less strained than the expanded ones.[52] All these reactions proceed with high rates; therefore, at any stage of polymerization, the equilibrium between alkoxycarbenium ions and various cyclic (formed by intramolecular reaction) and branched (formed by intermolecular reaction) oxonium ions is quickly established (Scheme 18).

4.10.2.3.1(iii) Secondary versus tertiary oxonium ions

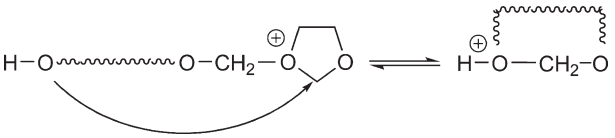
Polymerization of cyclic acetals initiated with protonic acids may lead to kinetic enhancement in macrocycles. This effect is due to the efficient end-to-end cyclization of the short growing macromolecules (Scheme 19).



Scheme 17 Formation of seven-membered oxonium ion in the cationic polymerization of DXL.



Scheme 18 Equilibria between alkoxycarbenium ions and cyclic or branched oxonium ions.



Scheme 19 End-to-end cyclization in the cationic polymerization of DXL.

Thus, tertiary oxonium ion active species are converted to secondary oxonium ions in this process. These equilibria have been studied by ion-trapping methods for the polymerization of DXL initiated with $HOSO_2CF_3$. The principle of the method is shown in Scheme 10.[36] Analysis of ^{31}P NMR spectra, based on the different chemical shifts of the tertiary ($\delta = 11.9$ ppm) and quaternary ($\delta = 31.4$ ppm) phosphonium ions, allows the determination of the relative concentrations of the secondary and tertiary oxonium ions. It was shown that in agreement with the end-to-end cyclization scheme, the concentration of the secondary oxonium ions is high for short growing chains, but decreases gradually with increasing chain length. This conclusion was later confirmed by studies of the ^1H NMR spectra of the same system. Protons in HO- end groups and H-O$^+$ < species exchange fast, giving one narrow signal. The averaged chemical shift of this signal allows determination of the relative contribution of both species.[53]

These observations prove that secondary oxonium ions are indeed formed by end-to-end cyclization, as shown in Scheme 19.

4.10.2.3.2 Reactivity of active species

It follows from the preceding discussion that in the polymerization of cyclic acetals (at least DXL) small but definite concentrations of alkoxycarbenium active species exist in equilibrium with oxonium active species. The equilibrium constant, measured for a model system, indicates that alkoxycarbenium ions constitute ca. 10^{-2}% of all active species in the polymerization of DXL at −78 °C in CH_2Cl_2. This proportion may vary substantially with the conditions applied and, of course, depends on the structure of the monomer. To estimate to what extent the alkoxycarbenium ions participate in propagation, the rate constants of model reactions have been measured (Scheme 20).

The corresponding values, determined using dynamic NMR line broadening, are $k_{oc} = 2 \times 10^6\ mol^{-1}\,l\,s^{-1}$ and $k_{ox} = 1.9 \times 10^4\ mol^{-1}\,l\,s^{-1}$ (both in SO_2 at −70 °C).[32] Thus, oxonium ions are only ca. 10^2 times less reactive than alkoxycarbenium species. Since the ratio of concentrations is ca. 10^4, it may be concluded that propagation proceeds predominantly on the oxonium ions.

4.10.2.4 Transfer and Termination

4.10.2.4.1 Chain transfer to polymer – transacetalization

Intermolecular chain transfer to polymer is well documented in the cationic polymerization of cyclic acetals. In the polymerization of TOX, as will be discussed in Section 4.10.3, chain transfer to polymer is essential for the preparation of thermally stable polyacetal. Intermolecular chain transfer to polymer is detrimental to the synthesis of monofunctional polymers such as macromonomers because segment exchange (scrambling) leads to disproportionation and formation of products having two, one, and none of the functional groups (Scheme 21).[54,55]

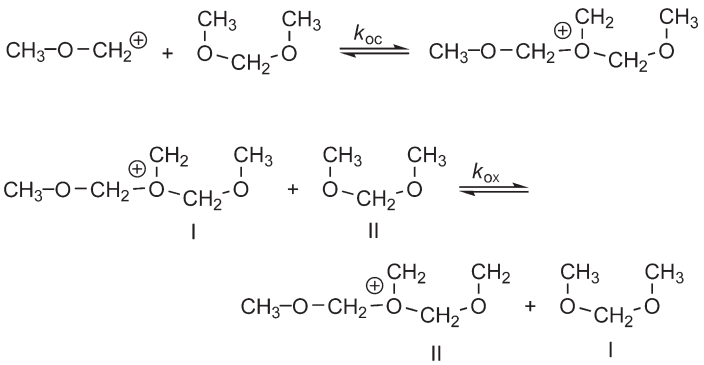
Intermolecular chain transfer to polymer prohibits also the synthesis of block copolymers by sequential polymerization of two cyclic acetals. Addition of DXP to a solution of living polyDXL resulted in further polymerization but the copolymer formed had a nearly statistical distribution of units.[42]

Chain transfer to polymer in cyclic acetal polymerization is a special case of transacetalization reaction which is well known in organic chemistry. By studying the model system it was found that in a mixture of DXL with alcohols in the presence of an acid, fast equilibration occurs as shown in Scheme 22.[56]

Active species in the polymerization of cyclic acetals undergo fast isomerization. This results in chain transfer to polymer, that is, formation (by intramolecular reaction) of cyclic structures or formation (by intermolecular reaction) of branched oxonium ions, followed by exchange of the linear fragments of the chain (transacetalization) (cf. Scheme 18).

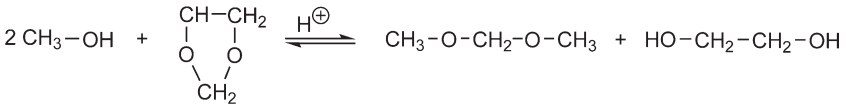
Chain transfer to polymer is facilitated by the higher basicity of oxygen atoms in the polymer chain than in the monomer molecule; this is a general feature of polyacetals. Backbiting (and/or end-biting) leads to the formation of macrocycles. Formation of branched structures results in transacetalization (also called scrambling). In branched ions, two (or all three for TOX) of the bonds between carbon and oxygen atoms bearing the positive charge are identical. Further reaction of branched oxonium ions may thus lead to redistribution of polymer segments, as shown in Scheme 23 for TOX polymerization.

This reaction, which is fast, results in continuous transfer of the monomer units or longer sequences between the chains.

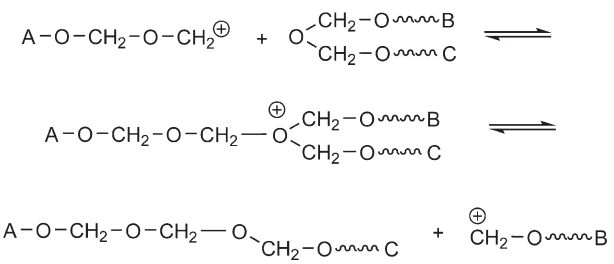


Scheme 20 Model reaction of alkoxycarbenium ions with acetals.

Scheme 21 Disproportionation of end-groups by intermolecular chain transfer to polymer.



Scheme 22 Equilibration of a mixture of DXL with alcohol in the presence of acid.



Scheme 23 Redistribution of segments by intermolecular chain transfer to polymer in the cationic polymerization of TOX.

Thus, when sequential polymerization of cyclic acetals was performed by introducing DXP into a solution of living polyDXL or vice versa, the copolymer isolated after longer reaction times showed DXL-DXL/DXL-DXP/DXP-DXP dyad distribution (determined by ^{13}C NMR) in ratios of 1:2:1, characteristic of random copolymers. When copolymerization was terminated after shorter reaction times, the proportion of heterodyads was lower, but at no stage of copolymerization could pure block copolymer be isolated.[42]

Transacetalization plays an important role in the copolymerization of TOX and DXL.[57] In these systems, due to the different reactivities of both comonomers, DXL polymerizes first. Therefore, at the early stages of polymerization, the soluble polymer, consisting essentially of DXL units, is formed. Nevertheless, the distribution of DXL units in the final product is close to random. This indicates that the originally formed polyDXL blocks undergo further fast and efficient scrambling. Thus, due to the transacetalization, thermally stable polymers containing randomly distributed oxyethylene units derived from DXL are formed. A small amount of the unstable fraction (< 5%) corresponds to oxymethylene units at the end of the chain. This fraction is removed by heating before processing the polymer (see Section 4.10.3).

4.10.2.4.2 Termination

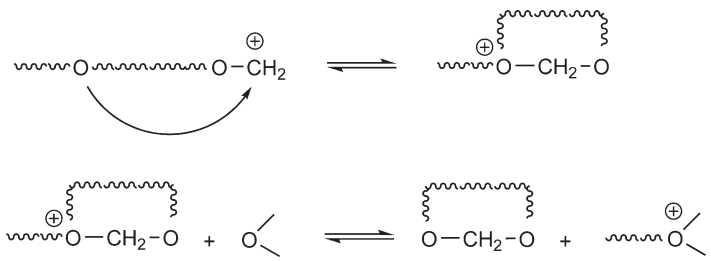
In the absence of impurities, and when stable counterions (SbF_6^-, AsF_6^-, $OSO_2CF_3^-$) are used, polymerization of simple cyclic acetals, namely DXL and DXP, proceeds without termination at least within the time needed to reach equilibrium. It has been shown (Table 2) that molecular weights in these systems are described by eqn [4] and the only end groups, identified quantitatively, are those coming from initiator and intentionally added terminating agent. It has to be remembered, however, that eventually, due to the presence of carboxonium ions in equilibrium with oxonium ions (cf. Scheme 16), hydride transfer reaction from monomer molecule to carboxonium ion may lead to the formation of macromolecules terminated with $-OCH_3$ groups while the 1,3-dioxolan-2-ylium cation may start a new chain (cf. Scheme 8). Also in the polymerization of TOX, hydride transfer to apparently living active species has been observed even several hours after equilibrium conversion of monomer had been reached. Some of this long-lived species may, however, become unavailable for propagation as a result of occlusion within the polymer particles.[57,58]

4.10.2.5 Formation of Cyclic Oligomers

4.10.2.5.1 Backbiting

Chain transfer to polymer leads to the formation of macrocyclic oxonium ions, which on further reaction may release a cyclic fragment (Scheme 24).

A thermodynamic approach to the ring-chain equilibria has been developed by Jacobson and Stockmayer (J-S theory),



Scheme 24 Intermolecular chain transfer to polymer leading to formation of cyclic fraction in the cationic polymerization of cyclic acetals.

discussed in more detail in the pertinent chapter of this volume. According to this approach, the concentration of each cyclic oligomer in equilibrium with a linear chain is related to the probability of the required conformation of linear chain being achieved and can be calculated using the rotational isomeric state model.

For DXL polymerization, these 'theoretical' equilibrium concentrations of cyclic oligomers have been calculated and compared with the values measured for real systems by gas–liquid chromatography (GLC).[34] The experimental curve shows a typical deviation from theory for oligomers with $n = 2$–4, which are still strained. (J-S theory is valid only for the strainless rings.)

DXL and macrocyclic formals are the only cyclic acetals for which cyclization has been studied quantitatively.[24,34,59] The formation of cyclic fraction may, however, be expected in the polymerization of any cyclic acetal. It has been indicated that cyclic oligomers are formed in the polymerization of TOX. Nonstabilized homopolymer always contains some amount (up to 25%) of a stable fraction,[58] which, at least partially, is assumed to be cyclic (instability is related to the hemiacetal groups, which are absent in cyclic macromolecules). Cyclic oligomers are also believed to be responsible for the bimodal molecular weight distribution observed by GPC.[60]

4.10.2.5.2 End-to-end cyclization

It has been shown that in certain systems, for example, in the protonic acid-initiated polymerization of DXL[36] or 1,3,6,9-tetraoxacycloundecane,[35] end-to-end cyclization may dominate over random backbiting at the early stages of polymerization, that is, when the growing chains are still relatively short (Scheme 25).

This leads to kinetic enhancement of cyclic macromolecules. This means that at the early stages of polymerization the concentration of a given cyclic oligomer is higher than when the final equilibrium is attained. This results from the contribution of the end groups of short chains, which essentially vanish when the high polymer is finally formed. Thus, the concentration of small cyclics grows, goes through a maximum when the end-to-end cyclization aids their formation most, and then decreases with increasing chain length, falling to the equilibrium concentration.

4.10.2.5.3 Proportions of cyclic and linear fractions

Reactions involving polyacetal chains, including intramolecular reactions, are fast compared to propagation, resulting in the simultaneous formation of macrocycles and linear polymers.

Therefore, the preparation of purely linear polymers is virtually impossible. The equilibrium concentration of individual cyclic oligomers is, however, not very high (ca. 10^{-2} mol l^{-1} for the cyclic dimer and similar values for oligomers with $n = 3$–5 in DXL polymerization).[34] The sum of the thus-calculated equilibrium concentrations of cyclics from $n = 2$ to infinity gives a relatively high value, 0.85 mol l^{-1}, for DXL polymerization. The actual measured values are somewhat lower than the calculated ones; thus the value 0.85 mol l^{-1} should be taken as an upper limit. The concentration of DXL in bulk equals 12.75 mol l^{-1} (at 25 °C). Thus, the lowest proportion of cyclic oligomers, starting from dimer, that can be attained for this monomer is close to 7.5 wt.%.

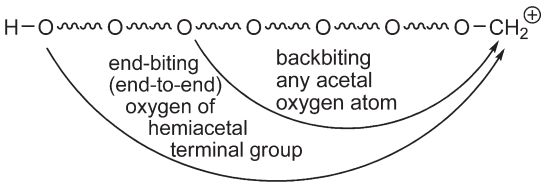
The fraction of cyclic oligomers at equilibrium is expressed as

$$f = \frac{\sum[\text{monomer units in cyclics}]}{[\text{monomer}]_0 - [\text{monomer}]_e} \quad [5]$$

Thus at low $[M]_0$, polyacetals at equilibrium may contain a considerably high proportion of the cyclic fraction. At the conditions when eqn [6] holds, almost all of the polymer can be cyclic.

$$\sum[\text{monomer units in cyclics}] > [\text{monomer}]_0 - [\text{monomer}]_e \quad [6]$$

Some authors observed almost exclusively cyclic polymers and concluded, without considering the consequences of the J-S theory, that the chain growth must proceed by ring expansion.[33] With our present knowledge of the mechanism of cyclization however, all experimental observations can be interpreted in terms of the conventional propagation mechanism (involving linear active species) coupled with backbiting and/or end-to-end cyclization.



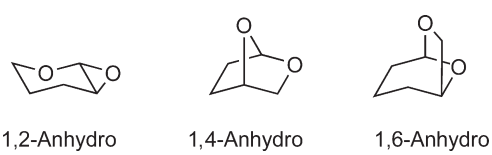
Scheme 25 End-to-end cyclization and back-biting in the cationic polymerization of cyclic acetals.

4.10.2.6 Bicyclic Acetals

The acetal bond appears in some anhydrosugars. Anhydrosugars are monosaccharide derivatives that in addition to five-membered furanose ring or six-membered pyranose ring contain another oxygen-containing ring formed through elimination of water from two hydroxy groups of sugar. Anhydrosugars containing acetal bonds may have skeletons shown in Scheme 26.

The bicyclic acetal, 6,8-DBO, possesses the structural skeleton of the 1,6-anhydrosugars and, because it is readily prepared from acrolein dimer, its cationic polymerization has been investigated. Mostly Lewis acids (BF_3, PF_5) were used as initiators, and at low temperature (−78 °C) polymers with M_n up to 10^5 could be obtained although dispersity was broad.[61–63]

Better control over molecular weights and dispersity was obtained using the 2-chloroethyl isobutyl ether/ZnI_2 initiating system. At −16 °C, the molecular weight increased linearly with conversion up to $M_n \sim 5 \times 10^3$ and dispersity was relatively low ($M_w/M_n \sim 1.3$).[64] In anhydrosugars, the ring is formed by condensation of two hydroxy groups, and the remaining hydroxy groups have to be blocked before polymerization.[65,66]



Scheme 26 Skeletons of typical anhydrosugars containing acetal bonds.

Cationic polymerization of anhydrosugars has been reviewed[20,67] and since then there has been little activity in this area. More recent studies revealed, however, that cationic polymerization of anhydrosugars displayed many of the elements of controlled polymerization: a linear increase in molecular weights with conversion and block copolymer formation.

In the polymerization of 1,4-anhydrosugar with blocked hydroxy groups initiated with $BF_3 \cdot Et_2O$, a linear increase in molecular weight with conversion was observed although dispersity was not narrow ($M_w/M_n \sim 1.6–1.7$). Block copolymers composed of two different polysaccharides could be obtained in sequential polymerization.[68]

Cationic polymerization of 1,6-anhydrosugar with blocked hydroxy groups initiated by the cumyl chloride (2-chloro-2-phenylpropane)/ZnI_2 initiating system gave polysaccharides with relatively low dispersity ($M_w/M_n \sim 1.25$). The kinetic plots of ln[M] versus time were linear and a linear increase in M_n with conversion was observed at least up to $M_n \sim 6 \times 10^3$. There was evidence of slow chain transfer at these polymerization temperatures, although a majority of polymer chains contained the initiator fragment. The authors concluded that through a proper combination of monomer structure, protecting groups, and initiators, other anhydrosugars may be polymerized with control over the molecular weights and end-group structures.[69]

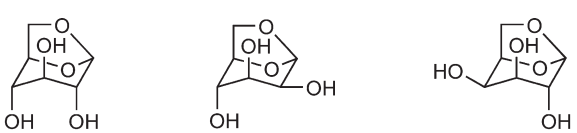
There are also reports on the cationic polymerization of anhydrosugars having free hydroxy groups. Anhydrosugars shown in Scheme 27 were polymerized at high temperatures (>130 °C) with sulfonium salts as initiators to highly branched polysaccharides with M_w in the range between 3×10^4 and 8×10^4.

The presence of branched units, as confirmed by ^{13}C NMR analysis, indicates that free HO groups participate in propagation.[70,71]

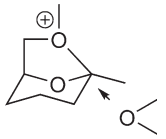
4.10.2.6.1 Stereochemistry of polymerization

Unsubstituted monocyclic acetals (symmetrical molecules) are not suitable for studies of the stereochemistry of polymerization. Because there are no reliable data on the stereochemistry of polymerization of the substituted monocyclic acetals, the only available information relating to the steric course of polymerization comes from studies of bicyclic acetals. This subject has been reviewed.[72]

For polymerization of 6,8-DBO, it has been shown that at −78 °C inversion of configuration occurs in nearly 100%. This result is in full agreement with the oxonium ion mechanism involving S_N2 substitution and an attack of the incoming monomer molecule from the 'opposite' side, along the carbon–oxygen bond as shown in Scheme 28.



Scheme 27 Anhydrosugars containing free hydroxyl groups that have been polymerized by cationic mechanism.



Scheme 28 Direction of nucleophilic attack leading to inversion of configuration in cationic polymerization of bicyclic acetal.

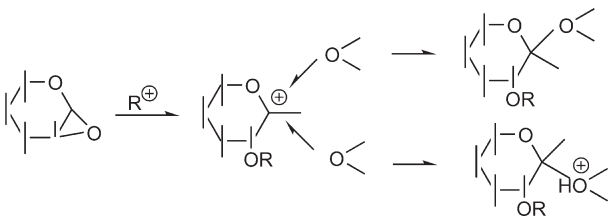
At higher temperatures, the stereospecificity of reaction is lower. It has been argued, however, that this effect is only apparent, that is, propagation proceeds with inversion of configuration, while racemization is due to the side reactions involving polymer chains (transacetalization).

The steric course of polymerization of anhydrosugars depends on the size of the fused rings.[65,66] Thus, for polymerization of 1,2- and 1,4-anhydrosugars, racemization has been observed and explained by participation of alkoxycarbenium ions in the propagation step (e.g., for 1,2-anhydrosugars, see Scheme 29).

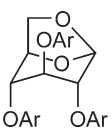
1,6-Anhydrosugars, which have a 6,8-DBO skeleton, polymerize mainly with inversion of configuration; thus α-monomers give β-polymers and vice versa. For example, 1,6-anhydro-2,3,4-tri-*O*-benzyl-β-D-glucose (Scheme 30) polymerizes at −60 °C in CH_2Cl_2 with PF_5 initiator (1 mol.%) to give a high-molecular-weight polymer (M_n up to 7×10^5) in 50% yield. The polymer, after debenzylation, has a specific rotation up to 197° and is identical to a naturally occurring polysaccharide (dextran) for which a highly specific α-structure has been established.[73] Natural dextran has $[\alpha]_D^{25}$ values between + 196° and + 199°.

For the polymerization of 6,8-DBO, it has also been shown that stereoselection operates to some extent. Thus, polymer formed from racemic monomer is enriched in isotactic dyads (up to 85%). Polymerization of a racemic mixture enriched in one of the enantiomers has also been studied, and it was shown that selection of the enantiomer present in excess leads to polymers with an enhanced proportion of this enantiomer.[27,74]

On the basis of these observations, the mechanism of enantiomer selection by growing chain ends has been proposed. According to this theory, steric repulsion is minimized when



Scheme 29 Participation of alkoxycarbenium ions in the propagation step for cationic polymerization of 1,2-anhydrosugars.



Scheme 30 1,6-anhydro-2,3,4-tri-*O*-benzyl-β-D-glucose.

the monomer incorporated into the growing species and the incoming monomer molecule have the same chirality.

4.10.2.7 Microstructure of Polymer Chain

Polymerization of cyclic acetals proceeds by opening one of the -O–CH_2–O- bonds; thus polyacetals are built up as shown in Scheme 31.

This was confirmed by ^{1}H and ^{13}C NMR spectroscopy; thus, for example, the ^{1}H NMR spectrum of polyDXL consists of two sharp singlets at $\delta = 4.76$ ppm (OCH_2O) and 3.73 ppm (OCH_2CH_2O).[75] For substituted cyclic acetals, breaking of either the O(1)–C(2) or the O(3)–C(2) bond may lead to a polymer of irregular structure. Indeed, by analyzing the methylene group signals in ^{1}H NMR spectra of poly(4-ethyl-1,3-dioxolane), it has been shown that the polymer is composed of both types of units (Scheme 32).[76]

4.10.2.8 Functional Polyacetals

Polyacetals containing functional groups were prepared by cationic copolymerization of cyclic acetals with methyl 2-oxopropanoate (methylglyoxylate (GM)) (Scheme 33).

In the copolymerization of DXL with GM, a large amount of mixed cyclic dimer (containing one DXL and one GM unit) was formed (up to 70%).[77]

Cyclization was eliminated when DXP was used instead of DXL and linear copolymers with M_n up to 2×10^4 containing 30–70 mol.% of GM units were obtained.[78] Partial replacement of the ester groups in GM-DXP copolymers with amide groups by reaction with α-amino-ω-methoxypoly(oxyethylene) (Jeffamine) led to graft copolymers in which the remaining ester groups were hydrolyzed to carboxylate groups. The resulting water-soluble graft copolymers containing hydrophilic side chains and carboxylate groups along the main chain belong to the class of double-hydrophilic graft copolymers used as modifiers of crystallization of inorganic salts.

Extensive transacetalization proceeding parallel to propagation essentially precludes the possibility of the synthesis of perfectly monofunctional polymers or block copolymers by cationic polymerization of cyclic acetals. Transacetalization is not that detrimental to synthesis of difunctional telechelic polyacetals and several such products have been obtained. Because polyacetals such as polyDXL readily undergo depolymerization in the presence of acids, telechelic polyacetals were used to synthesize degradable polyurethanes[79–81] or degradable polymer networks.[82–84]

Such networks that can be easily solubilized under mild conditions may be useful as materials. Besides, the possibility to study the residual material after hydrolysis of linear chains may provide more insight into the mechanism of network formation.[81]

PolyDXL bis-macromonomers were prepared by cationic polymerization of DXL initiated by triflic anhydride, end-capping of the resulting bifunctional living polymers with triethylamine, and nucleophilic substitution of ammonium end groups by a methacrylate anion.[85]

Another approach involved cationic polymerization of DXL in the presence of dialkylformals containing methacryloyl groups as chain-transfer agents (shown in Scheme 34).

Efficient transacetalization led to the formation of polymers containing polymerizable groups at both ends, as shown by ^{1}H NMR. Their degree of polymerization was governed by the ratio [monomer]/[chain-transfer agent] and the measured values were close to the calculated values up to $M_n \sim 10^4$.

Copolymerization of bis-macromonomers gave polymer networks which could be de-cross-linked at mild conditions in the presence of an acid. Analysis of degradation products indicated that polyDXL bis-macromonomers were quantitatively incorporated into the network structure.[85]

Polyacetals containing polymerizable acrylate groups at both ends were also prepared (but not fully characterized) by cationic polymerization of DXL initiated with triflic anhydride in the presence of HEMA (hydroxyethyl methacrylate). Radical copolymerization of those bis-macromonomers with acrylic acid led to degradable pH-sensitive networks.[86]

Block copolymers containing polyacetal blocks have been prepared by a combination of reversible addition-fragmentation chain-transfer (RAFT) polymerization and cationic ring-opening polymerization. Polystyrene (PSt) containing end groups with hydroxy and dithiobenzoate functions (as shown in Scheme 35) were obtained and used as macroinitiator for subsequent cationic polymerization of DXP and RAFT polymerization of methyl methacrylate (MMA). The product was mikto-arm ABC star copolymer containing PSt, PDXP, and PMMA arms.[87]

Water-soluble polyacetals are also used as drug carriers. Therapeutic application of some drugs is hindered by very low solubility in aqueous media. Water solubility may be greatly improved by the coupling of a hydrophobic drug to a hydrophilic polymer carrier. Water-soluble polyacetals were used as suitable carriers but these polymers were not made by ring-opening polymerization but by polyaddition of diols with divinyl ethers[88–91] or by controlled degradation of corresponding polysaccharides.[92] The application of polyacetals for drug delivery has been recently reviewed.[93]

The possibility of applying polyacetals as host polymers for polymer electrolytes has been explored.[94] Although completely amorphous polymer matrices were obtained for some

concentrations of dissolved lithium salts, the systems were not stable due to salt desolvation and polymer degradation.

4.10.3 Heterogeneous Polymerization of 1,3,5-Trioxane

As indicated in Section 4.10.1, in recent years there has been significant research activity in the field of heterogeneous polymerization of TOX. Therefore, this topic is presented in a more detailed way.

4.10.3.1 General Features of Heterogeneous Polymerization of 1,3,5-Trioxane

As noted earlier in this chapter, poly(oxymethylene) (POM) is thermally unstable and tends to depolymerize starting at the unstable hemiacetal hydroxy group releasing formaldehyde (methanal) by an 'unzipping' mechanism. The early strategy to prevent this depolymerization, used for the homopolymers prepared anionically, consisted in stabilizing the polymer chain ends by a suitable capping method. Industrially, a widely developed alternative way to obtain thermally stable POMs is to copolymerize cationically TOX with a few percent of EO or cyclic acetals (DXL, DXP).

POM also known as polyformaldehyde, the product of TOX polymerization, is insoluble in common organic solvents, including molten monomer. Thus, polymerization of this monomer proceeds as a heterogeneous process and conclusions based on the model studies of homogeneous systems cannot be directly adopted in TOX polymerization. The studies of the topochemical aspects of polymerization carried out by Mateva *et al.*[95] and Wegner *et al.*[96] strongly indicate that the active species in TOX polymerization are located on the surface of the growing polymer crystal. Thus, they cannot be directly observed or identified by spectroscopic methods.

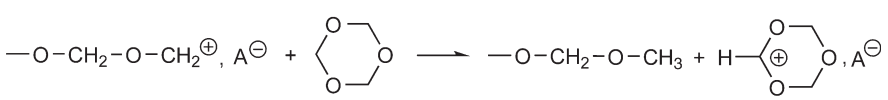
It is known that in this polymerization, even in the rigorously purified systems, the molecular weights corresponding to the lengths of the kinetic chains cannot be attained. This was attributed to the hydride transfer reaction shown in Scheme 36.[97]

As a result, the polymer would acquire -OCH_3 end groups and the 1,3,5-trioxan-2-ylium cation would start a new chain.[98] The stable -OCH_3 end groups may be responsible, at least partially, for the presence of ca. 25% of the thermally stable fraction in otherwise unstabilized polymers.[58] It has to be remembered, however, that this may also be due to the presence of a cyclic fraction.

The fact that hydride transfer reactions occur in TOX polymerization indicates that the fraction of the alkoxycarbenium active species may be significant, because only these species can participate in hydride transfer; no hydride transfer reaction was observed with oxonium ions.

Active species in TOX polymerization are located on the surface of the growing polymer crystals. Thus, monomer molecules, when being incorporated into the polymer chain, are at the same time transferred from the liquid into the crystalline phase. This affects the thermodynamics of polymerization and introduces an additional factor in the mechanism of chain growth.

The (co)polymerization of TOX, conducted in the bulk molten monomer, a monomer–comonomer mixture, or in solution (with precipitation of polymer), presents very specific features as propagation is essentially heterophasic at the interface between the liquid medium and the precipitated crystalline (co)polymer. The reaction starts by a short so-called 'induction' period during which the medium remains homogeneous and the conversion limited, followed by a rapid heterogeneous propagation–crystallization process going to complete conversion as soon as the -$(CH_2\text{-}O)_n$- sequences are long enough to nucleate the crystallization. Since the pioneering work of Jaacks and Kern[44,99] and Jaacks[100] (induction period), Wegner *et al.*[96] (heterophasic propagation), and Berlin *et al.*[101] (thermodynamics), several papers and patents have been devoted to the (co)polymerization of TOX either in bulk or in the presence of a polar or nonpolar diluent. Several sound reviews[1,3,5,102] summarized all the approaches, pointing out the numerous unclear aspects of this very complex



Scheme 36 Hydride transfer reaction in the polymerization of TOX.

polymerization, in particular the key role of the induction period in the understanding of the overall process and in the control of the stability of the final product.

4.10.3.2 The 'Induction' Period in the Homo- and Copolymerization of 1,3,5-Trioxane

The literature devoted to the homogeneous stage or 'clear' or 'induction' period of both homo- and copolymerization of TOX has been covered until the 1990s in the exhaustive reviews of Penczek and Kubisa[1] and Masamoto[102] and will not be reconsidered in detail here. We will rather focus on some more recent studies that afford new light on the complex processes. In the past two decades, high-field ^{1}H, ^{13}C, and 2D NMR techniques allowed to follow accurately the *in situ* formation and evolution of the intermediates and products involved during the homogeneous period, leading thus to the composition of the reaction medium at the onset of the precipitation stage. This composition could hardly be attained in the former studies and is a key factor governing as well the processes involved in this second stage such as the stability and properties of the final polyacetal.

The (co)polymerization can be initiated either by Friedel–Crafts-type initiators, essentially BF_3 and its etherates, or by strong protic acids ($HClO_4$, $HOSO_2CF_3$) and was previously studied generally in solution with solvents of various polarities (saturated hydrocarbons, halogenated hydrocarbons, benzene, nitrobenzene, etc.) in order to increase considerably the duration of the induction period to experimentally reach the concentrations of products and intermediates. For the $BF_3{\cdot}OR_2$ initiating system, after an early controversy there is now a general agreement that the reaction is initiated by the Brönsted acid resulting, in very low concentration, from the equilibrated reaction of the Lewis acid with residual water (coinitiation).[103–108] Few basic studies were devoted to initiation by protic acids. Nevertheless, it was reported that even with acid concentrations 100–300 times lower than those when using $BF_3{\cdot}OR_2$, the rates of polymerization were noticeably higher.[109] The observed induction periods when protic acid initiation is used are much shorter, indicating a higher initiation efficiency but making the experimental approach of the induction stage much more difficult.

4.10.3.2.1 Homopolymerization of 1,3,5-trioxane

The bulk homopolymerization of TOX, performed at the melting temperature of TOX (~63 °C) and initiated by $BF_3{\cdot}OEt_2$ in the absence (undetectable by the Karl Fischer method) and in the presence of a controlled amount of water, has been carefully examined using the *in situ* ^{1}H NMR technique.[110] It was shown that in the absence of added water, no significant amount of formaldehyde is formed and the polymerization does not proceed. In the presence of added water (0.13 mol.%, 20 times the amount of $BF_3{\cdot}OEt_2$), this water is rapidly consumed and the formation of formaldehyde is observed. Then further reaction of the HO-CH_2^+ cation with TOX leads, by direct insertion and/or backbiting, to higher cyclics, essentially 1,3,5,7-tetraoxane (TEOX) but also some 1,3,5,7,9-pentaoxane, which agrees with the earlier qualitative observations for solution and bulk polymerizations (Scheme 37).[111,112] The appearance of the -$(CH_2$-$O)_3$- (MMM) triads characteristic of TOX polymerization is delayed for about 60–100 s until the formaldehyde and TEOX concentrations reach their maximum values (Figure 1).

Then, at the end of the induction period, ca. 300 s, the POM sequences develop until they are long enough to allow the crystallization (Scheme 37) whereas the concentrations of formaldehyde and TEOX level off to constant values.

The rapid precipitation process shifts all equilibria toward the formation of the high polymer. Thus, it is concluded that formaldehyde formation does not essentially result, as considered in earlier studies, from the unzipping of short POM sequences but essentially from the opening of the protonated TOX ring.

As the system is initially far from equilibrium, it was proposed[110] that the decomposition of the carboxonium intermediate is favored, allowing a rapid buildup of formaldehyde until a steady-state concentration of 4×10^{-2} mol l^{-1} is reached, a value that is comparable with that reported (6×10^{-2} mol l^{-1}) in the early study of Jaacks and Kern[99] in the case of polymerization of TOX at 30 °C in CH_2Cl_2 solution (a much longer induction period). The subsequently formed TEOX is then protonated and releases formaldehyde and longer oxymethylene sequences, which favor the formation of the polymer and shorten the induction period.[110,111]

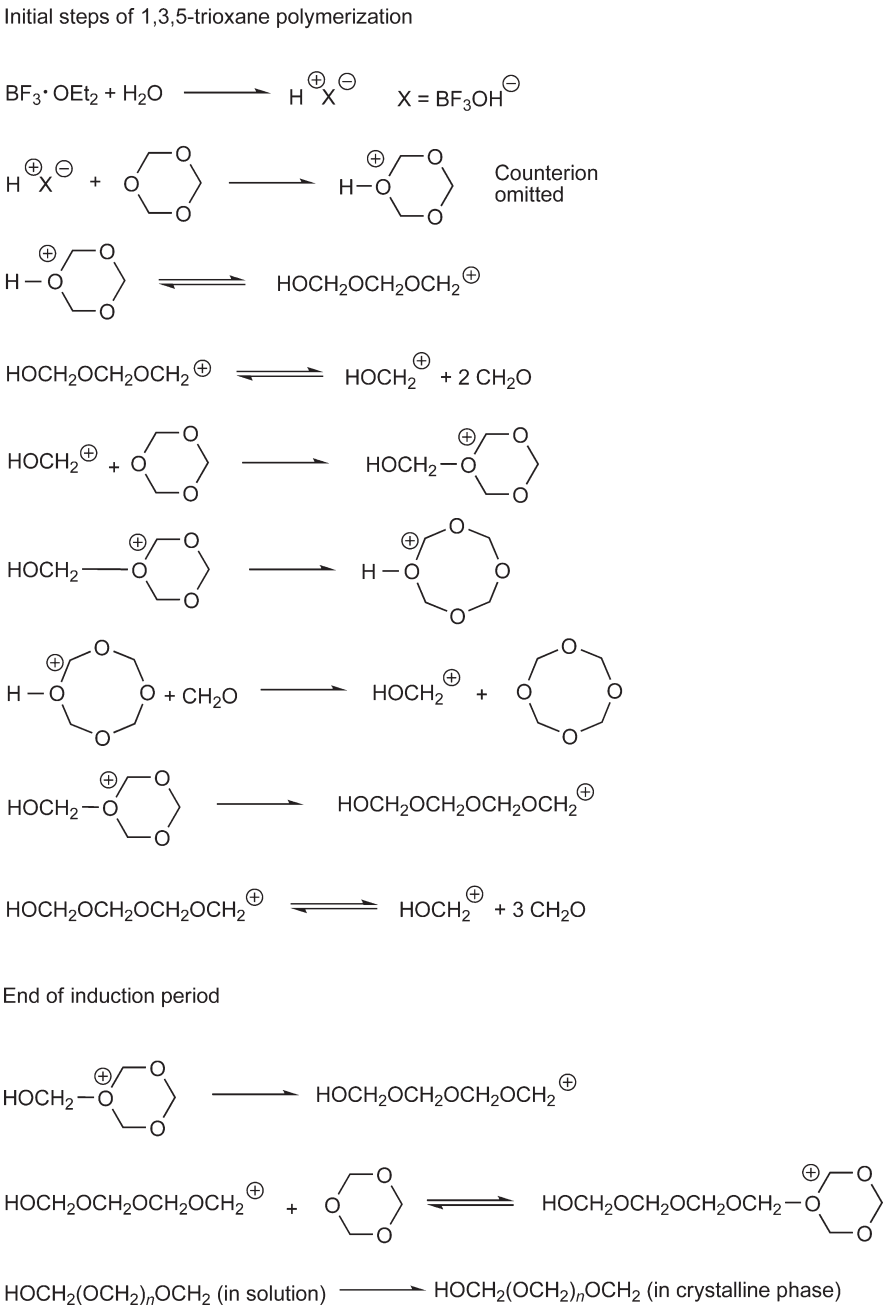
A recent study of the bulk polymerization of TOX initiated by perchloric acid at 80 °C has shown that the nature of the diluent of the initiator, even though present at very low concentration in the molten monomer, may have a strong effect on the duration of the induction period, varying from 1 to 3 s in the case of 1,4-dioxane to 20–30 s in the case of triglyme (Figure 2).[113]

This was explained by a very low concentration of reactive unsolvated initiating hydronium ions and propagating carboxonium when triglyme is used rather than when using dioxane, and thus by both slower initiation and propagation (Scheme 38).

This agrees with a much higher proton-binding ability of triglyme compared with dioxane, even though their reported pK_b (~6) values are close.[105,106,114] Even if the overall rate of propagation is decreased by the solvation of active centers, the rapid exchange between solvated and unsolvated species causes the rate of growth of each individual chain to be the same and also the time for the POM sequences to reach their critical crystallization length to be the same for all chains irrespective of their number. In other words, the duration of the induction period should be independent of the total concentration of propagating species but dependent on their average reactivity. Figure 2 confirms that the induction period is not much dependent on the initiator concentration but highly sensitive to potential solvation of propagating centers.

Water, necessary as coinitiator at low concentration for the Lewis acid-initiated polymerizations, becomes a strong retarder when used in excess, increasing the induction period. It acts as a transfer agent leading to hydroxy-terminated oligomers until it is sufficiently consumed.[110,115.]

For the polymerization initiated by perchloric acid diluted with either triglyme or 1,4-dioxane, a dramatic effect of water on the induction period is observed when using triglyme whereas this effect almost disappears when using dioxane (Table 3).[113]



Scheme 37 Chemical processes during the induction period of bulk polymerization of TOX[110].

This can again be explained by a very low concentration of unsolvated active centers when triglyme is used as a diluent of the initiator.

As previously considered in this chapter, propagation proceeds via oxonium and/or carboxonium ions, and these species are reasonably assumed to remain stable and active. The formation of formaldehyde during the process, resulting from thermodynamic depolymerization of trioxane and to a lesser extent from unzipping of open-chain active ends, indicates that carboxonium ions are in equilibrium with oxonium ions. This is also supported by the observation of methoxy and formate end groups resulting from hydride shift processes in transfer reactions to monomer or polymer, as oxonium ions do not abstract hydride anions.[1,5,58,97,100,102,116–118]

4.10.3.2.2 Copolymerization of 1,3,5-trioxane

The bulk and solution copolymerizations of TOX were extensively studied with EO and DXL but paradoxically not that much with DXP even though the copolymers issued from this last comonomer are also of major industrial importance. The higher basicities (by 3–4 orders of magnitude)[105,106] of the usual comonomers (EO, cyclic acetals) with respect to TOX lead essentially to protonation of the comonomer and to subsequent initiation of copolymerization consuming this comonomer more rapidly until its concentration becomes

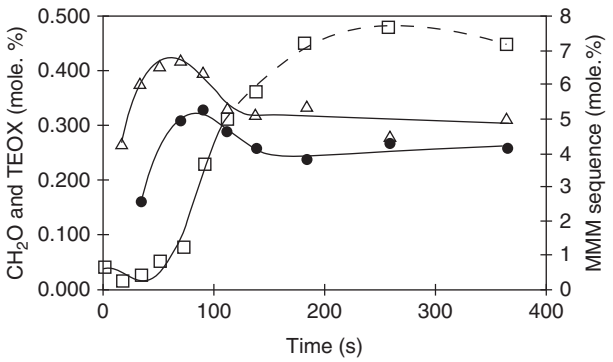


Figure 1 Kinetic profiles for each component in the course of trioxane homopolymerization in bulk at 63 °C, $[BF_3{\cdot}OEt_2] = 0.0073$ mol.%, and $[H_2O] = 0.13$ mol.%. low enough to allow the progressive incorporation of the trioxane units -$(CH_2\text{-}O)_3$- (MMM triad) and longer sequences. Thus the composition of the homogeneous medium during the induction period should comprise comonomer-enriched soluble chains together with formaldehyde, and higher cyclics, including those resulting from the comonomer. The further transacetalization processes, at the end of the induction period when TOX incorporation starts and then essentially during the heterogeneous stage, ensure the randomization of the distribution of the comonomer units along the POM chain and thus lead to the required thermal stability of the copolymer.

The duration of the induction stage in copolymerization is generally longer than in the case of homopolymerization of TOX. It also varies widely depending on the conditions of the reaction (comonomer and concentration, temperature, residual water, initiating system and its possible diluent, use of a solvent, purities of reactants, etc.). It is still very short (from a few seconds to minutes) in the case of the industrial copolymerization of TOX with low amounts (typically ~2–3 wt.%) of comonomer in bulk at the usual temperature (above T_m of the monomer). Therefore, many of the basic studies on mechanisms or kinetics were conducted either in solution at lower temperatures or in the melt with high comonomer concentration, in order to sufficiently extend the induction period or even to avoid the precipitation stage.

Table 3 Bulk homopolymerization of 1,3,5-trioxane initiated by perchloric acid at 80 °C. Dependence of the induction period on the amount of water present in the medium using triglyme and dioxane initiator solution[113]

The bulk copolymerization of TOX with EO has been considered in detail by the researchers of Hoechst Celanese and of Asahi Chemical Industry Co. One of the main features, observed by Weissermel *et al.*[58] in the 1960s, is that EO is converted into DXL during the first homogeneous stage of the reaction, and it was later confirmed that the TOX (co)polymerization does not start until complete EO transformation into DXL and higher cyclics, that is, that the comonomer is entirely consumed during the induction period.[102,119,120] Using quenching experiments during the copolymerization of 2 mol.% (~ 0.5 mol l^{-1}) of EO in molten TOX initiated at 70 °C (or 80 °C) by 1.25×10^{-3} mol l^{-1} $BF_3{\cdot}OBu_2$, it was confirmed that the rapid decrease in EO in the homogeneous stage of the reaction was accompanied by the formation of both DXL and 1,3,5-trioxepane (TXP) (**Figure 3**).[119]

Due to the difference in basicity between EO ($pK_b \sim 7.3$) and trioxane ($pK_b \sim 10$),[105] the cyclic oxonium resulting from protonation of EO was considered to be largely predominant. It has been assumed that its reaction with the formaldehyde from trioxane depolymerization should lead to the ring-expanded cyclic oxonium and then to DXL by proton exchange with EO. Further insertion of formaldehyde into the DXL-cyclic oxonium would then lead to TXP (**Scheme 39**).[119,120]

As long as EO is present, similar processes can also take place via backbiting of the terminal carboxonium ions of the possible EO or EO-rich oligomeric chains that are in equilibrium with their relevant cyclic oxonium ions. When all EO is consumed, both TXP and DXL copolymerize with TOX and then a POM copolymer with a random distribution of isolated -(CH_2-CH_2-O)- units is formed during the short heterogeneous second stage of the reaction.

The above proposal prevailed until the early 1990s even though some aspects remained unclear. First, it was assumed that owing to its very low basicity, TOX could not undergo nucleophilic attack onto the EO-cyclic oxonium; second, that the TXP results from initially formed DXL (which might be questioned from the plots in **Figure 3**); and third, that further ring expansion to higher cyclic formals was discarded due to the significant strain expected for 8–12-membered rings.

Masamoto and co-workers[121–125] reconsidered the homogeneous stage of the bulk copolymerization in similar conditions as above but using a broader range of EO

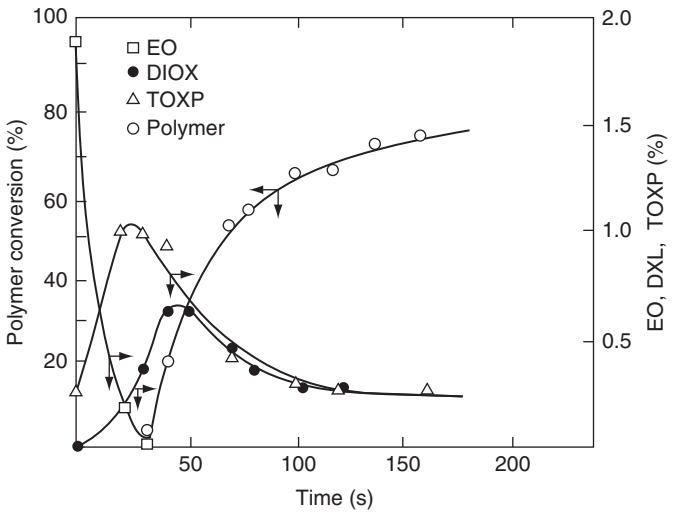

Figure 3 Concentration profile of reactants and intermediates in the bulk copolymerization of TOX with EO at 80 °C. Reproduced with permission from Collins, G. L.; Greene, G.; Berinardelli, F. M.; Ray, W. H. *J. Polym. Sci., Part A: Polym. Chem. Ed.* **1981**, *19*, 1597,[119] figure 3.

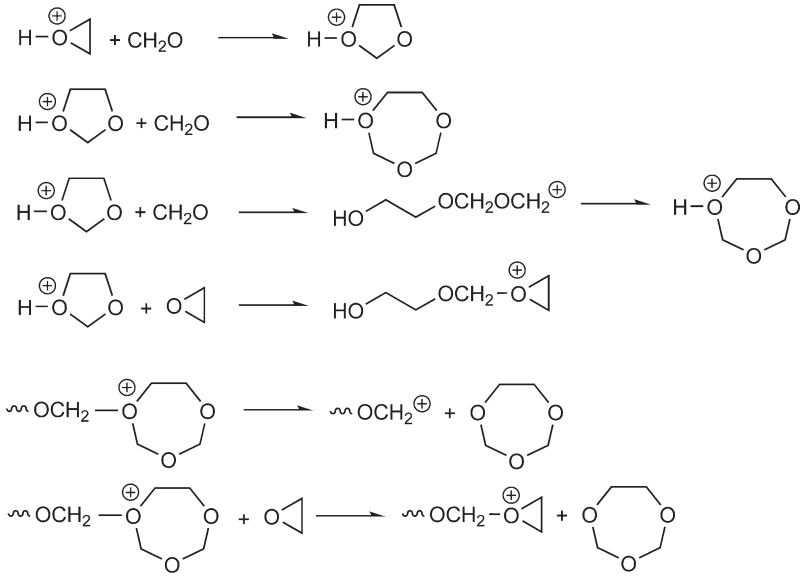

Scheme 39 Formation of DXL and TXP by insertion of formaldehyde in the EO- and DXL-cyclic oxonium ion.[119]

concentrations and proposed an alternative mechanism. A series of extracted aliquots versus time, analyzed by gas chromatography (GC) and NMR, clearly showed that higher cyclic formals, 1,3,5,7-tetraoxacyclononane (TOCN) and 1,3,5,7,10-pentaoxacyclododecane (POCD), appear first, as long as EO is still present, and then are consumed, whereas TXP and DXL develop progressively at the end of the induction period (**Figure 4**).[121–126]

These authors focused on the homogeneous period of copolymerization with different initial EO concentrations. The observed intermediates were isolated by microdistillation and preparative GC, and then characterized by NMR, EI-MS (electron impact mass spectrometry), and determination of their physical properties.[122,125,126]

At the lowest EO concentration (EO/TOX ~ 1 mol.%), the TOCN resulting from the insertion of the -CH_2CH_2O- grouping of EO into the trioxane ring was the only high cyclic formal observed, whereas at the highest concentration ($[EO]_0$ ~ 4 mol.%/TOX) two further intermediates POCD and 1,3,5,7,10,13-hexaoxacycloheptadecane (HOCP), issued from the insertions of two and three -CH_2CH_2O- groupings, could be quantitatively identified (**Figures 5(a)** and **5(b)**).[125]

It was concluded that the ring expansion resulting from successive insertions of EO units (-CH_2CH_2O-) into cyclic formals issued from TOX is the main initial process of the reaction during the induction period. The appearance of TXP and then DXL is delayed until most of EO is consumed. This conflicts with the previously proposed mechanism involving the prior formation of dioxolane by reaction of formaldehyde with the EO oxonium followed by the reversible insertion of formaldehyde unit (OCH_2) into the DXL oxonium leading to TXP.

The higher cyclic formals do exist exclusively in the presence of EO, which indicates that (1) their formation implies the reaction of TOX with EO oxonium (or EO carboxonium) and ring closure, and (2) their consumption generates formaldehyde in equilibrium with more stable lower cyclic formals, essentially TXP and then DXL, at the end of the homogeneous period (**Scheme 40**).[123]

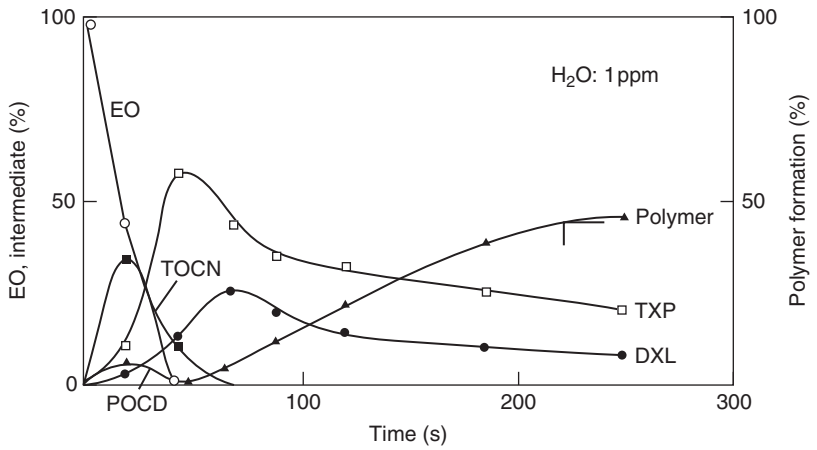

Figure 4 Concentration profiles of reactants and intermediates in TOX-EO bulk copolymerization at 70 °C. Scheme 40 Intermediates formed during the homogeneous stage of EO-TOX copolymerization.[123]

Owing to the long duration of the homogeneous period in the given experimental conditions, the reactions involving formaldehyde are thermodynamically controlled and TXP and DXL should be in equilibrium. The disappearance of the higher cyclic formals during this homogeneous period can also result from their copolymerization and insertion in the EO-rich soluble chains of the already formed EO-TOX copolymer. In that case, the final POM copolymer should exhibit a random distribution of EO single units and of $(EO)_{2\rightarrow n}$ sequences along the POM chain. Accurate pyrolysis/GC and hydrolysis analyses of the sequence distributions in models and commercial EO-based polyacetals unambiguously showed that for an EO/TOX fraction of 1–2 mol.%, the final copolymer presents an $(EO)_1/(EO)_2/(EO)_3$ composition of approximately 75/20/5 whereas further sequences can be quantitatively identified when EO content increases (up to $(EO)_7$ for 9 mol.% of comonomer).[123,125,127] Table 4 clearly shows that whatever the EO content the main sequences observed in the resulting copolymer are the isolated EO units issued from the TXP, DXL, and possibly tetraoxacyclononane together with the $(EO)_2$ sequences issued from the pentaoxacyclododecane, in accordance with the copolymerization pathway proposed by Yamasaki and Masamoto.[125]

A most important feature of the EO-TOX copolymerization is that at the onset of the heterogeneous phase of the reaction that generates most of the polyacetal, the bulk medium is essentially composed of TXP and DXL dissolved in the molten TOX, together with EO-rich soluble oligomers, which are the reservoirs of longer $(EO)_2\ldots(EO)_n$ sequences. Scrambling by chain transfer onto -$(CH_2$-O)- units (transacetalization) during this second stage leads to the final expected randomization.

The solution and bulk copolymerizations of TOX with DXL have also been extensively studied and present common features with both the TOX homopolymerization and the TOX-EO copolymerization considered above. The early works showed that due to its much higher basicity, DXL is preferentially protonated with respect to TOX and essentially consumed during the homogeneous period to give soluble polyDXL and DXL-rich copolymers of DXL with formaldehyde.[57] Higher cyclic formals like tetraoxane and trioxepane were also formed during the induction period and were supposed to result from the backbiting of the oxymethylium ends of the soluble copolymer chains. A later quantitative approach performed in 1,2-dichloroethane solution led to the conclusion that the

formation of TXP by insertion of formaldehyde (OCH_2) into the protonated DXL was more likely.[120]

In situ ^{1}H NMR experiments, based on previous assignment of the different M (oxymethylene) and E (oxyethylene) centered sequences,[128,129] were used to identify and follow quantitatively the intermediates formed during the induction period of the bulk copolymerization initiated by $BF_3{\cdot}OEt_2$ at 63 °C with different initial TOX/DXL ratios.[110] When TOX is in large excess, formaldehyde, tetraoxane (TEOX), and TXP are generated a long time before the appearance of the MMM, MEM/EME, and MME triads, characteristic of the poly(TOX), polyDXL, and copolymer sequences, respectively (**Figure 6**).[110] This confirms that the TXP formed during the induction period results from formaldehyde insertion into the protonated DXL rather than from a backbiting process. Formation of tetraoxane can be identified only when the instantaneous concentration of formaldehyde resulting from TOX depolymerization is significant, that is, for the higher TOX/DXL ratio. The duration of the induction period was not specified but, owing to the delayed appearance of the POM sequences, it was probably in the minutes timescale. When DXL is used in large excess (TOX/DXL 0.3/1), the protonation of TOX is less likely and formaldehyde is undetectable by NMR, indicating that it is immediately consumed to generate trioxepane. In this case, the only polymer sequences observed are those of the homopolymers of DXL and TXP (or their copolymers).

The events occurring during the homogeneous period of the bulk copolymerization of trioxane with DXL have been recently reexamined in conditions as above but using the pairs of labeled comonomers, TOX-d_6/DXL and TOX/DXL-2,2-d_2.[130,131] In both cases, ^{1}H NMR allowed to track the pathways of the -(CH_2-O)- oxymethylene (M) and -(CH_2-CH_2-O)- oxyethylene (E) units originating from the comonomers, and the fact that the -(CD_2-O)- (M′) units were undetectable drastically improved the spectral resolution. Detailed analyses of the evolution of the complex sets of pentad sequences involving E, M, and M′ units confirmed the previous general observations of Lu *et al.*[110] but the successive occurrence of the reactions in the course of the induction period was more precisely identified, which lead to a deeper insight into the complex mechanistic route of the copolymerization. Owing to the high initial DXL concentration in these experiments, the duration of the homogeneous period was drastically increased (hours), and most of DXL was consumed. Thus the medium at the onset of the heterogeneous period should be essentially composed of molten TOX and soluble E-rich copolymers together with some remaining comonomers

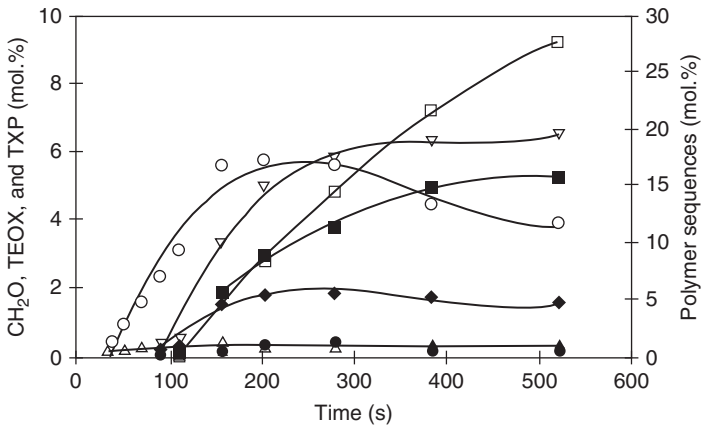

Figure 6 Kinetic profiles for each component during the course of the bulk copolymerization of TOX and DXL, mole ratio 2:1, at 63 °C. [$BF_3.OEt_2$] = 0.028 mol.%, [H_2O] = 0.05 mol.%. Scheme 41 Copolymerization of TOX and DXP.

and cyclics (TEOX), which does not necessarily reflect the situation of the industrial process involving only a few wt.% of comonomer and exhibits much shorter induction periods.

The copolymerization of TOX with DXP is the third process of industrial importance.[102] It was mentioned in the early works on polyacetals, but few specific studies were devoted until recently to this copolymerization (**Scheme 41**).[113,132–134]

The first detailed approach to the mechanisms involved during the homogeneous stage of the reaction was again based on *in situ* analyses using high-field ^{13}C NMR techniques in order to identify the intermediates in real time.[133,134] As B units from DXP cannot be adjacent, the sequences are limited to six M-centered (MMMMM, BMMMM, BMMMB, MBMMM, MBMMB, MBMBM) and three B-centered (MMBMM, BMBMM, BMBMB) pentads and their assignment to the relevant chemical shifts was established based on 2D NMR experiments and by comparison with the data from pentads of TOX/DXL copolymer (**Table 5**). Heptads and nonads could also be identified for some M-centered sequences.

The experiments were conducted in bulk at 70 °C and the M/B ratio was 9/1 (ca. 27 mol.% of DXP). In such conditions of high comonomer concentration, the reaction was slowed down and the crystallization of the copolymer was considerably delayed, allowing accurate measurements during the homogeneous stage.

The evolutions of the M-centered pentads are shown in **Figure 7**. After the injection of initiator, the MBMBM pentad characteristic of the homopolymer of DXP grows quickly. It is observed to incorporate 50% of the DXP during the first 15 min. Then it goes through a maximum, declines, and transforms into sequences bearing two adjacent M units, which progressively turn into pentads with three and four adjacent M units until the MMMMM sequence from the TOX-rich copolymer develops.

In contrast to DXL, no cyclic formal resulting from DXP ring expansion was observed during the homogeneous period. This could result from thermodynamics (instability of higher cyclics) but a significant difference of ring strain between the 1,3,5-trioxacyclononane expected from formaldehyde insertion into DXP and the 1,3,5,7-tetraoxacyclonane identified as intermediate in TOX/EO copolymerization is questionable. An alternative explanation could be the higher basicity of DXP with respect to DXL,[105,106,135] which makes the early formation of formaldehyde from protonated TOX much less likely when DXP is used as a comonomer. Thus the homopoly(DXP) is essentially produced at the beginning of the reaction whereas the copolymer appears progressively when the concentration of DXP is low enough to allow a significant formation of formaldehyde and its further incorporation in the growing chains. In these experimental conditions, most of the comonomer is consumed before the heterogeneous stage starts, which might not be verified in conditions of the industrial processes involving much lower comonomer concentrations.

The TOX/DXP bulk copolymerization initiated by perchloric acid at 80 °C has been recently reexamined over a broader range of comonomer concentration (from TOX/DXP 97/3 w/w, DXP 2.7 mol.% to TOX/DXP 80/20, DXP 18 mol.%).[113] Increasing the concentration of the comonomer in the molten trioxane increases significantly the induction period as shown in **Figure 8**.

In the conditions of the industrial copolymerization (DXP ~ 2–3 wt.%), the induction period is very short (a few seconds) but a dramatic effect of the initial DXP concentration on the duration of this induction period, that is, on the buildup of long $(-CH_2-O-)_n$ sequences, can be expected from extrapolation above ~ 25 wt.% of comonomer from the plots of **Figure 8**. This agrees with the very long induction period observed for an initial DXP concentration close to 30 wt.%.[133,134]

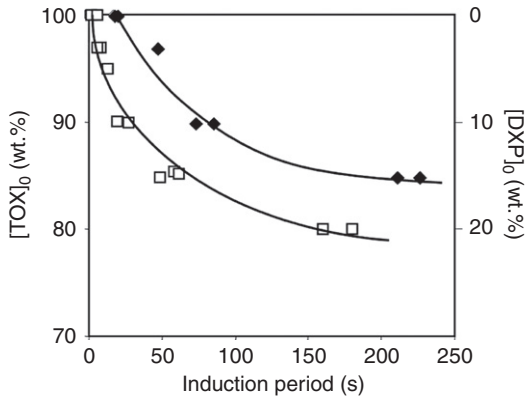

Figure 8 Copolymerization of TOX with DXP in bulk at 80 °C. The figure demonstrates variation of the induction period depending on the initial DXP content, using triglyme (♦) and dioxane (□) as diluents for the perchloric acid solution.Reproduced with permission from Sharavanan, K.; Ortega, E.; Moreau, M.; *et al. Macromolecules* **2009**, *42*, 8702,[113] figure 2.

Kinetic profiles of the components during the induction period (≤ 40 s) for a series of copolymerizations in the range TOX/DXP 80/20 to 97/3 w/w have been determined.

For the highest DXP concentration (ratio 80/20), the results agree well with the previous observations of Cui *et al.*[133] The DXP is rapidly consumed, essentially producing its homopolymer during the first half of the induction period. When the concentration of DXP is significantly lowered, TOX units are more and more incorporated, whereas the DXP homopolymer progressively disappears due to simultaneous depolymerization and transacetalization. For the lowest initial concentrations of DXP, the conversion during the induction period is drastically slowed down and leveled off, as shown for the 90/10 comonomer ratio in Figure 9 and Table 6. For the 95/5 and 97/3 ratios, the induction periods were too short and the (co)polymers were formed in a too low concentration to be accurately identified and followed with time but the concentration of the remaining DXP at the end of the induction period could be estimated by NMR.

The remaining comonomer concentration at the end of the induction period appears roughly constant (≈ 0.5–0.7 mol l^{-1}) and it represents the critical value below which the TOX sequences of the copolymer are long enough to spontaneously crystallize in bulk at 80 °C. The conversion of DXP at the end of the homogeneous period appears clearly dependent on its initial concentration and is very limited for the lowest initial concentrations (3–5 wt.%). Furthermore, the DXP homopolymerization is equilibrated. The value of the equilibrium concentration $[DXP]_{eq,ss}$ at 80 °C was estimated between 1 and 2 mol l^{-1} from literature data.[22,136] Even though the value is not fully reliable as in the present case, the DXP equilibrium concentration should be dependent on DXP-TOX, poly(DXP-TOX), and poly(DXP-DXP) interactions presently not quantified, and it was assumed to be definitely higher than the $[DXP]_0$ for the 95/5 and 97/3 TOX/DXP ratios. Thus a DXP homopolymer can hardly be formed and the copolymerization with TOX takes place from the very beginning producing copolymer chains with isolated DXP units. This agrees with the very short induction periods observed in the industrial processes.

It was concluded that at the onset of the heterogeneous stage, the composition of the medium could be radically different depending on the amount of the comonomer used. For high initial DXP concentrations, most of the comonomer has already been incorporated in a noticeable amount of soluble DXP-rich copolymer chains bearing $(BM)_n$ sequences, whereas for the lowest concentrations most of the comonomer still remains. The preformed copolymer, in low amount, is essentially TOX-rich with isolated comonomer units. In the latter case, the final polyacetal obtained after the further copolymerization–crystallization

stage should contain exclusively isolated BM units randomly distributed by transacetalization, allowing the highest crystallinity and the optimal stability.

4.10.3.3 The Polymerization–Crystallization Stage in the (Co)polymerizations of 1,3,5-Trioxane

In the usual conditions of (co)polymerization of TOX (low comonomer to monomer ratio), the first homogeneous stage or 'induction' period of the reaction is very short and ends as soon as the sequences $-(CH_2O)_n-$ $(M)_n$ are long enough to nucleate the crystallization. The final polyacetal is essentially produced during the second heterogeneous stage.

When crystallized from solution or from the melt, the POM is obtained as a stable trigonal form involving the packing of extended chains with a 9/5 helical conformation (space group $P3_1$) and a threefold screw symmetry.[137]

A metastable orthorhombic modification with a 2/1 helical conformation exists but it is transformed above 69 °C into the trigonal form.[138,139] Hexagonal lamellar single crystals are formed with chain axis orthogonal to the lamella surface (**Figures 10(a)** and **10(d)**).[95] It must be stressed that in the case of this TOX heterogeneous polymerization the relative rates of polymerization and crystallization are the key factor governing the final morphology and crystallinity. When the rate of polymerization R_p is much higher than the rate of crystallization R_c, the system behaves similarly as from crystallization from solution or melt of already formed coiled polymer chains, whereas if the rates are of the same order of magnitude ($R_c \geq R_p$) the polymerization and the crystallization take place simultaneously.[141] The latter case leads to extended-chain crystals and a higher crystallinity of the final polyacetal.

The crystallization of POM during the polymerization of TOX has been extensively studied by the Wegner group.[95,140,142,143] At the cloud point corresponding to the end of the induction period, small flat hexagonal crystals are formed with a narrow distribution of diameters. At first, a lateral tangential growth is observed and is explained by monomer insertion and chain transfer of soluble oligomers to active centers located at the side wall of the crystal (**Figures 10(b)** and **10(c)**).

Then, when polymerization is progressing, the crystal thickening starts by monomer insertion or chain transfer at the fold interface leading to a spiral growth due to a screw dislocation on the base surface of the lamella. The proposed explanation involves protonation of a terminal hydroxy group located at the interface or of an oxygen of the strained fold followed by TOX attack on the resulting oxonium and chain expansion along the chain axis. The actual mechanism probably involves a multistep process (**Scheme 42**).

Thus, the size of the crystals increases when the reaction progresses; at the same time the degree of crystallinity increases. This process does not stop even after equilibrium conversion is reached. This is explained in terms of dissolution (by depolymerization) of the smaller, less perfect crystals in favor of the thermodynamically preferred larger, more perfect crystals. The changes of crystal size and degree of crystallinity in the polymerization of TOX are illustrated by the data in **Table 7**.[95]

A low-M_n (ca. $1–3 \times 10^3$) fraction is observed in the generally bimodal size-exclusion chromatography (SEC) curves of POM. It was assigned to linear oligomers bearing -OH, -CHO, and $-OCH_3$ end groups and/or to macrocycles resulting from backbiting processes. The analysis of this fraction using hyphenated techniques (SEC/gradient polymer elution chromatography (GPEC)/NMR/matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF), etc.) is extremely complex[144] and the question of macrocycles remained open for a long time. Hasegawa *et al.*[145] submitted a POM sample to heat

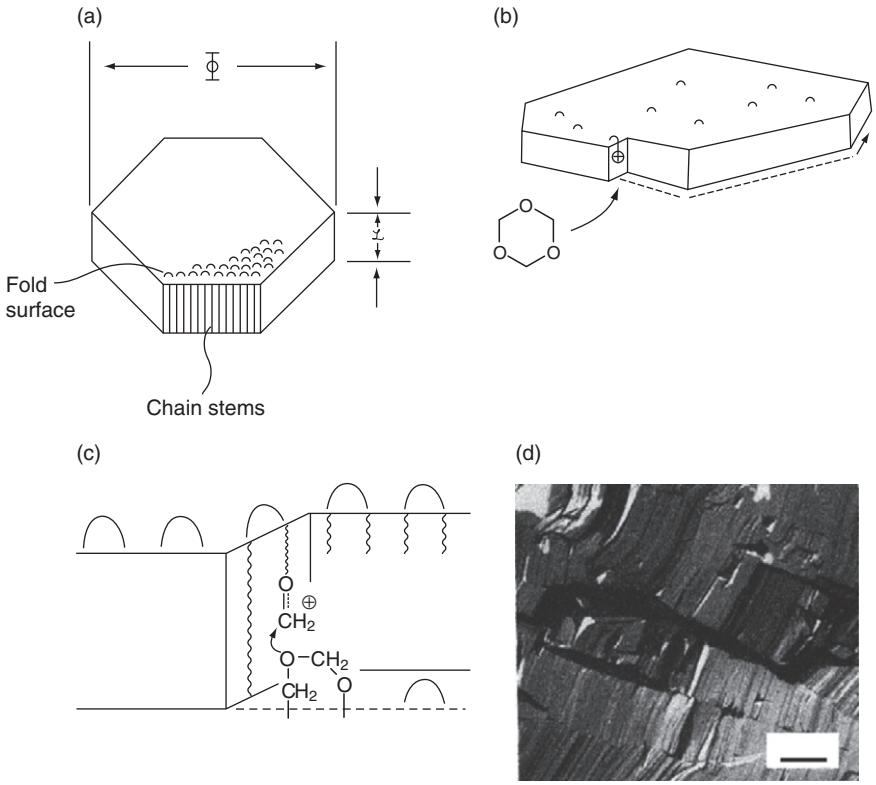

Figure 10 Crystallization of POM during the heterogeneous second stage of the polymerization of TOX: (a) extended-chain stems and folded interface. and alkaline degradations and isolated a low-molecular-weight fraction with a narrow distribution which should include only the linear oligomers with stable -OCH_3 groups at both ends and the possible macrocycles. It was shown (1) that the content of this fraction with methoxy end groups was very low, and (2) that the measured M_n was close to twice the calculated M_n for two 9/5 helical extended-chain stems of the crystal lamella. A backbiting involving the neighboring loop at the fold interface was proposed to explain both the narrow distribution and the dependence of the M_n of the formed macrocycles on the crystal morphology (Figure 11).

In the case of copolymerization of trioxane with a low amount of EO, DXL, or DXP, most generally used to obtain thermal stability, the localization of the comonomer units

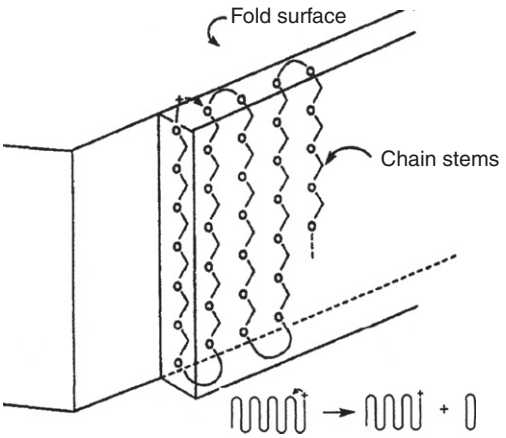

Figure 11 Formation of POM macrocycles by backbiting of an active center on the neighboring loop at the fold interface of the crystal lamella. Reproduced from Hasegawa, M.; Yamamoto, K.; Shiwaku, T.; Hashimoto, T. *Macromolecules* **1990**, *23*, 2629, scheme 4.[145]

within the semicrystalline organization of the copolymer is a central feature, and a major question to be addressed is the possibility of these comonomer units to be inserted randomly within the POM crystalline domains.

Dröscher *et al.*[143] prepared copolymers of trioxane and dioxolane which were almost completely crystalline for low comonomer concentrations. Even if a segregation was observed with an enrichment of the amorphous phase in comonomer units, an insertion of the -(CH_2-CH_2-O)- (E) segments in the crystalline -(O-CH_2)$_n$- domain was demonstrated. With respect to the trioxane homopolymer lattice, a lateral expansion (cell parameter *a*) and a contraction along the chain axis (cell parameter *c*) roughly proportional to the amount of comonomer were observed up to a mole fraction of 0.1. The density and melting point of the lattice decreased accordingly. It was also shown that for the same comonomer amount, the lattice cell of these 'extended-chain' copolymer crystals was larger than the one observed as-crystallized from the melt or solution.

The possible insertion of longer -O-(CH_2)$_4$- (B) segments in the crystalline -(O-CH_2)$_n$- lattice was recently examined in a solid-state NMR, wide-angle X-ray spectroscopy (WAXS), and differential scanning calorimetry (DSC) study of trioxane-dioxepane copolymers with a comonomer weight fraction from 0.03 to 0.3.[146] It has been shown that in these semicrystalline TOX-DXP copolymers, a part of the single dioxepane units, involved in isolated MMMBM and MBMMM pentads, is located in the crystalline phase and in the crystalline/amorphous interfacial regions. The sequences composed of more than one dioxepane unit should be rejected into the amorphous phase. The fraction *r* of B units to the total number of B and M units in the crystalline phase, including the noncrystalline/crystalline interfaces, was estimated, as well as the corresponding partitioning coefficient $P_{CI/CR}$. The latter corresponds to the ratio of *r* to the fraction *j* of B units in the copolymer and thus indicates the propensity for the dioxepane comonomer to be inserted in the crystallites and at their immediate interfaces. The variations of *r* and $P_{CR/CI}$ with the overall molar fraction φ of B units in the copolymers are presented in **Figure 12(a)**. For the lowest TOX/DXP ratio (97/3), $P_{CR/CI}$ equals 1. This means that the concentration of B units is the same in both amorphous and crystalline phases, that is, 3 wt.%, but the distribution of these B units along the POM chain should be quite different for the macromolecules of the two phases. As the initial concentration of dioxepane is increased in the feed, the partitioning coefficient $P_{CR/CI}$ decreases to a plateau value, indicating that the relative amount of B units inserted in the crystalline (and interfacial) regions gets lower and lower. A decrease in the average crystallite size occurs simultaneously with this progressive rejection of dioxepane in the amorphous phase (**Figure 12(b)**).

It was concluded that the isolated B unit which results from copolymerization of trioxane with a low concentration (ca. 3–5 wt.%) of dioxepane can be inserted in the crystal lattice and/or at its immediate interface. If an active center located on the crystal adds several successive units of DXP, the sequence cannot enter the crystal, and the active chain grows outside until either the formation of a TOX sequence long enough to allow a further crystalline accommodation or the occurrence of a transfer event. These results are in general agreement with the conclusions of the chemical approach of the induction period

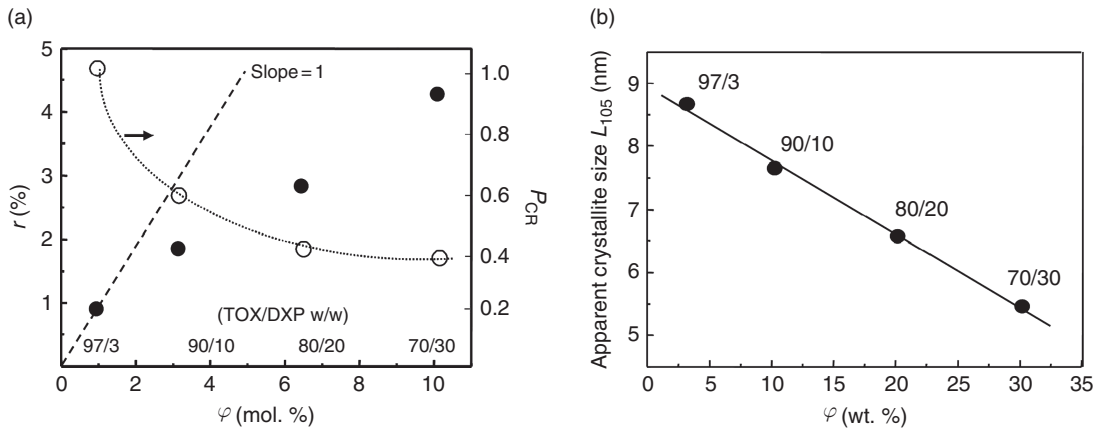

Figure 12 Insertion of isolated oxybutane-1,4-diyl (tetramethylene oxide) units (B) in the crystalline phase of trioxane-dioxepane copolymers:[145,146] (a) variation of the concentration *r* of units (B) in the interfacial and crystalline regions, and the partitioning coefficient P_{CR} of the B units with the overall molar fraction φ of B units in the TOX/DXP copolymers; (b) influence of the DXP content on the apparent crystallite size, L_{105}, estimated from WAXS measurements. developed in the previous section for the trioxane-dioxepane copolymerization.

4.10.3.4 Radiation-Initiated Solid-State Polymerization of 1,3,5-Trioxane

Solid-state polymerization of TOX can be initiated by different kinds of radiation, including γ-rays, X-rays, electron beams, or α-particles.[147–149] The mechanism of initiation is not well understood. It is, however, generally accepted that radiation induces cationic polymerization. Ions or radical ions are generated by electron transfer, the loss of hydrogen ions, or the heterolytic cleavage of TOX rings.

Radiation-induced solid-state polymerization of TOX was studied intensively in the past because it was believed that it could lead to large-scale production. The process is, however, highly irreproducible and extremely sensitive to impurities.[150] Thus, although high-molecular-weight polymers can be obtained in high yields (~80%) by direct irradiation of the crystalline monomer, interest in radiation-induced polymerization is vanishing.

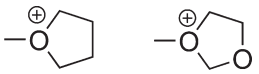
4.10.3.5 Properties of Poly(oxymethylene)

The only polyacetal that is made on an industrial scale (>500 × 10^3 tons per year) is POM also known as polyformaldehyde. This is a highly crystalline polymer (50–60% crystallinity for commercial products) with a crystalline melting point of ca. 180 °C and a density of 1.42 g cm^{-3} (both density and melting point, however, decrease with increasing content of oxyethylene units). The polymer is insoluble in common organic solvents; it dissolves well only in strongly hydrogen-bonded solvents (e.g., phenols) at above 100 °C, or in hexafluoroacetone at room temperature.

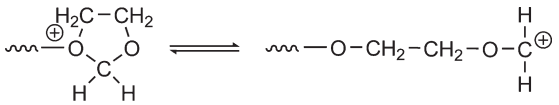
Polyformaldehyde is perfectly stable in even strongly basic media and moderately stable in acidic media; it is a high-performance engineering plastic.

Outlook

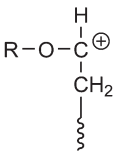
There are certain similarities between cationic ring-opening polymerization (CROP) of cyclic acetals and cyclic ethers. Essentially the same group of initiators may start the polymerization and in both cases the major growing species are tertiary oxonium ions of similar structure as shown below for polymerization of five-membered cyclic ether and cyclic acetal:



There are also, however, distinct differences between CROP of these two groups of oxygen-containing heterocyclic monomers. CROP of cyclic acetals is a ring-opening polymerization. In some respect, however, it may be considered as a borderline case between typical ring-opening and vinyl polymerization. The growing species in the CROP of cyclic acetals are mostly tertiary oxonium ions as in typical CROP of cyclic ethers. The presence of carboxonium ions in equilibrium with their oxonium counterparts and their not-negligible (due to much higher reactivity) role in propagation have been clearly established. As shown in the scheme below, carboxonium growing species of cyclic acetal polymerization bear some resemblance to growing species of vinyl ether polymerization:



cyclic acetals



vinyl ethers

The other characteristic feature of CROP of cyclic acetals is reversibility of propagation and the high extent of chain transfer to polymer.

The smallest ring of cyclic acetal is a five-membered (weakly strained) ring; therefore, polymerization of cyclic acetals is a reversible process. Thus, an understanding of polymerization thermodynamics is important for designing workable polymerization process. Certain limitations stemming from reversibility of propagation may be overcome if polymerization, as in the case of CROP of TOX (cyclic formaldehyde trimer), proceeds with precipitation of polymer (insoluble in any solvent). Additional contribution of enthalpy of crystallization shifts the equilibrium toward polymer and polymerization of six-membered monomer, which in solution would be highly reversible, proceeds to high conversion. This is of practical importance because CROP of TOX is one of the two routes used in industry to manufacture polyacetal (polyformaldehyde).

The other characteristic feature of CROP of cyclic acetals is the high extent of chain transfer to polymer. These processes occur in many ring-opening polymerizations but because linear acetals (chain units) are more basic than cyclic acetals (monomers) they are especially pronounced in the case of cyclic acetal polymerizations. Chain transfer to polymer may be detrimental, leading to the formation of cyclic fractions or precluding the formation of block copolymers, but it may also be beneficial. In order to improve thermal stability of polyformaldehyde the sequence of -O-CH_2- units has to be from time to time interrupted by -CH_2-CH_2- units, which are introduced by copolymerizing TOX with few mole% of EO or DXL. To achieve an optimum effect, comonomer units should be distributed randomly along the chain. Due to efficient transacetalization coupled with reversibility of propagation step, this is achieved irrespective of propagation kinetics. These factors as well as the high rate of polymerization make the cationic copolymerization of TOX an industrially attractive route to polyacetal thermoplastics.

Acknowledgments

This chapter is based on large fragments of the chapter 'Cationic Ring-Opening Polymerization: Acetals' coauthored by

S. Penczek and P. Kubisa from the first edition of *Comprehensive Polymer Science,* Vol. 3, Part I. The authors of this chapter wish to express their gratitude to Professor Stanislaw Penczek for the permission to use large fragments of the text from the first edition in the present chapter.

Biographical Sketches

Przemysław Kubisa, born in 1940, received MSc degree in 1963 from Warsaw University of Technology. From 1963 until 1969 he was employed in the Institute of Plastics in Warsaw as a research associate and in 1969 he joined the Center of Molecular and Macromolecular Studies (CMMS) of the Polish Academy of Sciences in Lodz. In 1972 he received his PhD (under the guidance of Prof. S. Penczek) and in 1978 his habilitation from Technical University in Lodz. P. Kubisa was a post doc in the University of Massachusetts (group of Prof. Otto Vogl) (1974) and a visiting scientist in the University of Massachusetts (1979, for a period of 6 months) and Institute Ch. Sadron in Strasbourg (1984).

P. Kubisa's research interest covers various aspects of ionic (mostly cationic) ring-opening polymerization of oxygen-containing heterocyclic monomers. He is the author or coauthor of 140 original papers and 40 book chapters or review papers. From 1991 until 2007 he was the Deputy Director of CMMS and in 2005 he succeeded Prof. S. Penczek as Head of Polymer Chemistry Department (until 2009). Presently, he is a Titular Member of IUPAC Polymer Division.

Prof. Jean-Pierre Vairon, born in 1937, studied chemistry and chemical engineering in Bordeaux (ENSCB) and got his doctoral degree in Paris (Sorbonne, 1968) in the field of mechanisms and kinetics of polymerization. He was successively associate and full professor of polymer chemistry at the University P. and M. Curie (UPMC). He became director of the polymer unit UMR 7610 associated to CNRS in 1992. He was also in charge of the polymer section and the materials program (PIRMAT) at the Department of Chemistry of CNRS (1982–90), chairman of the Scientific Council of Chemistry at UPMC (1994–97), chairman of the Theses and Habilitations Committee for Chemistry (1993–98) at UPMC, chairman of the French Polymer Group, chairman of the Polymer Division of the French Chemical Society (1994–97), and in charge of the European ERA program in chemistry at CNRS-INC (2004–10). He is a member of the French National Committee for Chemistry, a titular member of the Polymer Division of IUPAC, and French representative at the IUPAC Council. Emeritus since 2003, he is still active in polymer chemistry research. He has about 170 scientific publications and patents, and has been the supervisor of about 45 PhD students. He is Dr. h.c. of the Russian Academy of Sciences and Honorary member of the Polish Chemical Society.

4.11 ROP of Cyclic Esters. Mechanisms of Ionic and Coordination Processes

A Duda, Polish Academy of Sciences, Lodz, Poland

4.11.1 Introduction

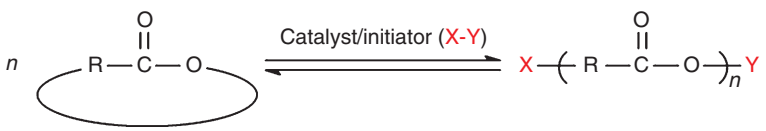
Ring-opening polymerization (ROP) of aliphatic cyclic esters leads to aliphatic polyesters, a rediscovered class of polymers important in practice that show compatibility with natural environment (including human body) and are able to undergo hydrolytic and biological degradation after desired exploitation time.[1]

Two important discoveries that are related to mechanisms of the ROP of cyclic esters, and were made during the mid-1950s, were the following: (1) realization of a living polymerization system by Szwarc;[2] and (2) a thermodynamic description of the reversible chain-growth polymerization by Dainton and Ivin.[3] In contrast to polyesterification, living ROP provided a precise tool for the synthesis of polyesters having required molar masses and fitted with desired end groups. At this point, it should be remembered that Carothers was the first to study the polymerization mechanisms of lactones and lactides (LAs) in a more systematic way:[4,5]

where R = $(CH_2)_x$ (lactones) or $CH(CH_3)C(=O)OCH(CH_3)$ ((di)lactides).

Initially, thermodynamic polymerizability of aliphatic cyclic esters was analyzed in qualitative terms by Hall and Schneider.[6] Later, at the Gorki University, enthalpies and entropies of polymerization were determined for the most important cyclic esters.[7–12]

Until about 1975, the major effort in studies of polymerization of cyclic esters was directed toward finding an efficient initiator and/or catalyst leading eventually to the living process. Commercial availability of β-lactones and of ε-caprolactone (CL) was one of the reasons that already started extensive research programs on their polymerization at Goodrich in 1948[13] then at Union Carbide,[14] Dutch Shell,[15] and Japanese companies.[16,17] Some attempts to elucidate the polymerization mechanisms in these studies were also undertaken, particularly taking into account the ambident structure of cyclic ester monomers. Hall[18] and later Lenz and co-workers[19] carried out extensive kinetic measurements of the anionic polymerization of β-lactones, but the determined apparent



[1]

rate constants of propagation were not related to the elementary reactions.

Successful application of alumoxanes by Vanderberg[20] in stereospecific polymerization of oxiranes prompted several research groups to use these initiators for synthesis of stereoregular polyhydroxyalkanoates by polymerization of β-substituted β-lactones.[21–24] A serious drawback of this system was an unknown concentration of the actually propagating species; eventually, it was impossible to control molar masses of the resulting polyesters.

Teyssie, looking for the structurally similar but better defined initiators, introduced bimetallic alkoxido-μ-oxido compounds (e.g., $(BuO)_2Al\text{-}O\text{-}Zn\text{-}OAl(OBu)_2$) and polymerized CL in a controlled manner.[25] Similar results have been obtained with a much simpler and commercially available aluminum triisopropoxide ($Al(O^iPr)_3$).[26]

Two research groups (Slomkowski and Penczek[27] and Deffieux and Boileau[28]) applied in β-propiolactone (PL) polymerization anionic initiators bearing alkaline metal countercations complexed with crown ethers or cryptands. Concentration and structure of the involved active species have been determined, either by their direct spectroscopic observations[29,30] or by ^{31}P nuclear magnetic resonance (NMR) measurements of the polymerizing mixtures after end-capping with a phosphorus-containing reagent.[31]

Studies of cationic polymerization, carried out in parallel, solved an initial controversy concerning the nature of active species, that is, acylium versus tertiary oxonium cations, in favor of the latter ones.[32,33] Attempts of several laboratories to prepare high-molar-mass aliphatic polyesters in the controlled cationic process eventually failed.[34–39] The first example of a controlled cationic process involving cyclic ester is the activated monomer (AM) polymerization of CL, conducted in the presence of an alcohol.[40] More recently, Basko and Kubisa[41–44] published a series of papers that confirm applicability of the AM mechanism to the controlled synthesis of aliphatic polyesters. Interestingly, it has been also shown for the first time that triflic acid initiation of L,L-lactide (L,L-LA) polymerization, without a purposely introduced alcohol, leads to the living process proceeding in agreement with the AM mechanism.[44]

In spite of the living character of the anionic polymerization of PL, it was revealed that in the case of β-substituted β-lactones or medium-size cyclic esters (LA and CL) this process suffers from various side reactions such as chain transfer to monomer, racemization, segment exchange, or formation of macrocyclic esters.[45–48] Finally, it has been concluded that in the so-called coordination-insertion (pseudoanionic) polymerization, initiated with covalent metal alkoxides ($R_nMtOR'_{n-x}$, where Mt is Zn, Al, Sn, Ti, etc.), these side reactions can be kinetically suppressed or even eliminated.[25,49–52] Correlation of the selectivity parameters, defined as the ratio of rate constants of propagation and transfer (k_p/k_{tr}), with the reactivity of active species (k_p) showed that these polymerizing systems conform to the reactivity–selectivity principle.[53,54]

Systematic kinetic measurements, carried out during the past decade[55–62] revealed the importance of aggregation phenomena in the pseudoanionic polymerizations. The solution of the pertinent kinetic scheme involving aggregation[55–57] allowed determination of the absolute rate constants of propagation on the covalent species. Then, it has been shown that aluminum trialkoxide initiators of various degrees of aggregation may differ considerably in their reactivity toward cyclic esters.[26,63–66]

Application of bulky ligands that fill the space around the 'countercation' metal atom in covalent initiators prevent the aggregation – initially by Inoue and co-workers[67–69] and then by Spassky and co-workers[70,71] – resulted in new mechanistic implications. Inoue introduced a notion of 'immortal' polymerization for the already known processes with reversible chain transfer (the use of this expression is discouraged by IUPAC[72]). Polymerizations initiated with bulky chiral Schiff base Al alkoxides revealed a possibility of the stereoelective polyester synthesis starting from the chiral cyclic ester monomers.[71]

Another possibility of accelerating kinetics of the coordination polymerization of slowly polymerizing monomers (e.g., LAs) has been indicated by the DuPont team[73,74] and then explored by Feijen and co-workers[75,76] and Spassky *et al.*[77] Application of rare earth metal (La, Y, Sm, etc.) alkoxides as initiators resulted in polymerization rates characteristic for ionic active species but with kinetic suppression of side reactions on the level similar to that obtained with covalent alkoxides. The actual structure of the growing species is not yet known. Later, the use of initiators based on Zn alkoxides, which bear bulky ligands, gave a similar kinetic effect in polymerization of LA and β-butyrolactone (β-BL).[78,79]

ROP of CL and LAs seems to be a mature field. Controlled polymerization methods elaborated for these monomers allow preparation of the corresponding aliphatic polyesters in an impressively broad range of M_n: from $\approx 10^2$ up to $\approx 10^6$ g mol^{-1} (see, e.g., Reference 61). Living and controlled polymerization conditions have been established for PL already in 1976,[27,28] but the controlled polymerization of the corresponding β-substituted monomers (e.g., β-BL) still pose a serious challenge[45,46,79,80] due to chain transfer and termination side reactions. It is worth noting, however, that systematic studies carried out among others by Carpentier[81] with various ligand/metal alkoxide combinations led recently to a remarkable progress, particularly in the stereocontrolled polymerization of the racemic β-BL.

Catalyst, which is still the most important in the practical, synthetic, and industrial applications, is tin(II) 2-ethylhexanoate (tin octoate, $Sn(Oct)_2$).[82–84] Therefore, $Sn(Oct)_2$-catalyzed polymerizations of cyclic esters have been systematically studied since 1980s.[85–90] The detailed mechanism of this process remained obscure for a long time. Complementary kinetic, mass spectrometric, and NMR measurements revealed that the initiating and then growing species have the tin(II) alkoxide structure and are formed from the starting carboxylate in the exchange reaction with hydroxy-group-containing compounds (ROH).[91–96] The results coming then from other laboratories, thus, confirmed the formulated polymerization mechanism in the cyclic ester/$Sn(Oct)_2$/ROH system.[97–102]

Finally, in these introductory remarks, the metal-free organocatalytic polymerization of cyclic esters should also be mentioned (see, e.g., References 103–105 and the corresponding papers cited therein). Actually, this area has a long history that has been recently given a new life. Polymerization of β-lactones initiated, for example, with phosphines was already described in the early 1980s, including stereoselective

polymerization of unsymmetrically substituted monomers with optically active phosphines (References 106 and 107 and preceding papers cited therein). In the new series of organocatalytic polymerizations, usually the molar masses are limited and it is not convincing that polymerizations are living indeed, even if this expression is used throughout the papers. Initiation with phosphines or other organic bases leads to zwitterions, and the anionic part, alkoxide anion, is becoming active species known to lead to the chain transfer in CL and LA polymerization.

The same may happen in polymerization initiated with carbenes, providing as well alkoxide anions, at least according to the reaction scheme given by the authors of the pertinent papers (e.g., References 105 and 108). Also, in this process, molar masses are rather moderate and do not exceed $M_n \approx 3 \times 10^4\,g\,mol^{-1}$.

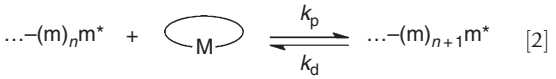
The metal-free, organocatalytic polymerizations encompassing anionic and cationic processes are also thoroughly reviewed in Chapter 4.06 and, therefore, are omitted in this chapter.

Mechanisms of ionic and coordination processes of aliphatic cyclic esters polymerizations have been reviewed systematically since the late 1960s (see, e.g., References 109–116), also including chapters in the first edition of the *Comprehensive Polymer Science*.[117,118] This chapter is based on the previous reviews coauthored by the present author;[111,114,119–122] however, it is supplemented by additional and more recent data (until the beginning of 2011).

4.11.2 Thermodynamics of ROP of Cyclic Esters

A more general description of the thermodynamics of ROP of cyclic monomers is given by Penczek in Chapter 4.02. The ability of a cyclic ester to polymerize by the ring-opening mechanism is determined by two equally important factors – conversion of monomer molecules to macromolecules (of linear or more complex topologies) must be allowed both thermodynamically and kinetically. Practically, this means that (1) the monomer–macromolecule equilibrium has to be shifted to the right-hand side (macromolecule), and (2) the corresponding polymerization mechanism should exist that could enable conversion of monomer molecules to polymer repeating units, within an operable polymerization time.

An elementary reaction of the macromolecular chain growth can be written as



[2]

where M = $(CH_2)_xC(O)O$ (lactone) or $[CH(CH_3)C(O)O]_2$ (lactide); m* denotes the active species, and k_p and k_d are the rate constants of propagation and depropagation, respectively.

The formal thermodynamic criterion of a given monomer polymerizability is related to a sign of the Gibbs energy of polymerization (cf. eqn [3]):

$$\Delta G_p(xy) = \Delta H_p(xy) - T\Delta S_p(xy) \qquad [3]$$

where x and y denote monomer and polymer states, respectively (i.e., x and/or y = l, liquid; g, gaseous; c, solid amorphous; c′, solid crystalline; s, solution), $\Delta H_p(xy)$ and $\Delta S_p(xy)$ the corresponding enthalpy and entropy of polymerization, and T the absolute temperature.

In agreement with general rules of thermodynamics of chemical processes, only for $\Delta G_p(xy) < 0$ the polymerization is possible. It has to be stressed, however, that the $\Delta G_p(xy)$ values usually depend on the monomer and polymer states. Further discussion will be related to ROP carried out in solution or in the monomer/polymer melt and at constant temperature and pressure.

Gibbs energy of polymerization (ΔG_p) may be expressed as a sum of standard enthalpy of polymerization (ΔG_p^o) and a term related to instantaneous concentrations of monomer ([M]) and growing polymer ([…-m*]):

$$\Delta G_p = \Delta G_p^o + RT \ln \frac{[\ldots\text{–}(m)_{i+1}m^*]}{[M][\ldots(m)_i m^*]} \qquad [4]$$

where R denotes the gas constant and T the absolute temperature.

Following Flory's assumption that the reactivity of the active center, located at a sufficiently long polymer chain, does not depend on its polymerization degree (P_i), and taking into account that $\Delta G_p^o = \Delta H_p^o - T\Delta S_p^o$ (where ΔH_p^o and ΔS_p^o denote a standard polymerization enthalpy and entropy, respectively), we obtain:

$$\Delta G_p = \Delta H_p^o - T(\Delta S_p^o + R \ln[M]) \qquad [5]$$

In contrast to polymerization of a large majority of unsaturated monomers, ROP of cyclic monomers is often accompanied by the presence of a relatively high concentration of the unreacted monomer when the process comes to equilibrium. This feature is related to pronounced reversibility of the propagation step (i.e., relatively high k_d in comparison to k_p, eqn [2]). Thus, the value of the equilibrium monomer concentration ($[M]_{eq}$) at a given temperature is usually taken as a measure of the thermodynamic polymerizability of the monomer. The corresponding thermodynamic formalism has been developed by Dainton and Ivin in 1948–1958[3,123] and then by Tobolsky and Eisenberg.[124–126]

At equilibrium ($\Delta G_p = 0$), that is, after the polymerization does not occur, the monomer concentration ($[M]_{eq}$) assumes a value determined by standard polymerization parameters (enthalpy, ΔH_p^o and entropy, ΔS_p^o) and polymerization temperature (see, e.g., References 123–133):

$$\ln[M]_{eq} = \left(\frac{\Delta H_p^o}{RT}\right) - \left(\frac{\Delta S_p^o}{R}\right) \qquad [6]$$

Depending on the starting monomer concentration ($[M]_0$), or actually on the $([M]_0 - [M]_{eq})/\Sigma[\ldots\text{–}m_i^*]$ ratio, for a given concentration of active species ($\Sigma[\ldots\text{–}m_i^*]$), polymers of various number-average polymerization degrees (P_n) could be formed (note that eqn [5] is valid only under Flory's assumption that the reactivity of the active center, located on a sufficiently long macromolecule, does not depend on its polymerization degree (P_i)).

Thus, the polymerization is possible only when $[M]_0 > [M]_{eq}$. For shorter, oligomeric chains ($P_n \leq 20$), not conforming to the Flory's assumption in the expressions for $[M]_{eq}$, reactivities of active species have to be taken into account (see Appendix in Reference 134):

$$\ln\left(\frac{P_n}{P_n - 1}[M]_{eq}\right) = \frac{\Delta H_p^o}{RT} - \frac{\Delta S_p^o}{R} \qquad [7]$$

Figure 1 gives an example of application of relationship [7] for determination of the standard thermodynamic parameters in the ROP of 1,4-dioxan-2-one (DX) using the experimentally determined $[M]_{eq}$'s at various temperatures.

The slope and intercept of this dependence gives an access to ΔH_p^o and ΔS_p^o values, respectively.[134] Another typical method of ΔH_p^o and ΔS_p^o determination is based on the monomer and polymer combustion and specific heat measurements.[7–12] In turn, the thus determined thermodynamic parameters allow estimation of the corresponding $[M]_{eq}$ values, which is particularly useful when $[M]_{eq}$ is close to 0.

The values of thermodynamic parameters characterizing the polymerization ability of representative cyclic esters are compared in Table 1.

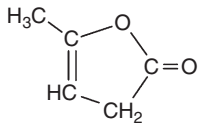
The driving force for the polymerization of the majority of cyclic esters is their ring strain, reflecting the deviation from the non-distorted bond angle values, bond stretching and/or compression, repulsion between eclipsed hydrogen atoms, and nonbonding interactions between substituents (angular, conformational, and transannular strain). For systems in which the specific monomer–polymer–solvent interactions can be neglected, enthalpy of polymerization is a measure of the ring strain.

Polymerization of the majority of monomers is accompanied by an entropy decrease, mostly due to the loss of the translational degrees of freedom. In this situation, polymerization is thermodynamically allowed only when the enthalpic contribution to ΔG_p prevails (thus when $\Delta H_p < 0$ and $\Delta S_p < 0$, the inequality $|\Delta H_p| > -T\Delta S_p$ is required; cf. eqn [5]). Therefore, the higher the ring strain, the lower the resulting monomer concentration at equilibrium (eqn [6]).

Although the formation of the three-membered α-lactone intermediates in the nucleophilic substitution of α-substituted carboxylate anions was postulated on the basis of quantum mechanical calculations,[138] these cyclic esters have never been isolated. The four-membered PL ranks among the most strained cyclic monomers and its equilibrium monomer concentration is unmeasurably low, namely, about 10^{-11} mol l^{-1} at room temperature. However, the six-membered monomers, namely, L,L-LA or DX, have relatively high equilibrium monomer concentrations that cannot be neglected in practical considerations. Thus, the equilibrium concentration appeared considerably high, especially at elevated temperatures (at which L,L-LA is usually polymerized). For the temperature range from 80 to 133 °C, $[L,L\text{-LA}]_{eq}$ changes from 0.058 to 0.151 mol l^{-1}. This six-membered cyclic diester (dilactone) assumes irregular skew-boat conformation, in which two ester groups can adopt planar conformation, and has, therefore, a relatively high enthalpy of polymerization equal to 22.9 kJ mol^{-1}. This is very close to the ring strain of δ-valerolactone (VL) and CL, equal to 27.4 and 28.8 kJ mol^{-1}, respectively. Strain comes in these compounds from C–H bond interactions and from distortion of the bond angles. The carbonyl group introduces a certain extent of strain into six-membered rings due to the flat geometry of the ester grouping (…–CH_2–C(=O)–O–…). In contrast, high ring strain in the four-membered PL is mostly due to the bond angle distortion and bond stretching.

In the five-membered cyclics, ring strain comes almost exclusively from the conformational interactions. It is known, however, that the five-membered lactones are not strained because of the reduced number of the C–H bond oppositions, caused by the presence of the carbonyl group in the monomer ring. Indeed, for γ-butyrolactone (γ-BL) we have $\Delta H_p^o = 0.4$ kJ mol^{-1} and $\Delta S_p^o = -0.4$ J mol^{-1} K^{-1}. These give $[\gamma\text{-BL}]_{eq} \approx 5.1 \times 10^3$ mol l^{-1}, whereas the monomer concentration in bulk does not exceed 13 mol l^{-1}. Therefore, in the majority of polymer chemistry textbooks it is stated that γ-BL is not able to polymerize.[127,139–143] γ-BL is indeed not able to give a high-molar-mass homopolymer, but this feature is sometimes incorrectly identified with the inability of BL to undergo the ring-opening reaction at all.

Interestingly enough, introduction of the double bond into the five-membered lactone ring introduces some extent of strain and makes its polymerization feasible as it was observed for α-angelicalactone (Structure 1).[144]



1

Hall and co-workers[145,146] explained some of these thermodynamic features in terms of comparison of the

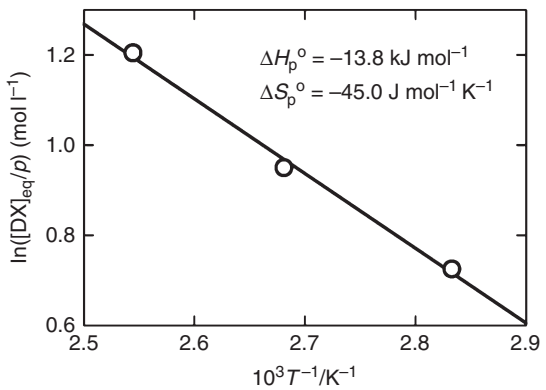


Figure 1 Plot of $\ln([DX]_{eq}/p)$ (where $p = (P_n - 1)/P_n$) on the reciprocal of the absolute temperature (eqn [7]). Bulk oligomerization of 1,4-dioxan-2-one (DX) initiated with a butan-1-ol/tin(II) octoate mixture.[134]

exergonic character of the ring-opening processes and stability of the coiled conformation of compounds modeling the corresponding polyester chain by means of quantum mechanical calculations.

The thermodynamic data in Table 1 characterizing large lactones (tridecanolactone and pentadecanolactone) suggest that an increase in the ring size leads to a rather small ring strain (if any) and to an increase in the polymerization entropy. The latter is due to a relatively high flexibility of the long polymethylene sequences in the resulting polymer chains.

Figure 2 illustrates characteristic changes of the standard thermodynamic parameters with increasing ring size of lactones shown on the example of bulk polymerization of lactones. Similar dependencies were also observed for other monomers, with only slight changes of positions of the local minima or maxima on the thermodynamic parameter – ring size (n) dependences.[128,133,139] Although ΔG_p^o is temperature dependent, this figure gives at least a qualitative picture of ΔG_p^o versus n changes.

It has also to be stressed that analysis of a given polymerization process, based on the values of the corresponding thermodynamic parameters available in the literature, requires some caution. First of all, ΔH_p^o and ΔS_p^o depend substantially on the monomer and polymer states. For example, thermochemical measurements (heats of combustion and specific heats) gave for 16-membered pentadecanolactone in the liquid phase $\Delta H_p^o = 3$ kJ mol^{-1} and $\Delta S_p^o = 23$ J mol^{-1} K^{-1}, whereas in the crystalline phase $\Delta H_p^o = -39$ kJ mol^{-1} and $\Delta S_p^o = -86$ J mol^{-1} K^{-1}.[10] The difference between these two sets of parameters is caused by the contribution of enthalpies and entropies of phase transitions (crystallization/melting).

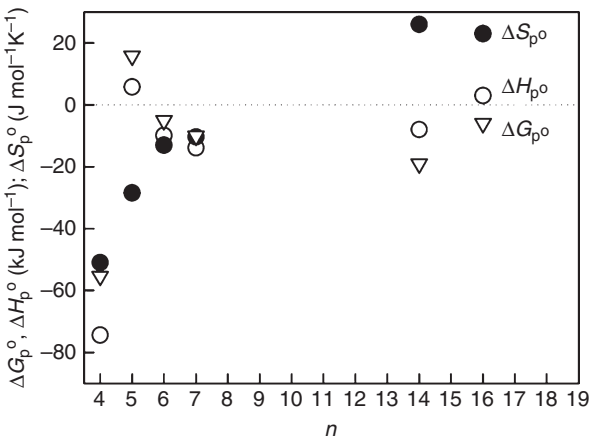

Figure 2 Dependences of standard Gibbs energy (ΔG_p^o, ▽), enthalpy (ΔH_p^o, ○), and entropy (ΔS_p^o, ●) of lactone polymerization on the ring size (n). Temperatures from 350 to 430 K, monomer and polymer liquid. Data taken from References 7–10, 12, and 137.

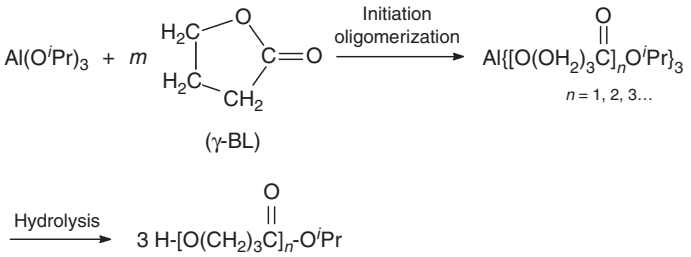
4.11.2.1 Thermodynamics of ROP of Cyclic Esters: Some Particular Cases

4.11.2.1.1 Thermodynamics of γ-BL (co)polymerization

As already mentioned, several polymer chemistry textbooks claimed that polymerization of γ-BL and/or its ring opening at ambient conditions is not possible.[128,139–143]

Actually, in polymerization of γ-BL initiated with $Al(O^iPr)_3$, a series of short-chain oligomers are formed:



[8]

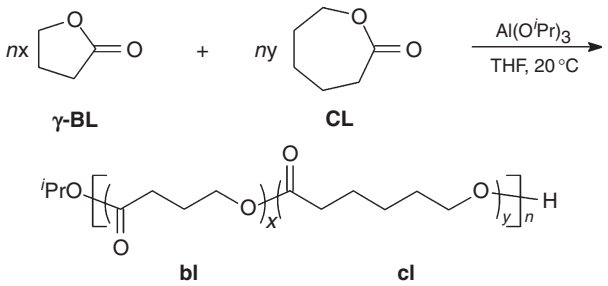
Both gel permeation chromatography (GPC) and mass spectroscopy show that oligomers are indeed formed (Figure 3).

These results indicate again that the equilibrium constants for the first few monomer additions (K_0, K_1, …) are not the same, as those for addition to a high polymer (K_n). Apparently, there is an influence of the head end group and the conformational flexibility of the macromolecule. Formally, the contribution to the Gibbs energy of the simple concentration term, $RT\ln[M]$ is based on the assumed equality $[\ldots\text{-}(m)_n\text{-}\ldots] \approx [\ldots\text{-}(m)_n\text{+}1\text{-}\ldots]$. For short poly(γ-BL) (Pγ-BL) chains, when this equality does not hold, the expression for the Gibbs energy should read

$$\Delta G_n = \Delta H_n - T\left(\Delta S_n^{\circ} - R\ln\frac{[\text{poly}(\gamma\text{-BL})_{n+1}]}{[\gamma\text{-BL}][\text{poly}(\gamma\text{-BL})_n]}\right) \qquad [9]$$

For mostly short chains, the inequality takes place, $[\text{poly}(\text{BL})_n] > [\text{poly}(\gamma\text{-BL})_{n+1}]$, and the entropic term may outweigh the $\Delta H_n \geq 0$, making $\Delta G_n < 0$ and, thus, allowing shorter chains to be formed.

γ-BL also copolymerizes with other lactone monomers, giving high-molar-mass copolymers.[147–151] For example,



[10]

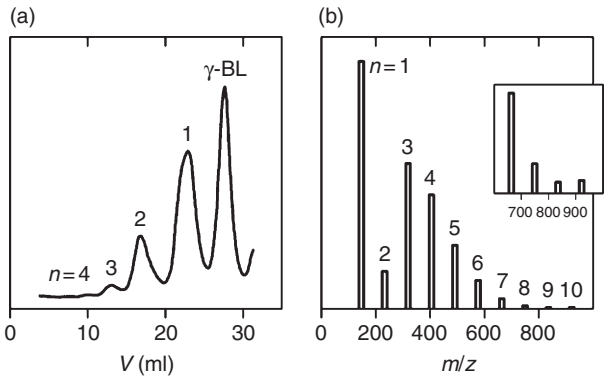


Figure 3 Oligomerization of γ-butyrolactone (γ-BL) initiated with $Al(O^iPr)_3$. (a) GPC trace and (b) mass spectrum (chemical ionization) of the isolated series of linear oligomers: H-[O(CH$_2$)$_3$C(O)]$_n$-O^{i}Pr. Conditions of oligomerization: $[\gamma\text{-BL}]_0 = 3.8\ \text{mol l}^{-1}$, $[Al(O^iPr)_3]_0 = 0.2\ \text{mol l}^{-1}$, THF, 80 °C.[148]

The dependence of the bl polymer units content in the copolymer (X_{bl}), on the γ-BL monomer content in the feed (X_{BL}) is shown in Figure 4. As it could be expected from copolymerization of a monomer unable to give high polymers, even at the high excess of γ-BL in the feed the bl content in copolymer should not exceed 50 mol-%. Thus, one could expect formation of the copolymer close to alternating at a sufficiently large excess of γ-BL. Actually, ^{13}C NMR spectra analysis pointed to the pseudoperiodic copolymer structure.[149] The γ-BL/CL copolymer synthesis was successful because the γ-BL monomer addition to its own …–bl* active chain ends is highly reversible, whereas γ-BL is winning in additions to …–cl* active chain ends since γ-BL is taken in a high excess over CL ([γ-BL] > [CL]) (Figure 4).

4.11.2.1.2 Copolymerization of LA after reaching polymer–monomer equilibrium

The situation of a monomer incapable of giving high polymers at a certain temperature and in a certain monomer concentration range is similar to a monomer that does homopolymerize, but is reaching its polymer–monomer equilibrium. At these conditions, no further increase in conversion takes place. Introduction of another monomer at this moment, capable of homopolymerizing (and copolymerizing), leads to formation of the block copolymer with a junction unit following the first homopolymer block and buildup of a graded copolymer. This was observed when LA has been brought to the polymer–monomer equilibrium and then CL was introduced into the system.[153]

The actual process is illustrated by the kinetic data in Figure 5. Thus, homopolymerization of LA has been brought to equilibrium and reached $[LA]_{eq} = 0.06\ \text{mol l}^{-1}$. Then CL was introduced at $[CL]_0 = 0.84\ \text{mol l}^{-1}$ and copolymerization started. LA was virtually consumed when less than $0.2\ \text{mol l}^{-1}$ of CL remained and finally homopolymerization of CL proceeded. One could imagine that the proper choice of a monomer and other conditions would give even a lower proportion of comonomer needed for complete conversion of LA.

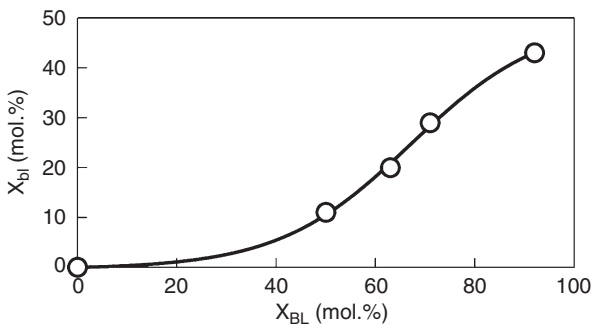

Figure 4 Dependence of the γ-butyryl (bl) unit content in the γ-butyrolactone (γ-BL)/ε-caprolactone (CL) copolymer ($X_{bl} = 100[bl]/([bl] + [cl])$) on the γ-BL monomer content in the feed ($x_{BL} = 100[BL]_0/([BL]_0 + [CL]_0)$).[152]

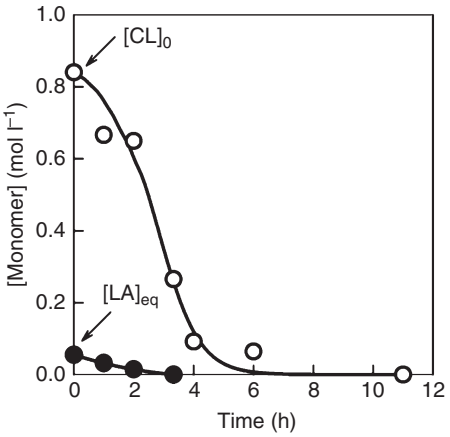

Figure 5 Kinetics of copolymerization of L,L-lactide (LA) (•) and ε-caprolactone (CL) (○). Conditions: $[CL]_0/[LA]_{eq} = 15.3$, $[CL]_0 = 0.89\ mol\ l^{-1}$; 80 °C, THF, M_n (living PLA) = 4780.[153]

This phenomenon is of interest since it allows a polymer to be produced with complete conversion of a monomer below its $[M]_{eq}$.

$$([LA]_{eq})_{co} = \frac{1}{1 + ([\ldots\text{–cl–la}^*]_{eq}/[\ldots\text{–la–la}^*]_{eq})} \times ([LA]_{eq})_{homo} \qquad [11]$$

Equation [11], derived in Reference 153, shows that except $[\ldots\text{–cl–la}^*] = 0$, the equilibrium concentration of LA in copolymerization would always be lower than that in homopolymerization. The research should, thus, be directed toward comonomers giving an as-high-as-possible ratio of active centers resulting from cross- and homopropagations: $[\ldots\text{–cl–la}^*]/[\ldots\text{–la–la}^*]$.

4.11.2.1.3 Polymerization in heterogeneous systems

Polymerization of industrially important monomers, such as DX or LA, is usually carried out above the melting temperature of their polymers in homogeneous melt. Under these conditions (i.e., above 110 °C for poly(DX) and 180 °C for poly(LA)), the equilibrium monomer concentrations are relatively high, namely, $[DX]_{eq} > 2.5\ mol\ l^{-1}$ and $[LA]_{eq} > 0.32\ mol\ l^{-1}$, because of the moderate ring strain in the six-membered monomers. The molar fraction of the unreacted monomers can be, however, reduced by aging the living polymerization mixtures below the melting temperature of the polyesters formed. Under these modified conditions, poly(DX) and poly(LA) crystallize, and the volume of the liquid phase, in which the unreacted monomer still remains, decreases. Then, [M] increases temporarily above the $[M]_{eq}$ and then an additional polymerization of the monomer proceeds, leading to an apparent decrease in $[M]_{eq}$ (actually molar fraction of M), resulting eventually in almost complete monomer consumption. This result is achieved despite the conclusions that could be drawn from the values of the thermodynamic parameters in Table 1 for both discussed monomers.[154,155] This problem has already been discussed for the example of 1,3,5-trioxane bulk polymerization, in the first edition of the *Comprehensive Polymer Science*.[156] Similar phenomena may also take place in other heterogeneous polymerizing systems (see also Chapter 4.25).

4.11.3 Kinetics of the ROP of Cyclic Esters

4.11.3.1 Kinetic Polymerizability

Polymerizability, in the frame of the formalism of propagation kinetics, is related to the sign of the molar Gibbs energy of activation ($\Delta G_p^{\neq}$) – a measure of the energy barrier in the elementary act of propagation (eqn [2]), for which $\Delta G_p^{\neq}$ assumes exclusively positive values. The instance for which $\Delta G_p^{\neq} < 0$ means that a given reaction is more complex and does not exclusively corresponds to the elementary act of the polymer chain growth. The resulting rate constant of propagation (k_p, eqn [12], Reference 157) for a given mechanism and structure of active centers should assume values assuring operable polymerization times at a given temperature.

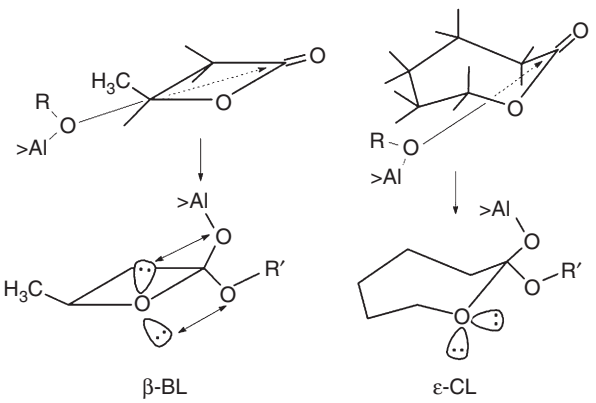
$$k_p = \frac{k_b T}{h} \exp\left(-\frac{\Delta G_p^{\neq}}{RT}\right) = \frac{k_b T}{h} \exp\left(-\frac{\Delta H_p^{\neq}}{RT} + \frac{\Delta S_p^{\neq}}{R}\right) \qquad [12]$$

where k_b, h, $\Delta H_p^{\neq}$, and $\Delta S_p^{\neq}$ denote the Boltzmann constant, Planck constant, enthalpy, and entropy of activation, respectively.

As it is already stressed in the Introduction, the fulfillment of thermodynamic requirements is a necessary but not sufficient prerequisite for a polymerization to occur. In general, the 'thermodynamic polymerizability' cannot be taken as a direct measure of monomer reactivity. For instance, the rate constants of alkaline hydrolysis of γ-BL and CL at comparable conditions are close to each other (1.5×10^{-4} and $2.6 \times 10^{-4}\ l\ mol^{-1}\ s^{-1}$, respectively)[158] although the corresponding ring strains differ considerably (cf. Table 1).

The difference in ring strain of β-lactones and higher lactones could also suggest that the polymerization rate of the former should be much higher than, for example, that of CL. However, the opposite is true: for example, in the $Al(O^iPr)_3$ – initiated polymerization, k_p(β-BL) = 4×10^{-3} and $k_p(CL) \approx 30\ l\ mol^{-1}\ s^{-1}$ ($[M]_0 = 2\ mol\ l^{-1}$, 80 °C, THF);[159] see also a similar difference in PL and CL reactivities[160–162] in ionic polymerization. This observation can, possibly, be explained by two effects (Scheme 1).[29,33,163,164]

Steric hindrance that hampers the attack of active species on the acyl carbonyl is much more pronounced in the flat β-BL molecule compared with the folded CL molecule. Moreover, the nucleophile addition leads to a change in hybridization of the attacked carbon atom from sp^2 to sp^3. In the β-BL case, an



Scheme 1

additional strain appears caused by interaction of the free electron pair of the endocyclic oxygen atom with the exocyclic C=O group in the *cis* conformation forced by the ring topology. The gauche conformation in the CL case does not produce any additional energy barrier of that kind.

The order of monomer reactivities may also depend on the polymerization mechanism as has been revealed, for example, by kinetic studies of polymerization of the 6-, 7-, 9-, 12-, 13-, 16, and 17-membered lactones initiated with the zinc 2-ethylhexanoate/butan-1-ol system[165] or catalyzed enzymatically.[165,166] For the resulting Zn alkoxide propagating species, the following relative rates have been measured: 2500, 330, 21, 0.9, 1, 0.9, and 1, respectively (bulk polymerization, 100 °C). Since the active species operating in polymerization of various lactones in this system are structurally identical, namely,….–C(O)$(CH_2)_{m-1}CH_2O$–Zn–…, the order of the resulting polymerization rates is equivalent to the order of lactone reactivities. Comparison of the lactone ring sizes with the relative polymerization rates shows that the larger the lactone ring, the lower is its reactivity (reactivities of the 12-, 13-, 16-, and 17-membered lactones are practically identical taking into account the experimental error). It can be expected that in the transition state of propagation this strain is partly released and the resulting $\Delta H_p^{\neq}$ is lower for strained monomers in comparison with the nonstrained ones. Probably, this is the main reason why the lactone reactivities decrease with increasing their sizes and eventually reach a constant value for larger rings. Other factors, such as the electrophilicity of the monomer acyl or steric hindrance hampering the approach of the active species to the lactone ester group, probably play a minor role.

Interestingly, the relative rate order of the enzymatic polymerization shows an inverse dependence on the ring size, namely, 0.10:0.13:0.19:0.74:1.0 for the 7-, 12-, 13-, 16-, and 17-membered lactones, respectively.[165] This kinetic behavior can be explained assuming that in enzymatic polymerization, the rate-determining step involves formation of the lactone–enzyme complex. The latter reaction is promoted by hydrophobicity of the lactone monomer, which is higher for large lactone rings. Concluding, thermodynamic and kinetic polymerizabilities for enzymatic processes with regard to the monomer ring sizes are in the opposite order.

The reaction of initiator with monomer (eqn [13a]) should lead to active species capable of adding new monomer molecules (eqn [13b]) faster than they undergo any side reactions (e.g., termination (eqn [13c]) or transfer to monomer (eqn [13d])).

$$\mathrm{I} + \text{M} \xrightarrow{k_i} \text{I-m}^* \qquad [13a]$$

$$\text{…–(m)}_n\text{m}^* + \text{M} \underset{k_d}{\overset{k_p}{\rightleftharpoons}} \text{…–(m)}_{n+1}\text{m}^* \qquad [13b]$$

$$\text{…–(m)}_n\text{m}^* + \text{X} \xrightarrow{k_t} \text{…–(m)}_n\text{m-X} \qquad [13c]$$

$$\text{…–(m)}_n\text{m}^* + \text{M} \xrightarrow{k_{tr}} \text{…–(m)}_n\text{m} + \text{m}^* \qquad [13d]$$

where I denotes the initiator molecule, X the terminating agent, and k_p, k_d, k_t, and k_{tr} the rate constants of propagation, depropagation, termination, and chain transfer to monomer, respectively.

For an ideal living polymerization, $k_t = 0$ and $k_{tr} = 0$ (however, a transfer could occur though reversible[72]). ROP of cyclic esters, the subject of this chapter, could also proceed as living processes. However, the molar mass and end group control of the resultant polymer are possible only when $k_i \geq k_p$ and $k_{tr} = 0$.

4.11.3.2 Initiators and Active Centers: Structures and Reactivities

Extensive lists of initiators and catalysts used in anionic and coordination polymerizations can be found in several reviews (see, e.g., References 111, 167, and 168). In spite of the fact that dozens of 'new' initiators were reported every year in the past decades, for the purpose of this discussion, it is enough to say that, for the four-membered PL, ionic metal carboxylates (most often with K^+, Li^+, or Na^+ counterions) can be used, whereas for higher lactones and LAs, exclusive initiation with the alkoxides is possible. Multivalent metal (e.g., Zn, Sn(II), Al, Sn(IV), Ti, or Zr) alkoxides, giving a good compromise between reactivity and selectivity, lead to propagation on the covalent metal–alkoxide polarized bonds, presumably by a coordination mechanism. In turn, multivalent metal carboxylates or acetylacetonates require the presence of a coinitiator, such as hydroxy or primary amino group for initiating cyclic ester polymerization.

Initiation of β-lactone polymerization with ionic alkoxides proceeds in such a way that it initially results in acyl–oxygen and alkyl–oxygen bond scission in *c*. 1:1 proportion (**Scheme 2**). However, independent of the chemistry at earlier stages, the eventual active species are carboxylate anions.[29–31]

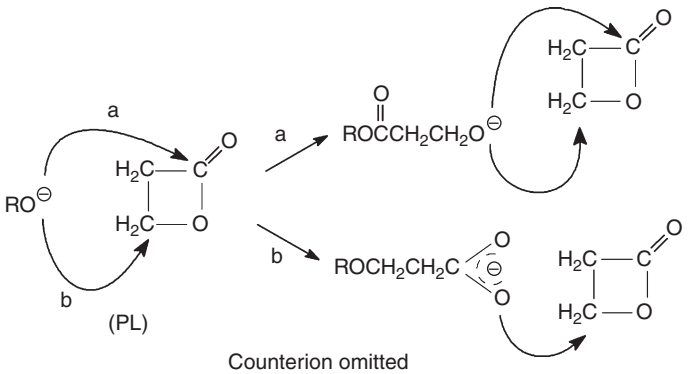
The observed inversion of configuration if the substituted β-carbon is attacked (e.g., in the enantiomerically enriched β-BL) points to the S_N2 mechanism in the active species attack.[169]

The alkyl–oxygen bond scission is known only for β-lactones, whereas for higher lactones and LAs exclusively the acyl–oxygen bond scission proceeds and the active species are alkoxide anions.

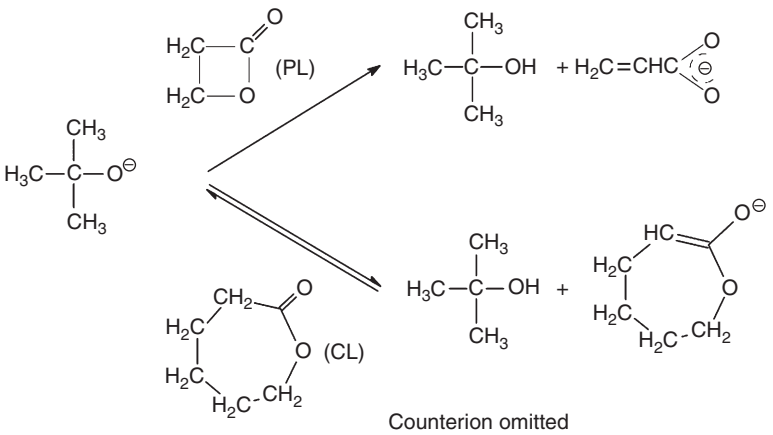
Anions of high basicity and, due to steric hindrance, low nucleophilicity (e.g., *tert*-butoxide) initiate the polymerization mostly by proton transfer and in the irreversible (e.g., PL) or reversible (e.g., CL) mode (**Scheme 3**).[170]

The idea of the –C–C– bond breaking in initiation of the four-membered lactone polymerization has recently been shown to be wrong.[171] Actually, Szwarc himself expressed some doubts about this unusual hypothesis much earlier (p 69 in Reference 172).

In contrast to PL, which polymerizes by the action of soft and moderately reactive carboxylate anions, less strained cyclic esters (e.g., CL or LA) require stronger nucleophiles to propagate and, as a consequence, are usually plagued by side reactions. On the other hand, it has been found that coordination ROP of CL or LA initiated with covalent metal alkoxides may proceed in a perfectly controlled way due to a high selectivity, as is quantitatively expressed by high k_p/k_{tr} ratios.[50,53,54,173,174] This feature provides a flexible way not only for synthesis of linear homopolymers, but also for a great



Scheme 2

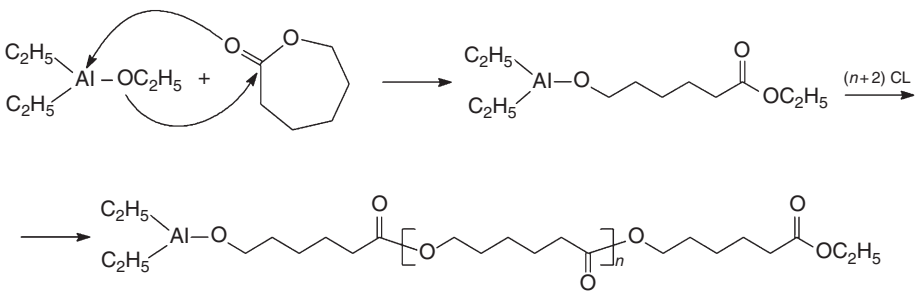


Scheme 3

variety of macromolecules differing in architecture. Polymerization of CL initiated with dialkylaluminum alkoxide is a typical example. The initiation proceeds by a simple monomer insertion, mechanistically identical with the subsequent propagation steps. A comparison of ^{1}H NMR spectra of the initiator and those of the reacting mixture (**Figure 6**) suggests the quantitative initiation and absence of side reactions during the PCL chain growth (eqn [14]).

The related monomer/active species coordination/complexation phenomena and possible chelation effects are discussed in more detail by Lewinski *et al.*[177,178] on the examples of CL and LA polymerization.

Whenever the alkoxides exist in different aggregated forms, it may happen that one form is more reactive than the other one. If, in addition, the exchange between these forms is slow, in comparison with the rate of initiation, then only this reactive form is engaged in initiation, leaving the other form(s) intact, when the polymerization is over. This is the case of initiation of CL with $Al(O^iPr)_3$, consisting of a trimer (reactive) and tetramer (unreactive) at least at ambient temperatures (**Scheme 5**).[65,66]



[14]

The monomer insertion may be preceded by the monomer coordination. The elementary reaction of the Al alkoxide active species with the CL monomer proceeds then analogously to the $B_{AC}2$ mechanism, however, with the participation of polarized covalent bonds (**Scheme 4**).[176]

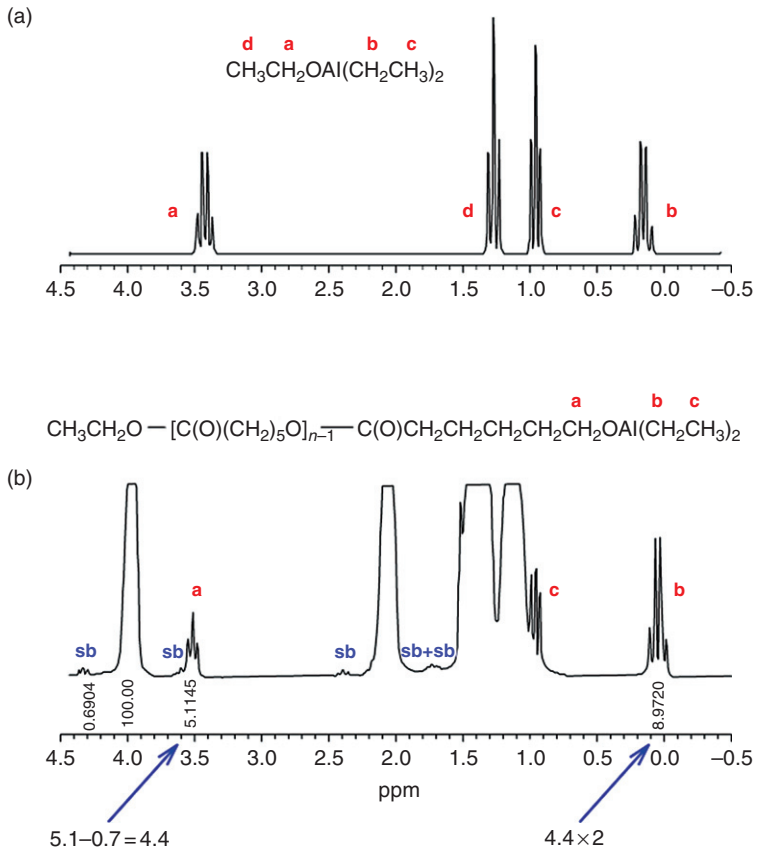


Figure 6 Selective initiation with $(C_2H_5)_2AlOC_2H_5$ (I) of the polymerization of ε-caprolactone (CL). ^1H NMR (200 MHz) spectra of (a) initiator and (b) living PCL. Conditions of polymerization: $[CL]_0 = 2.0$ mol l^{-1}, $[I]_0 = 0.097$ mol l^{-1}, C_6D_6 as solvent, 25 °C (sb = side bands).[175]

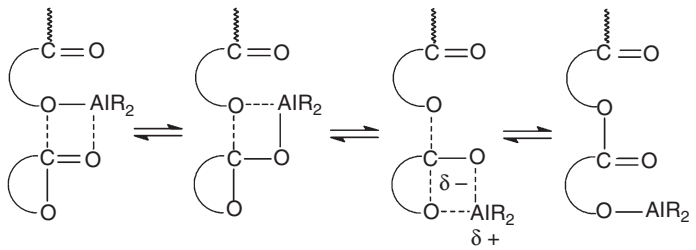
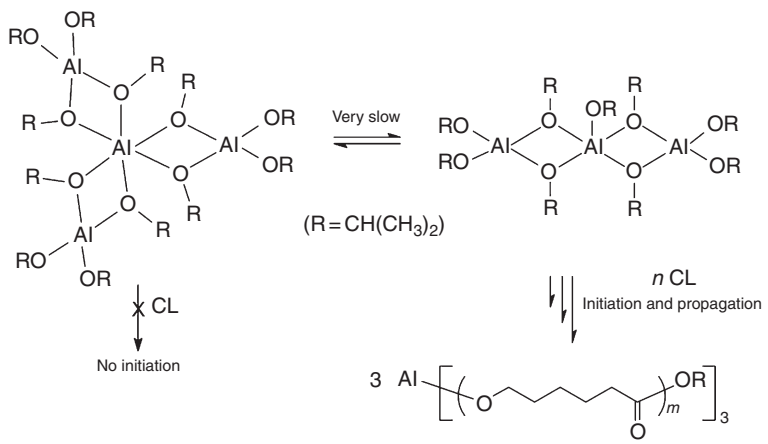


Scheme 4



Scheme 5

At higher temperatures (e.g., above 100 °C), the rate of trimer-tetramer exchange may approach the rate of initiation since the temperature coefficient of the rate of exchange is higher than that of initiation.[60]

4.11.3.3 Initiation with Covalent Carboxylates

For a long time, the initiation of polymerization of higher lactones and LAs with covalent (Sn or Zn) carboxylates was under dispute. Leenslag and Pennings[84] and later Zhang *et al.*[88] proposed a mechanism involving reaction of $Sn(Oct)_2$ with a coinitiator, thus leading to the corresponding alkoxide. The hydroxy group may be present as an impurity or may be deliberately added in a compound to the system (e.g., water, alcohol, or hydroxy acid (ROH)), (eqn [15]):

$$\begin{aligned} &Sn(Oct)_2 + ROH \rightleftharpoons OctSn\text{-}OR + OctH \\ &OctSn\text{-}OR + ROH \rightleftharpoons RO\text{-}Sn\text{-}OR + OctH \end{aligned} \qquad [15]$$

where Oct stands for $O(O{=})CCH(C_2H_5)C_4H_9$ (2-ethylhexanoate (octoate)) group and OctH for 2-ethylhexanoic (octanoic) acid.

Then, the resulting tin(II) mono- and/or dialkoxide initiates polymerization in the same manner as the other metal alkoxides. However, there was, at that time, no direct proof of such a mechanism and several other mechanisms have been proposed.[84–90] The most often cited was the 'trimolecular' mechanism[86] in which first the catalyst–monomer complex is formed. This mechanism has conclusively been shown not to operate since it excludes the presence of Sn atoms covalently bonded to the growing macromolecules. The matrix-assisted laser desorption ionization (MALDI) time-of-flight (TOF) mass spectral measurements of the cyclic ester/ROH/$Sn(Oct)_2$ system revealed the presence of tin(II) alkoxides in the growing polyester chains.[92] Moreover, the kinetic studies also clearly supported this sequence of the exchange reactions.[91,93–96]

In Figure 7, the LA polymerization rates in two systems are compared, namely, that initiated with $Sn(Oct)_2$/BuOH and with $Sn(OBu)_2$/OctH.[93] Polymerization at $[Sn(Oct)_2]_0$ = 0.05 mol l^{-1} with no alcohol added is very slow (plot 1). It is certainly co-initiated by compounds containing hydroxy groups, adventitiously present in the system as impurities. Polymerization initiated at $[Sn(OBu)_2]_0 = 0.05$ mol l^{-1} was 2.4×10^2 times faster than that with $Sn(Oct)_2$ alone (plot 4). In the next two experiments, $[Sn(Oct)_2]_0$ and $[Sn(OBu)_2]_0$ were equal (0.05 mol l^{-1}) and 0.1 mol l^{-1} of BuOH and OctH were added.

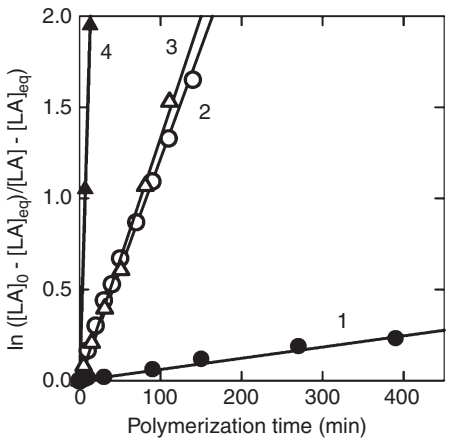


Figure 7 Comparison of kinetics of L,L-lactide (L,L-LA) polymerization initiated by $Sn(Oct)_2$ (1), $Sn(Oct)_2$/BuOH (2), $Sn(OBu)_2$/octanoic acid (OctH) (3), and $Sn(OBu)_2$ (4). Conditions: $[LA]_0 = 1.0$ mol l^{-1}, $[Sn(OBu)_2]_0 = [Sn(Oct)_2]_0 = 0.05$ mol l^{-1}, $[OctH]_0 = [BuOH]_0 = 0.10$ mol l^{-1}, THF, 50 °C.[93]

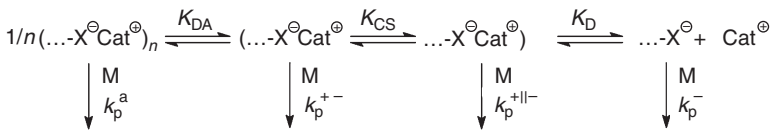
As it is seen in Figure 7 (plots 2 and 3), polymerization rates in the $Sn(Oct)_2$/BuOH and $Sn(OBu)_2$/OctH systems are practically the same, which strongly supports the proposed mechanism of the actual initiator formation (eqn [15]).

Therefore, these other views could be left aside. Besides hydroxy-group-containing compounds, primary amines can also play a role of the initiator in the $Sn(Oct)_2$-catalyzed polymerizations giving eventually tin(II) alkoxides as the growing species[95] (it has to be stressed that the distinction between initiator and catalyst in such binary systems is not always straightforward and those terms are frequently used interchangeably).

4.11.3.4 Propagation in Anionic ROP of Lactones

Ionic (e.g., alkoxide or carboxylate) active species can participate in the polymerization in different physical forms – ions, ion pairs, and ionic aggregates – which are interchanged slower or faster (Scheme 6).

For example, equilibrium constants of dissociation (K_D) in polymerization of CL and PL change typically at room temperature in the range from $\leq 10^{-10}$ (for $Cat^+ = K^+$) to 10^{-5} mol l^{-1} ($Cat^+ = K^+$ complexed with dibenzo-18-crown-6 (DBC)).[111]



$Cat^{\oplus}$ - countercation
M - monomer
K_{DA}, K_{CS}, and K_D - equilibrium constants of deaggregation, between contact and separated ion pairs, and of dissociation, respectively
k_p^a, k_p^{+-}, $k_p^{+||-}$ and k_p^- - the corresponding rate constants of propagation

Scheme 6

Quantitative studies of the elementary reactions in polymerization of cyclic esters were started by converting or 'upgrading' polymerization of PL from the nonliving to the living conditions. This happened in the mid-1970s when two papers appeared in the same issue of *Macromolecules* revealing that application of crown ethers[27] or cryptands[28] leads to a large increase in the observed rate of polymerization and suppression of transfer reactions. This increase in the rate of polymerization when initiated with crowned potassium acetate was more than 100-fold. In agreement with the knowledge existing at that time on the influence of crown ethers and cryptands on the behavior of ionic reactions, it was assumed that these additives break aggregates of ion pairs, converting the otherwise unreactive aggregates into the unimeric ion pairs with complexed cations. A further consequence was the increase in concentration of the free ions due to a much higher dissociation constant of the crowned ion pairs.

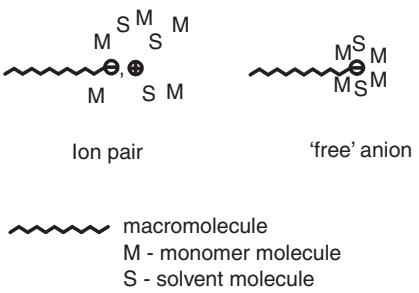
Polymerization was first-order in the monomer; the apparent rate constant increased with the independently determined degree of ionization (α). Besides, molar masses were linear functions of conversion up to $M_n = 2 \times 10^4$. From the corresponding plots of the apparent rate constants of propagation (k_p^{app}) on α (Szwarc plot), both k_p^- and $k_p^{\pm}$ have been determined.[160,161]

Results of these measurements have led to the observation of an unexpected phenomenon. The ion pairs behave in a 'normal' way; at $[PL]_0 = 1.0$ and $3.0\,mol\,l^{-1}$, their reactivity was the same (**Figure 8(c)**), which means that the crowned ion pairs are not specifically solvated by components of the system. This is because ion pairs are electrically neutral and their cation is not easily accessible due to its crowned character. On the contrary, the reactivities (rate constants) of the ions depend on $[PL]_0$, that is, on the solvating power of the reaction medium (it has been assumed that the monomer can solvate ions).

Comparison of k_p^- and $k_p^{\pm}$ at various temperatures is given in **Figure 8**. At low temperature, the reactivity of ions approaches the reactivity of the ion pairs in both CH_2Cl_2 and dimethylformamide (DMF) solvents. In DMF, a temperature could be found at which an inversion of reactivities of both species takes place (isokinetic point). Apparently at this low temperature, the solvation of ions is so strong that an additional energy is required to remove solvating molecules from their immediate environment. Thus, the ions are becoming relatively less reactive. Similar phenomena were also observed in the polymerization of CL.[162]

Thus, one can assume that solvent (S) and monomer (M) molecules (**Scheme 7**) are packed in a disorderly way in the available space around the macroion pair (–, +) being not oriented in any specific way. On the contrary, macroions are specifically solvated, and the thermodynamic potential of the monomer molecules solvating the active species differs from that of the monomer in solution.

The lower the temperature, the more perfect becomes the solvation shell around ions; removal of solvent and/or monomer molecules, a necessary step preceding propagation, becomes more and more difficult. Thus, the activity of ions decreases faster with lowering temperature than the reactivity of ion pairs, where the solvation is not important. Then, at a certain temperature, the reactivities become equal, which is followed by their inversion after a further temperature decrease. van Beylen and Szwarc discussed this system in their book,[179] and expressed some doubts on the above-presented picture. Particularly they say on p 112 (Szwarc and van Beylen[179]): "Since the solvated ions contribute to the electric conductance but not to the propagation and the fraction of the free ions was determined by conductance, the propagation rate constant, k_p, is too low". This statement points to another possible explanation than that given in the original papers.[161,162] It has been assumed there that all of the 'free' ions are solvated, and that there are no two distinct populations, solvated, of low reactivity if any and nonsolvated, of higher reactivity. In the next part of



Scheme 7

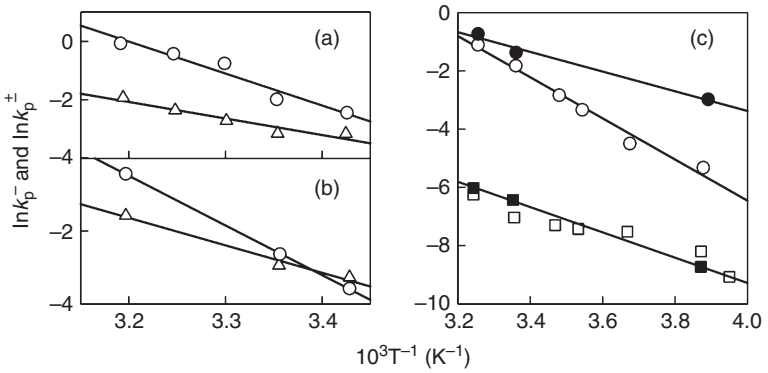


Figure 8 Semilogarithmic dependences of the rate constants of propagation on ions (k_p^-) and ion pairs ($k_p^{\pm}$) vs. reciprocal of the absolute temperature in the polymerization of PL. (a) k_p^- (○), $k_p^{\pm}$ (Δ), $[PL]_0 = 5 \times 10^{-1}\,mol\,l^{-1}$ in DMF; (b) k_p^- (○), $k_p^{\pm}$ (Δ), $[PL]_0 = 1\,mol\,l^{-1}$ in DMF; (c) k_p^- (●), $[PL]_0 = 1\,mol\,l^{-1}$; k_p^-(○), $[PL]_0 = 3\,mol\,l^{-1}$; and $k_p^{\pm}$ (■), $[PL]_0 = 1\,mol\,l^{-1}$; $k_p^{\pm}$ (□), $[PL]_0 = 3\,mol\,l^{-1}$ in CH_2Cl_2.[160,161]

the cited monograph, however, it is added (Szwarc and van Beylen[179]): "If, however, its (of the monomer) orientation in the solvation shell is improper for its insertion and its presence hinders the addition of another monomer, the reactivity of the solvated ion might indeed be very low". This is very close to the explanation given by the authors of the original work.

4.11.3.5 Propagation in Coordinated ROP of Cyclic Esters

The quantitative data on k_p in coordination polymerization are available almost exclusively for cyclic esters. A more detailed analysis of the reactivity–selectivity relationships has been presented in the already published papers.[50,53,54,173,174] Among the first works when coordination initiators were used, the works of Teyssie *et al.* on $Al(O^iPr)_3$[26,180] and the dinuclear μ-oxo-alkoxido compounds have to be mentioned.[25] The actual step of propagation on the >Al–O–… bond has been described in terms close to our present understanding of this reaction. The living character of polymerization has also been demonstrated. Some time later, Kricheldorf *et al.*[64] revealed a similar behavior for the other multivalent metal (Sn(IV), Ti, Zr) alkoxides.

4.11.3.5.1 Dialkylaluminum alkoxide active species

Depending on the structure of the resulting active centers (mostly on the number of growing polyester chains at one metal atom), propagation may also be accompanied by aggregation of the alkoxide species. In the trimeric $Al(O^iPr)_3$ aggregate/CL system, the macroalkoxide species assume exclusively the three-arm unimeric structure,[66] whereas for R_2AlOR'/CL, dimeric and trimeric aggregates prevail at higher concentrations of active centers.[55,56,58,181] Similar phenomena have been observed for ionic centers earlier.[48]

Aggregation may be diagnosed from the external kinetic order in active centers[55,56,58,60,181] and from the $^{27}A1$ NMR data.[185] In the majority of the reported cases, aggregates are not reactive. The corresponding kinetic scheme reads (Scheme 8):

The $(P_i^*)m$ species are dormant and 'retain their ability to grow'[182] and, therefore, polymerization involving these species is living, providing that the aggregation and deaggregation rates are high enough compared with that of propagation.

$$P_i^* + M \xrightarrow{k_p} P_{i+1}^*$$

$$m\,P_i^* \underset{}{\overset{K_a}{\rightleftharpoons}} (P_i^*)_m$$

$$(P_i^*)_m + M \xrightarrow{\text{no reaction}} \times$$

P_i^* - nonaggregated, unimeric active centers
$(P_i^*)_m$ - aggregated species
m - aggregation degree
M - monomer molecule
k_p - rate constant of propagation
K_a - equilibrium constant of aggregation

Scheme 8

Solution of the kinetic Scheme 8 gives two useful dependences, eqns [16] and [17],[55,56,58]

$$\ln r_p = \ln k_p (mK_a)^{-1/m} + \frac{1}{m}\ln[I]_0 \qquad [16]$$

$$r_p^{1-m} = -mK_a k_p^{1-m} + k_p[I]_0 r_p^{-m} \qquad [17]$$

where $r_p = d[M]/[M]dt = t^{-1}\ln([M]_0/[M])$, $[M]_0$ and $[M]$ denoting the starting and instantaneous concentrations of monomer, $[I]_0$ the starting concentration of initiator (being equal at the properly chosen (living) conditions to the total concentration of active species – growing and dormant), and t the polymerization time.

Fitting the experimental data (i.e., r_p and $[I]_0$) available from the kinetic measurements to eqn [16] allows determination of the degree of aggregation (m). However, this approach does not allow determination of K_a and k_p, but merely their product.

The way of determining both k_p and K_a is possible especially when the degree of aggregation can be estimated as described above.[55,56] Equation [17] gives a direct access to both k_p and K_a.

Figure 9 shows example of the r_p versus $[I]_0$ dependences (eqn [16]) obtained in polymerization of CL initiated with Et_2AlOEt and carried out in CH_3CN, THF, and C_6H_6 as solvents.[58] The resulting plots reveal that the order in initiator decreases in all solvents from 1 to 1/3 with increasing total concentration of active centers (equivalent to $[I]_0$ in the living polymerization conditions). This behavior clearly points to the aggregation of the active centers of unimeric aluminum alkoxide (…–C(=O)$CH_2CH_2CH_2CH_2CH_2OAlEt_2$) into the unreactive trimers.

Although it has been known that the degree of aggregation is equal to 3 for polymerization conducted with diethylaluminum alkoxide, but it was decided to test the equation for the known value equal to 3 and to see the results by introducing for the aggregation number an incorrect value equal to 2. The former value gives indeed the straight line as required whereas

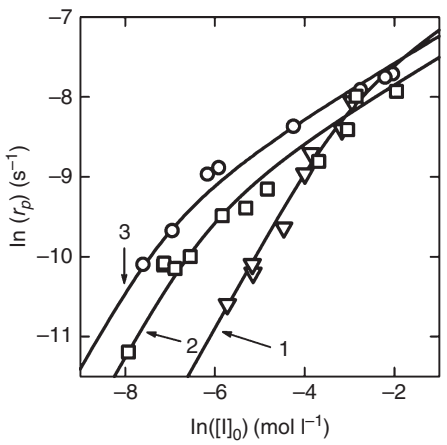

Figure 9 The external order in initiator dependences (eqn [16]) obtained in polymerization of ε-caprolactone (CL) initiated with Et_2AlOEt. Conditions: $[CL]_0 = 2$ mol l^{-1}; solvents – CH_3CN (1), THF (2), and C_6H_6 (3); 25 °C. Points, experimental; lines, computed numerically assuming kinetic Scheme 8.[58]

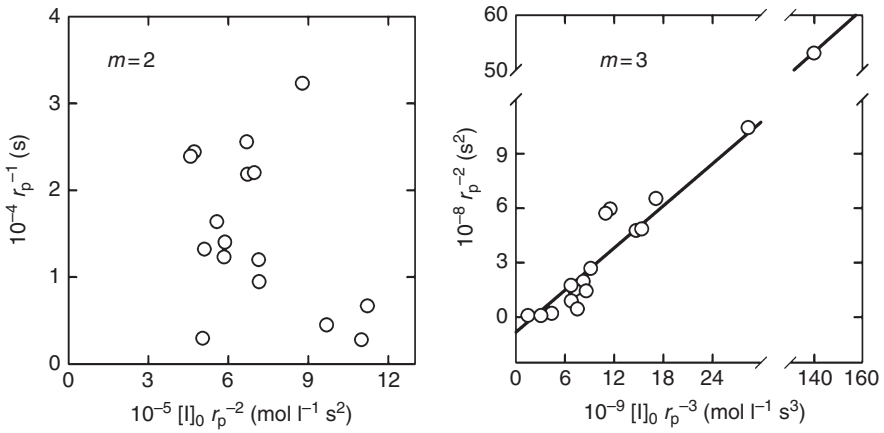

Figure 10 Polymerization of ε-caprolactone (CL) initiated with Et_2AlOEt (THF, 25 °C). Test of eqn [17] for the degree of aggregation *m*. Only for $m = 3$, a straight line was obtained as required. Primary kinetic data taken from Duda, A.; Penczek, S. *Macromol. Rapid Commun.* **1994**, *15*, 559.[56]

assuming the incorrect value gives highly dispersed points (Figure 10).

In Table 2, the values of k_p and K_a determined for the CL/Et_2AlOEt system in solvents of various polarities and solvating power are collected.

These data reveal that the higher the dielectric permittivity of solvent, the lower are both k_p and K_a. Namely, the increase in ε of 2.3–37 causes a decrease in k_p of 8.6×10^{-2}–7.5×10^{-3} l mol^{-1} s^{-1} (i.e., 11 times) and a simultaneous decrease in K_a of 2.4×10^5–7.7×10^1 mol^{-2} l^2. Therefore, for lower total concentrations of active centers, when the nonaggregated, actually growing species dominate (Figure 9), the polymerization rate order, measured for a given $[I]_0$, is as follows: r_p (C_6H_6) > r_p (THF) > r_p (CH_3CN). However, for higher $[I]_0$, when concentration of the unreactive aggregates increases and this increase is higher for the less polar solvents, the polymerization rates tend to converge and, at $[I]_0 = 0.1$ mol l^{-1}, r_p's measured in C_6H_6, THF, and CH_3CN become almost identical (Figure 9). CH_3CN is the most polar of the three used solvents and it apparently breaks down the aggregates. Thus, in the studied range of concentrations, the active species are mostly unimeric (i.e., reactive). In both THF and C_6H_6, the equilibrium between aggregated (unreactive, dormant) and not aggregated species persists although, at a sufficiently low concentration for a given system, the fraction of aggregated species may be negligibly small and no longer important. Both the alkoxide active center and the lactone molecule have dipolar structures. An analysis of the influence of the solvent dielectric permittivity, as a macroscopic parameter, on the k_p of the dipolar molecule–dipolar molecule reaction in terms of the electrostatic effects shows that an increase in ε should lead to a higher k_p. In the analyzed case, the reverse order is observed, namely, k_p in CH_3CN is lower than that in THF and benzene. Such behavior may be related to specific solvation of the growing dialkylaluminum alkoxide by dipolar solvents (THF, CH_3CN), strong enough already in the ground state, thus increasing $\Delta H_p^{\neq}$. Apparently, the specific solvation effects predominate over the electrostatic field effects and, as the net result, the k_p decreases with increasing polarity and solvating power of the solvent.

Table 2 Propagation rate constants (k_p) and equilibrium constants of aggregation (K_a) for polymerization[a] of ε-caprolactone initiated by diethylaluminum ethoxide[58]

Solvent	*Dielectric permittivity (ε)*	k_p *(mol^{-1} l s^{-1})*	K_a *(mol^{-2} l^2)*
CH_3CN	37	7.5×10^{-3}	7.7×10^1
THF	7.3	3.9×10^{-2}	5.5×10^4
C_6H_6	2.3	8.6×10^{-2}	2.4×10^5

[a] $[CL]_0 = 2$ mol l^{-1}, 25 °C.

In studies of CL polymerization, the kinetically determined proportion of the actual growing unimeric species P_i^* was compared with the proportion of P_i^* measured by ^{27}Al NMR spectrometry.[183] The corresponding spectrum is in Figure 11(a). It shows two peaks – for tetracoordinate (Al(4) in unimeric P_i^* species) and for pentacoordinate (Al(5) in $(P_i^*)_3$ aggregated species) aluminum atoms.[184,185] The interconverting species are depicted in Scheme 9. The concentration of the Al(4) propagating species, estimated from the spectrum in Figure 11(a), is set equal to ≈10% of the total, thus being comparable with that determined from the kinetics (Figure 11(b)).

The exchange rates of aggregated (dormant) and unimeric (propagating) species in the CL/R_2AlOR system are high enough to govern an even growth of all macromolecules, as can be judged from M_w/M_n values determined for the resulting poly(CL) and ranging from 1.03 to 1.13.[51]

4.11.3.5.2 Aluminum trialkoxide active species

Propagation on aluminum trialkoxide active species was a matter of controversy concerning the question how many chains grow from one Al atom in that species. Eventually, it has been revealed that, independently of the monomer used, three polyester chains grow from one Al atom (see Scheme 4 for CL polymerization).[66] It was shown[65,66] that an early assumption of Kricheldorf[64] was correct in that all three alkoxide groups in $Al(O^iPr)_3$, if properly used, are active in building the chains.

However, the structure of the living PCL given in Scheme 5 is an oversimplification because the ^{27}Al NMR spectra of the growing species show that an additional coordination takes place.[63,66] In Figure 12, an ^{27}Al NMR spectrum of $Al(O^iPr)_3$

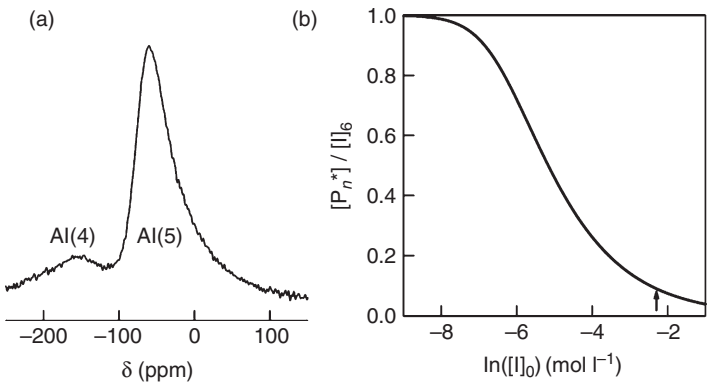

Figure 11 (a) ^{27}Al NMR spectrum of polymerizing mixture: CL/Et_2AlOEt/THF + 10 vol.% of C_6D_6. Conditions: $[CL]_0 = 2$ mol l^{-1}, $[Et_2AlOEt]_0 = 0.1$ mol l^{-1}, 25 °C. (b) Dependence of the mole fraction of the unimeric, nonaggregated active centers ($[P_n^*]/[I]_0$) on their total concentration ($[I]_0$) as determined from the kinetic measurements for the CL/Et_2AlOEt/THF system. Conditions: $[CL]_0 = 2$ mol l^{-1}, THF, 25 °C. The arrow indicates the $[P_n^*]/[I]_0$ obtained for $[I]_0 = 0.1$ mol l^{-1}.[183]

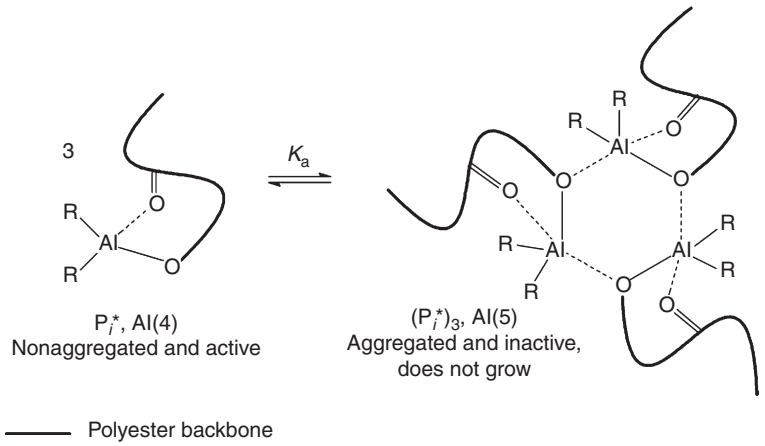

Scheme 9

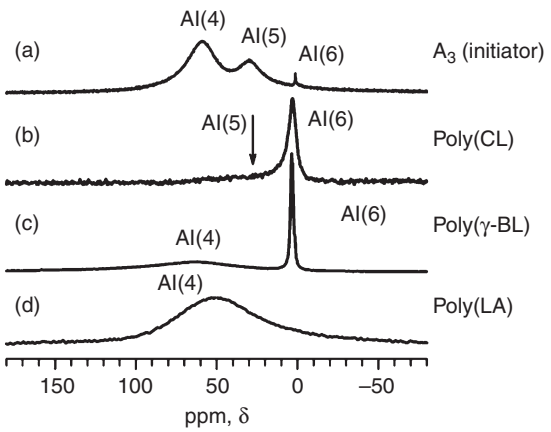

Figure 12 ^{27}Al NMR (75 MHz ^{27}Al, 70 °C, benzene-d_6) spectra of the aluminum triisopropoxide trimer (A_3) and the living polyesters prepared with A_3. (a) A_3; (b) living poly(ε-caprolactone); (c) living poly(γ-butyrolactone); and (d) living poly(L-lactide). Polymerization conditions (concentrations in mol l^{-1}): $3[A_3]_0 = 0.1$, $[CL]_0 = 2.0$, $[\gamma\text{-BL}]_0 = 3.8$, $[LA]_0 = 1.0$, 80 °C, benzene-d_6.[186]

trimer (A_3) is compared with those of the living poly(ε-caprolactone) (PCL), living poly(γ-butyrolactone), and living poly(L-lactide) (PLA); all three polyesters were prepared with A_3 as an initiator. In the initiator itself the tetra- and pentacoordinated Al atoms are present (see the formula in Scheme 4). The spectrum of A_3 exhibits signals at $\delta \approx 60$ and 30 ppm in the expected proportion (2:1), marked in Figure 12(**a**) as Al(4) and Al(5). A small signal in the vicinity of $\delta = 0$ ppm is due to the presence of ≈1.5 mol.% admixture of the tetramer (A_4). In the PCL spectrum, a strong peak at $\delta \approx 4$ ppm due to the hexacoordinated Al atoms (Al(6)) prevails but a small shoulder in the field characteristic of Al(5) is also apparent (Figure 12(**b**)). The spectrum of Pγ-BL shows, apart from the sharp peak of Al(6), a broad signal coming from Al(4) (Figure 12(**c**)), whereas in PLA the Al(4) atoms are present (Figure 12(**d**)).

The observed additional coordination of Al atoms in growing species could result from the intramolecular complexation by the acyl oxygen atoms from the polyester repeating units, as it was originally proposed by the Liege group.[63] Some of the structures are illustrated schematically below (Al(4)1, Al(4)2, Al(5), and Al(6)).

Polymerization of CL exhibited approximately first-order propagation both in monomer (internally) and in active species. The apparent k_p value (encompassing both five- and six-coordinate species) is equal to $0.62\,l\,mol^{-1}\,s^{-1}$ (25 °C, THF).[66] Most probably, propagation proceeds on the more labile five-coordinate species in intramolecular dynamic equilibrium with the hexacoordinate one. Thus, the absolute k_p could be considerably higher.

In PLA, according to the ^{27}Al NMR spectrum (Figure 12(**d**)), hexacoordinated species are not present. This may result from the steric hindrance caused by methyl groups. Moreover, the fractional kinetic orders of active species, observed by Kowalski *et al.*[60] in the polymerization of LA initiated with A_3, suggest that the aggregation–deaggregation equilibrium 2 Al(4)1 ⇆ Al(4)2 (see structures **2**) takes place and the propagation proceeds on the nonaggregated species Al(4)1. Therefore, kinetics of LA polymerization was analyzed in terms of Scheme 8. $K_a = 92\,mol^{-1}\,l$ and $k_p = 8.2 \times 10^{-3}\,l\,mol^{-1}\,s^{-1}$ (80 °C, THF) were determined in this way.

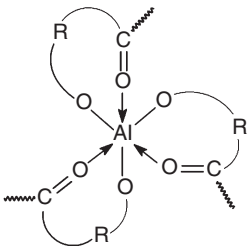
Al(5) **2c**



Al(6) **2d**

4.11.4 Livingness of Polymerization in Processes Initiated with Multivalent Metal Alkoxides

Despite the relatively complex kinetics, polymerizations of CL, LA, and other cyclic esters initiated with a number of metal alkoxide initiators fulfill the criteria required for the living process.[114] Figures 13 and 14 show, on the example of CL and LA polymerizations initiated with $R_nAl(OR')_{3-n}$, $R_nSn(OR')_{3-n}$, $Fe(OR)_3$, and $Ti(OR)_4$ alkoxides, the dependencies of ln $\{([M]_0 - [M]_{eq})/([M] - [M]_{eq})\}$ on time and of M_n on the monomer conversion, respectively.[148] Both dependences are linear. Thus, Figure 13 indicates that the polymerization is devoid of termination whereas Figure 14 points to the absence of chain transfer. The lines in Figure 14 correspond to the M_n – conversion dependences calculated assuming that each alkoxide group starts growth of one macromolecule whereas points are experimental.

Good agreement between the calculated and experimental plots suggests that the functionality of multivalent metal alkoxide initiators is equal to the number of alkoxide groups. Some of these initiators, such as $Sn(OBu)_2$ allowed preparation of PLA in the controlled way,[61] with M_n as high as $\approx 10^6$.

It should be added that in the vast majority of the recently reported kinetic studies of the ROP of cyclic esters, the first-order kinetic internal order in the monomer was observed, that is, the experimental plots $\ln\{([M]_0 - [M]_{eq})/([M]_0 - [M])\}$ versus time were linear. Atypically, in LA polymerization initiated with Zn alkoxide bearing 2-[(2-methoxyphenyl) amino]-4-[(2-methoxyphenyl)imino]pent-2-ene bidendate ligand, the second-order kinetics was observed for LA (based on the linearity of the $(1/[LA]) - (1/[LA]_0)$ vs. time plot). A mechanistic explanation of this result, however, has not been given.[187]

In a discussion of the coordination polymerization of cyclic esters, the rare earth metal (e.g., La, Sc, Sm, Y, Yb) alkoxides must also be mentioned. These initiators applied first at the DuPont[73,74] and then in other laboratories[75–77] provided much higher polymerization rates when compared with Sn or Al alkoxides. For example, in the polymerizing system LA/Y $(OAr)_3/^i$PrOH (where Ar = 2,6-di-*tert*-butylphenyl), the value of

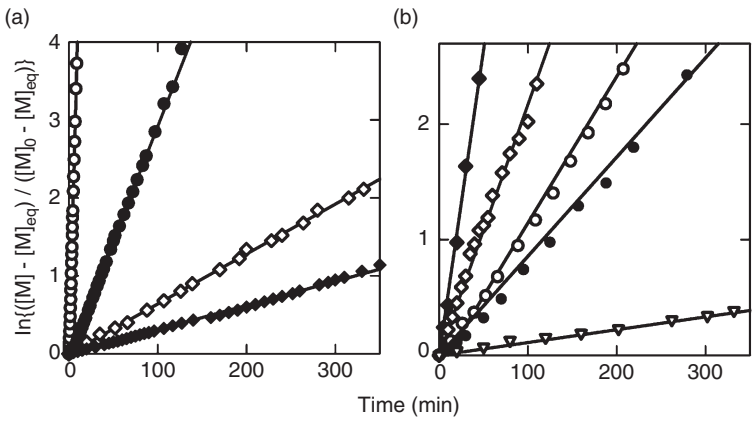


Figure 13 Kinetics of ε-caprolactone (a) and L,L-lactide (b) polymerization initiated with metal alkoxides ($R_nMt(OR')_{x-n}$). Conditions (concentrations in mol l^{-1}): (a, ○) $3[A_3]_0 = 3 \times 10^{-3}$, 25 °C; (a, ◊) $[Sn(OBu)_2]_0 = 3.3 \times 10^{-3}$, 80 °C; (a, ♦) $[Et_2AlOEt]_0 = 8 \times 10^{-3}$, 25 °C; (a, ♦) $[Bu_3SnOEt]_0 = 9.9 \times 10^{-2}$, 80 °C; (b, ◊) $[Ti(O^iPr)_4]_0 = 10^{-2}$, 80 °C; (b, ○) $[Fe(OEt)_3]_0 = 1.4 \times 10^{-3}$, 80 °C; (b, •) $3[A_3]_0 = 2 \times 10^{-2}$, 80 °C; (b, ∇) $[Sn(OBu)_2]_0 = 3 \times 10^{-3}$, 50 °C; (b, ∇) $[Bu_3SnOEt]_0 = 5 \times 10^{-2}$, 80 °C; $[CL]_0 = 2$, $[LA]_0 = 1.0$; THF.[148]

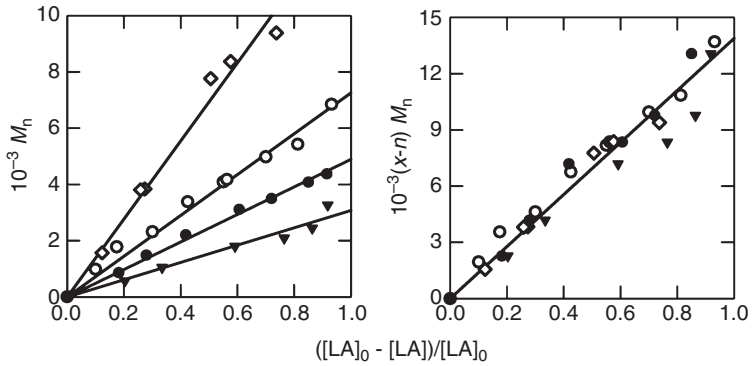

Figure 14 Dependence of M_n of poly(L-lactide) on the monomer conversion. Polymerization of L,L-lactide initiated with metal alkoxides ($R_nMt(OR')_{x-n}$): Bu_3SnOEt (◊), $Sn(OBu)_2$ (○), $Al(O^iPr)_3$ trimer (A_3) (•), and $Ti(O^iPr)_4$ (▼). Conditions: $[LA]_0 = 1.0$ mol l^{-1}, $[R_nMt(OR')_{x-n}]_0 = 10^{-2}$ mol l^{-1}, THF, 80 °C (for $Sn(OBu)_2$ at 25 °C).[148]

$k_p^{app} \geq 10$ l mol^{-1} s^{-1} (CH_2Cl_2, 22 °C) can be estimated.[75] This means that the polymerization proceeds with the rate more typical for the ionic polymerization of cyclic esters.

4.11.5 Extent of Molar Mass Control in Processes Initiated with Multivalent Metal Alkoxides

A number of well-defined macromolecules with well-controlled size and end groups were prepared with Al and Sn (II) initiators. As it is seen in **Figure 15(a)**, M_n's of PCL could be controlled up to $\leq 5 \times 10^5$ with dialkylaluminum alkoxide initiators.[188]

After understanding the difference between $Al(O^iPr)_3$ trimer and tetramer (cf. **Scheme 4**), the isolated trimer has become the most versatile initiator for the controlled polymerization of cyclic esters. It provides fast and quantitative initiation, moderately fast propagation ($k_p = 0.6$ l mol^{-1} s^{-1} compared with 0.039 l mol^{-1} s^{-1} for Et_2AlOEt (25 °C, THF)),[56,66] and relatively good selectivity (with regard to transesterification, see Section 4.11.7).[54] Thus, $Al(O^iPr)_3$ in the form of a trimer seems to be ideally suited for the synthesis of aliphatic polyesters. Apart from good selectivity, it provides a direct control of polymerization degree of the resulting polyester by simply adjusting the $([LA]_0 - [LA]_{eq})/3[Al(O^iPr)_3]_0$ ratio. On the other hand, there is an upper limit of $M_n \approx 3 \times 10^5$ of PLA and PCL, which can be obtained with $Al(O^iPr)_3$,[66,189] whereas with $Sn(OBu)_2$, $M_n \approx 10^6$ has been reached (see **Figure 15(b)**).[61] The reasons for such a limitation are not yet well understood, but they could be related to the concentration of impurities and/or the intramolecular complexation of Al atoms in the active centers by the acyl oxygen atoms from a growing polyester chain.[60,66]

$Sn(Oct)_2$ is probably the most often used catalyst in the polymerization of cyclic esters. This is mostly due to its commercial availability, physical state (liquid), and higher chemical stability in comparison with alkoxides. P_n of the polyester formed in the cyclic ester (M)/$Sn(Oct)_2$/initiator (ROH or RNH_2) systems is determined by the $([M]_0 - [M])/[initiator]_0$ ratio due to the fast initiation and exchange reactions – chain transfer to water, alcohol, or amine and then to the resulting macroalcohol. Using the standard high-vacuum technique and $Sn(Oct)_2$ of 99.0 mol.% purity, it was possible

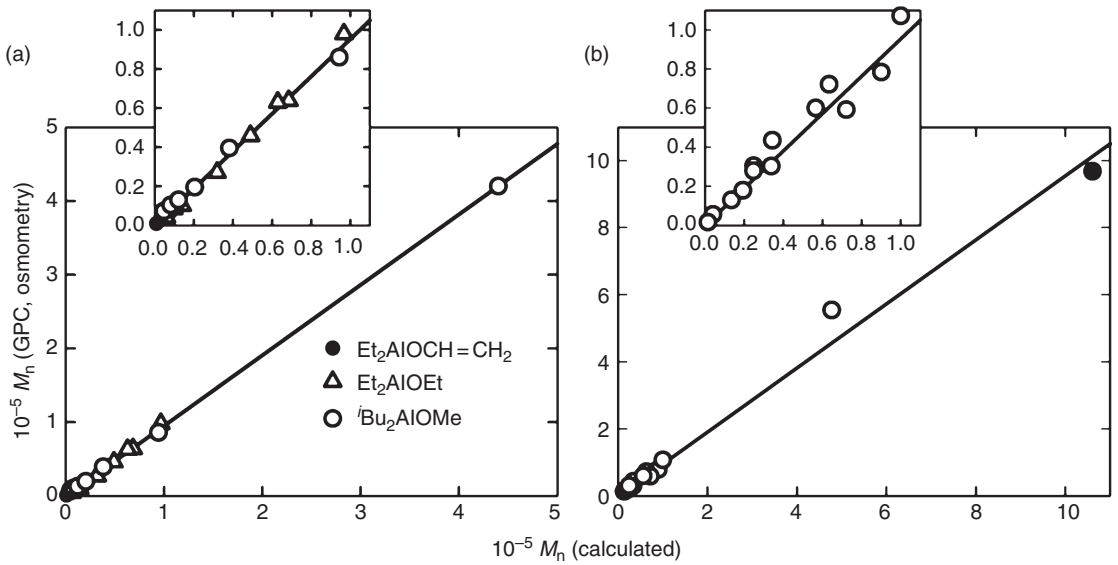

Figure 15 Measured vs. calculated (predicted) molar masses of polyesters obtained by (a) polymerization of ε-caprolactone initiated with R'_2AlOR (THF, 25 °C) and (b) polymerization of (L,L)-lactide initiated with $Sn(OBu)_2$ (○, THF, 80 °C) and (•, bulk, 120 °C).[61,188]

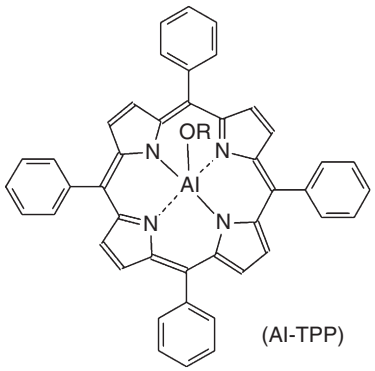
to obtain both PCL and PLA with M_n up to $\approx 9 \times 10^5$. Thus, $M_n \approx 10^6$ seems to be a limit of M_n for the aliphatic polyesters prepared by ROP using the usual techniques, and this limit is, most probably, related to the concentration of impurities. A similar threshold value ($M_v \approx 9 \times 10^5$) was reported by Pennings and co-workers[87] some time before. It is not known whether there is a true termination reaction in these polymerizations.

4.11.6 Controlled Polymerization of Cyclic Esters Initiated with Single-Site Metal Alkoxides

In the group of Al-based initiators, the successful application of aluminum porphyrins in polymerization of cyclic esters should be mentioned. The structure of a typical initiator Al tetraphenylporphyrin (Al-TPP) is shown in structure **3**.



(Al-TPP)

3

The reason for quoting this structure is not only the fact that this class of initiators, developed by Inoue and Aida,[190,191] lead to living processes, but also because more than 20 years later the structurally related 'single-site' initiators became important in the stereocontrolled polymerization of LAs and β-substituted β-lactones (e.g., β-BL). The discovery of the Japanese researchers seems almost forgotten.

Application of single-site catalysts/initiators may also be of interest since it might remove the mechanistic complexity resulting from the aggregation–deaggregation exchange reactions, in which multiple-site alkoxides are usually engaged (see, e.g., References 78, 192–194, and the papers cited therein). According to the definition given by Chamberlain *et al.*:[193] "Single-site catalysts are those polymerization catalysts where enchainment of monomer occurs at a metal center (Mt, the active site) which is bound by an organic ligand (L). This ancillary ligand remains bound throughout the catalytic reaction, modifying the reactivity of the metal center. Typical single-site catalysts for lactone polymerization are of the form L_nMtOR, where the alkoxide group (OR) is capable of propagation".

This concept and definition comes from the studies of olefins polymerization, where the first generations of catalysts were heterogeneous and provided several catalytic sites on the surface of catalysts. Using the same expression in the polymerization of cyclic esters is somehow ambiguous. Indeed, studied in Lodz, the dialkylaluminum alkoxides (R'_2AlOR)[51,55,56,58] belong, in principle, to this category since, at the properly chosen conditions, R′ ligands remain unreactive and the propagation proceeds on the alkoxide group. With R′ being the lower alkyl group, aggregation of active centers takes place. However, deaggregation could be observed, when simple ligands, such as *N,N,N′*-trimethylethylenediamine, were attached to the otherwise aggregated species.[55] Besides, application of the bulky ancillary ligands L in the employed catalysts hampers chain transfer to macromolecules slowing down both intra- and intermolecular transesterification,[53,190,191] which manifests itself in the decreasing M_w/M_n values for the prepared polyesters.

The new generation of the single-site catalysts explored until now in CL polymerization do not show any particular advantage over the multiple-site ones, like $Al(O^iPr)_3$, with respect to the molar mass control as well as molar mass distribution (MMD) or the end group control in the resulting PCL.[187,195–198] Results reported for polymerization of LAs[78,187,193,199] and β-substituted β-lactones[200] initiated with Zn or Mg aminoalkoxides or β-diiminates; point to a considerable rate increase of this process compared with the polymerizations initiated with $Al(O^iPr)_3$.[60,201] For example, for L,L-LA, $k_p = 2.2\,l\,mol^{-1}\,s^{-1}$ at 25 °C ($t_{1/2} = 2.5$ min at $[I]_0 = 10^{-2}\,mol\,l^{-1}$) has been determined.[78]

With regard to β-BL polymerization, two interesting facts were noted: (1) in spite of the single-site structure of the resulting active species, which bear a bulky bidentate ligand, dimer–monomer equilibria were observed and (2) in contrast to the ionic process, exclusive nucleophilic attack on the acyl carbon atom, resulting in the retention of configuration, was observed (**Scheme 10**).[200]

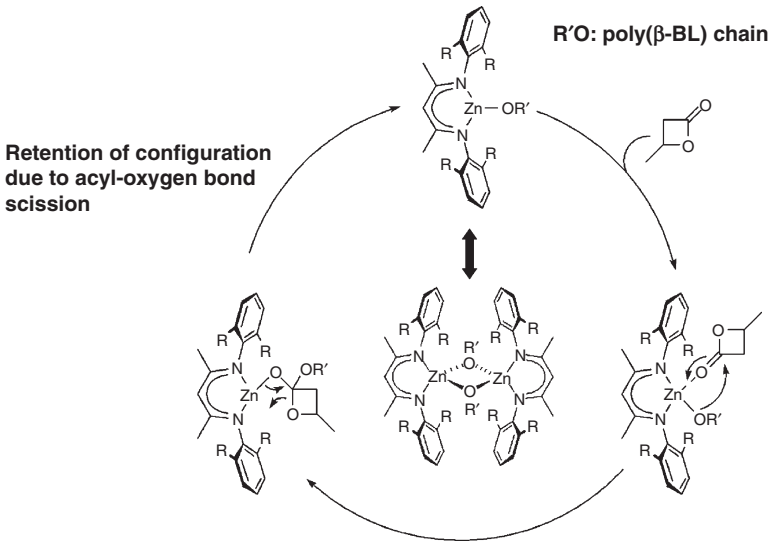
Application of discrete (single-site) catalysts based on the rare earth metals, magnesium, calcium, or zinc, leading to fast propagation, creates an opportunity of synthesis of aliphatic polyesters with a minute content of the metal-based catalyst and alcohol (ROH) as coinitiator/transfer agent controlling the molar mass and structure of end groups.[202,203]

4.11.7 Transfer Processes in the Anionic and Coordination Polymerizations of Cyclic Esters

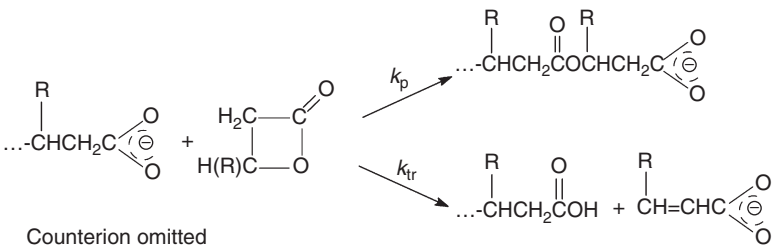
Transfer processes in polymerization can be divided into at least two categories: irreversible and reversible ones. The irreversible transfer leads inevitably to a remarkable departure from livingness. A typical example is polymerization of β-lactones (**Scheme 11**).

Anionic polymerization of PL with alkali metal counterions as growing species has, perhaps, a measurable transfer to monomer (**Scheme 11**, R = H) as it could be estimated from M_n of the resulting PPL being not higher than $10^5\,g\,mol^{-1}$ even at room temperature.[161] Thus, the question arises whether this system 'fully' conforms to the living polymerization definition (*vide infra*).

β-BL (**Scheme 11**, R = H) is a much better proton donor and the departure from livingness for this monomer is much more pronounced.[45,46] Application of Bu_4N^+ as counterion resulted in enhancement of the k_p/k_{tr} ratio and allowed preparation of poly(β-BL) (Pβ-BL) with $M_n \leq 2 \times 10^5$ but its molar masses could hardly be controlled.[80] Kinetic studies, supported by



Scheme 10



Scheme 11

M_n measurements, allowed to determine the selectivity parameter $k_p/k_{tr} = 4 \times 10^4$ for PL (K^+/DBC, CH_2Cl_2, 20 °C), and $k_p/k_{tr} = 2.0 \times 10^2$ for BL (K^+/DBC, THF, 20 °C).[46] The latter ratio is equal to the maximal number-average degree of β-BL polymerization that can be achieved at these conditions. Both electronic and steric effects of the methyl group are responsible for a lower value of the k_p/k_{tr} ratio for β-BL, when compared with PL. This is at least partly due to differences in the rate constants of propagation (10^{-6} and 4×10^{-3} l mol^{-1} s^{-1} at 20 °C, respectively).

On the other hand, in the purely anionic polymerization of five- or higher-membered cyclic esters, the carbonyl carbon of the monomer is attacked with subsequent acyl–oxygen bond scission and reformation of the alkoxide anion. In the coordination polymerization, this is also the carbonyl carbon that is now first coordinated with alkoxide species and then the acyl–oxygen bond is broken with reforming of the covalent alkoxide chain end. In the already formed macromolecular chains, the same ester bonds are present as those being the site of the nucleophilic attack in the monomer molecules. These processes are illustrated in Scheme 12, where the active centers are shown as …–OMt, for both anionic and covalent centers.

Investigations in this area started from the early work of the Nagoya group[47,204] and have been further quantitatively developed in Lodz.[48,50,53,54,174] Derivation of the corresponding kinetic equations giving access to the rate constant of transfer is based on the kinetic Scheme 13.

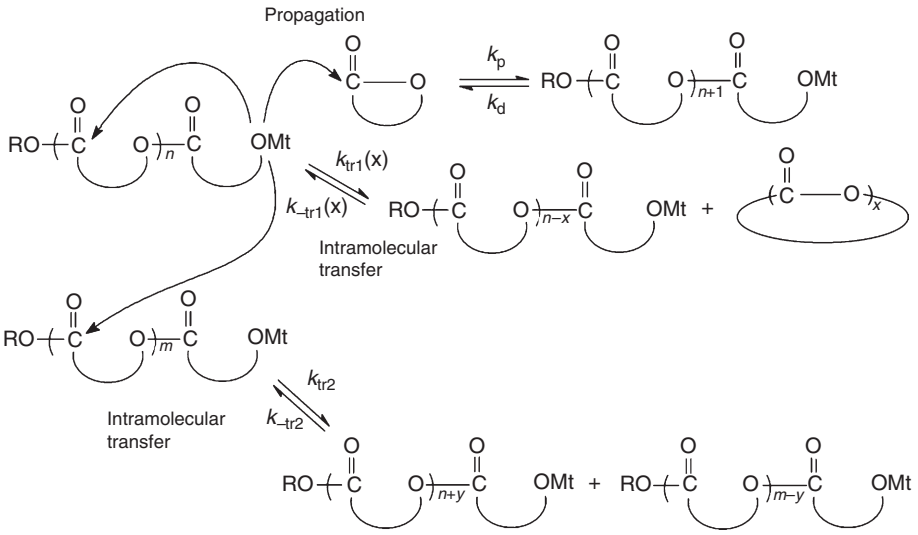
The intramolecular process is relatively easy to study quantitatively. This is because the products of the chain transfer (by unimolecular transesterification) are cyclic compounds and their concentration can be measured, for example, by standard chromatographic methods. Thus, propagation and formation of cyclic oligomers are competitive reactions taking place simultaneously.

The solution of the kinetic Scheme 13 (taking into account propagation and intramolecular transfer only) for some monomers (e.g., CL) for which propagation is practically irreversible gives eqn [18].[50]

$$\beta = \frac{k_p}{k_{tr1}(x)} = \frac{\ln([M(1)]_0/[M(1)])}{[M(x)]_{eq} \cdot \ln\{[M(x)]_{eq}/([M(x)]_{eq} - [M(x)])\}} \quad [18]$$

where $\beta = k_p/k_{tr1}(x)$ is the selectivity parameter showing how many elementary acts of propagation (at $[M(1)] = 1$ mol l^{-1}) are accompanied by one macrocyclization (M(1) stands for monomer and M(x) for cyclic oligomer of polymerization degree x).

Thus, the value of β is a direct measure of selectivity of a given active species. In Reference 50, GPC traces recorded for polymerizing mixtures CH_3O^-Na/CL and $(C_2H_5)_2AlOC_2H_5$/CL (THF, 20 °C) are compared. With alkoxide anions, before the monomer is consumed, there is already a large proportion of cyclics, whereas when the aluminum-based covalent active



$k_{tr1}(x)$ - rate constant of intramolecular transfer
$k_{-tr1}(x)$ - rate constant of macrocycle propagation
k_{tr2}, k_{-tr2} - rate constants of intermolecular transfer

Scheme 12

species are used there are no detectable cyclics when full monomer conversion is reached. Naturally, at equilibrium, the composition of both systems should be the same, but it takes a long time in the covalent process to attain the equilibrium.

Using the described kinetic approach, the ratios k_p/k_{tr1} were determined for a few initiating systems. This ratio can differ by a factor as large as 10^3. The corresponding data are collected in Table 3. There are two phenomena involved, namely, reactivity and steric hindrance. The higher the reactivity of a species of comparable steric hindrance around growing species, such as Sm trialkoxide and Al trialkoxide, the lower the selectivity. This is often the case for other chemical reactions. If, on the other hand, the reactivity in propagation is the same but steric hindrance differs, then the more sterically hindered species is more selective. This is the case for dialkylaluminum alkoxides. The highest selectivity, however, was observed for a low-reactive Al alkoxide that bears a bulky bidentate (+)-(*S*)-2,2′-[1,1′-binaphthalene-2,2′-diylbis(nitrilomethylidyne)]

[b]Polymerization conditions: 80 °C, THF, SBO_2: (+)-(*S*)-2,2′-[1,1′-naphthalene-2,2′-diylbis(nitrilomethylidyne)]diphenolate ligand, SB = Schiff base (Duda, A.; Kowalski, A. unpublished results).

diphenolate ligand. The plausible explanation is that more bulky substituents do not affect propagation whereas in macrocyclization, the chains have more problems in achieving the conformation needed for the reaction to occur.

In the intermolecular transfer (by bimolecular transesterification), one active polyester macromolecule reacts with another, also active, and possibly two active ones are reproduced.[173,174,205] Thus, in the intermolecular transfer, the only change that is observed is broadening of the MMD. At a certain conversion, bimodal MMD appears. This is a novel and general phenomenon that was not considered earlier in macromolecular chemistry. It is generally accepted that in polymerization bimodality appears exclusively when two species are propagating with different rate constants and these species do not exchange fast enough.

The rate constant of intermolecular transfer (k_{tr2}) or the k_p/k_{tr2} ratio can be determined on the basis of the change of a function of monomer conversion $\{([M]_0 - [M])/[M]_0\}$.

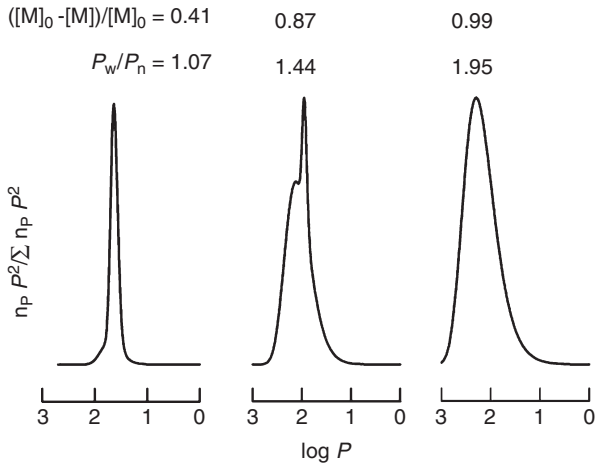

Figure 16 Computed (Monte Carlo method) chain length distributions (P_w/P_n) as a function of the monomer conversion ((($[M]_0 - [M]$)/$[M]_0$). Conditions: $[M]_0/[I]_0 = 10^2$, $k_p >> k_d$.[173]

Figure 16 shows a simulation of the MMD for high k_p/k_{tr2}, that is, for a relatively slow transfer, numerical simulations were based on the kinetic Scheme 13, omitting the intramolecular transfer. Thus, chains are initiated at once and they grow giving in the beginning a distribution close to the Poissonian.

They undergo transfer all the time, but approximately only once for 100 steps of propagation. A new population of macromolecules that participated in transfer reacts slowly with the populations with Poisson distribution. The M_n of the populations participating in the segmental exchange (i.e., intermolecular transfer) is the same, but M_w differs and this appears on the size-exclusion chromatography (SEC) traces, resulting in bimodal and broader distribution. Finally at equilibrium, the M_w/M_n value equal to 2, typical for the most probable distribution, independently of the initiator used, is reached.

Thus, numerical simulation of $M_w/M_n = f((([M]_0 - [M])/[M]_0)$ plots for various assumed k_p/k_{tr2} was applied up to the best fit with the experimental dependence. A typical result is shown in Figure 17 for various covalent alkoxides. The lines were

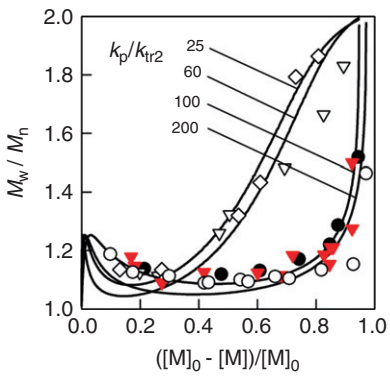

Figure 17 Dependences of M_w/M_n on $([M]_0 - M])/[M]_0$ determined for L,L-lactide polymerization initiated with: (◊) Bu_3SnOEt, (▽) $Fe(OEt)_3$, (▼) $Al(O^iPr)_3$, (●) $Sn(Oct)_2$/BuOH, (○) $Sn(OBu)_2$, THF solvent, 80 °C (for $Sn(OBu)_2$, 20 °C). Points, experimental; lines, computed assuming $k_p/k_{tr2} = 200$, 100, 60, and 25, respectively.[206]

generated for a given ratio of k_p/k_{tr2} and the points are experimental. On this basis, it was possible to determine k_p/k_{tr2} for a given system.[173,174,205]

As it follows from Figure 17, the M_w/M_n ratio in some systems is close to the value expected for a Poisson distribution even for conversions as high as over 80%. Divalent tin has particularly good selectivity. Recently, even better selectivity was observed for >AlO^iPr with bidendate, bulky phenolate-type ligands, similarly as used for the studies of intramolecular transfer (Table 3). It is also worth noting that comparing the extent of transesterification for a different initiator/monomer system on the basis of the M_w/M_n values measured for the resultant polyester is reliable only for the same monomer conversion and $[M]_0/[I]_0$ ratio.

Figure 18 compares, thus, the obtained $\gamma = k_p/k_{tr2}$ with propagation rate constants (k_p) and with the atomic number of metal atoms involved in active species. It is remarkable that for a series of similar alkoxides as growing centers, this dependence conforms to the rules of the reactivity–selectivity principle. Moreover, the larger the size of the metal atom in the growing species, the higher the rate constant of propagation, as it could be expected in the case of lower alkoxide bond energies for larger atomic radii.

Although we are looking for the ways of getting the best possible selectivities, in practice, it is not much important for a homopolymer to have a narrow distribution. Slowing down chain transfer is, however, important for the well-controlled block copolymers and other controlled architectures. Indeed, due to high selectivity of alkoxido {(+)-(*S*)-2,2′-[1,1′-binaphthalene-2,2′-diylbis(nitrilomethylidyne)]diphenolato}aluminum (for the structure, see Figure 19), well-defined LA/CL block copolymers could be prepared by initiating CL polymerization with the living PLA block, which was earlier impossible even with an also highly selective Al trialkoxide.[207]

Thus, in the vast majority of papers reporting on attempts to synthesize the CL/LA block copolymer (PCL-*b*-PLA or PLA-*b*-PCL), the importance of the order in which both the comonomers are polymerized was stressed. When the CL monomer was polymerized first, the living PCL* macromolecules were then able to initiate the PLA chains growth, giving eventually the PCL-*b*-PLA copolymers. On the other hand, numerous attempts of initiating CL polymerization with living PLA* were unsuccessful.[208]

Such a situation had important practical implications since the well-defined multiblock [PLA-*b*-PCL]$_n$ copolymers could be only prepared by coupling of the reactive α,ω-ditelechelic oligomers.

The impossibility of preparing the PLA-*b*-PCL copolymers in the previous works, when starting with polymerization of CL from the living PLA*, was, most probably, related to the rates of the elementary reactions as shown in Scheme 14.

Thus, whenever the …–cl* active species are formed, their attack on the PLA chain is faster than CL propagation ($k_{tr2} > k_{clCL}$). Therefore, in order to prepare the block copolymer, the ratios of the rate constants have to be reversed, that is, k_{clCL} has to be larger than k_{tr2}. Eventually, in agreement with GPC, ^{1}H and ^{13}C NMR evidence, this was possible due to application of a highly selective Al alkoxide initiator supported

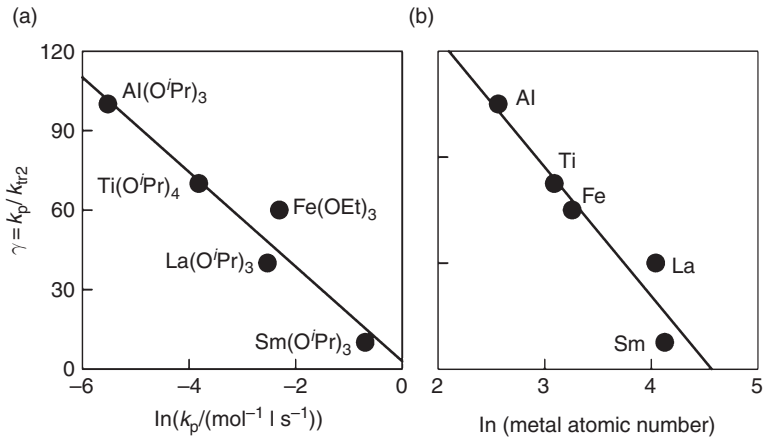

Figure 18 Dependences of $\gamma = k_p/k_{tr2}$ on ln k_p (a) and on the atomic number of the metal atoms involved in active species (b), determined in polymerizations of L,L-lactide initiated by the covalent metal alkoxides (THF, 80 °C).[54,174]

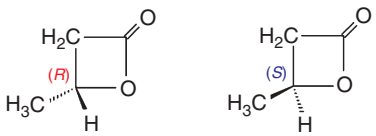
by a bulky ligand (see Figure 19). In addition, CL macrocyclization was completely eliminated.

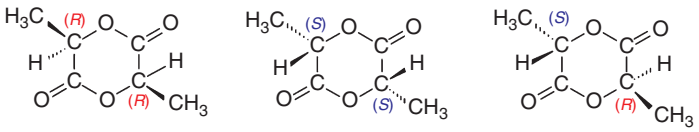
In spite of the fact that polymerization of cyclic esters with anionic or covalent active centers proceeds with inevitable chain transfer (intra- and/or intermolecular) to macromolecules, these processes should not be considered as departing from the living conditions. The proper choice of initiator coupled with kinetic control can exclusively provide macromolecules retaining the ability to grow and eliminate formation of macrocyclics at the kinetically controlled conditions.

4.11.8 Stereochemically Asymmetric ROP of Cyclic Esters

Stereochemically asymmetric ROP polymerizations of cyclic esters (hereafter 'stereocontrolled' processes) involve chiral monomers. There are two major cyclic esters that bear centers of chirality: β-BL and LAs (see structures 4). In this section, a notion of the absolute configuration will be used; thus, the relative configurations D and L correspond to the absolute configurations *R* and *S*, respectively.



(*R*)-β-BL **4a** (*S*)-β-BL **4b**



(*R,R*)-LA **4c** (*S,S*)-LA **4d** (*R,S*)-LA **4d**

In agreement with IUPAC recommendations,[209] two types of processes, involving chiral monomers can be distinguished: (1) 'asymmetric enantiomer-differentiating polymerization', an asymmetric polymerization in which, starting from a mixture of enantiomeric monomer molecules, only one enantiomer is polymerized; and (2) a polymerization in which, starting from the racemate of a chiral monomer, two types of polymer molecules, each containing monomer units derived from one of the enantiomers, form in equal amounts is termed 'racemate-forming enantiomer-differentiating polymerization' (see also Figure 20).

In the literature concerning the ROP of heterocyclic monomers, the 'asymmetric, enantiomer-differentiating polymerization' and 'racemate-forming enantiomer-differentiating polymerization'[209] are informally named as 'stereoelective' and 'stereoselective' processes. Stereoelective means that from a racemic monomer mixture only one enantiomer is 'elected' to be enchained into the polymer chain; stereoselective process initiated with racemic (site control) or achiral (chain-end control) initiator gives different populations of macromolecules (poly(*R*) and poly(*S*)) growing separately. In these processes, either the site-control mechanism (SCM), for chiral initiators, or chain-end control mechanism (CEM), for achiral initiators, can operate. Thus, in the latter case, the first addition (initiation) of (*R*)- or (*S*)-monomer decides on a given chain configuration.

β-BL monomers are, in principle, available in the form of pure enantiomers (*R*)-β-BL and (*S*)-β-BL (only in the laboratory-scale quantities) or as the equimolar (*R*)-β-BL/(*S*)-β-BL racemic mixture (*rac*-β-BL). Since LA monomers

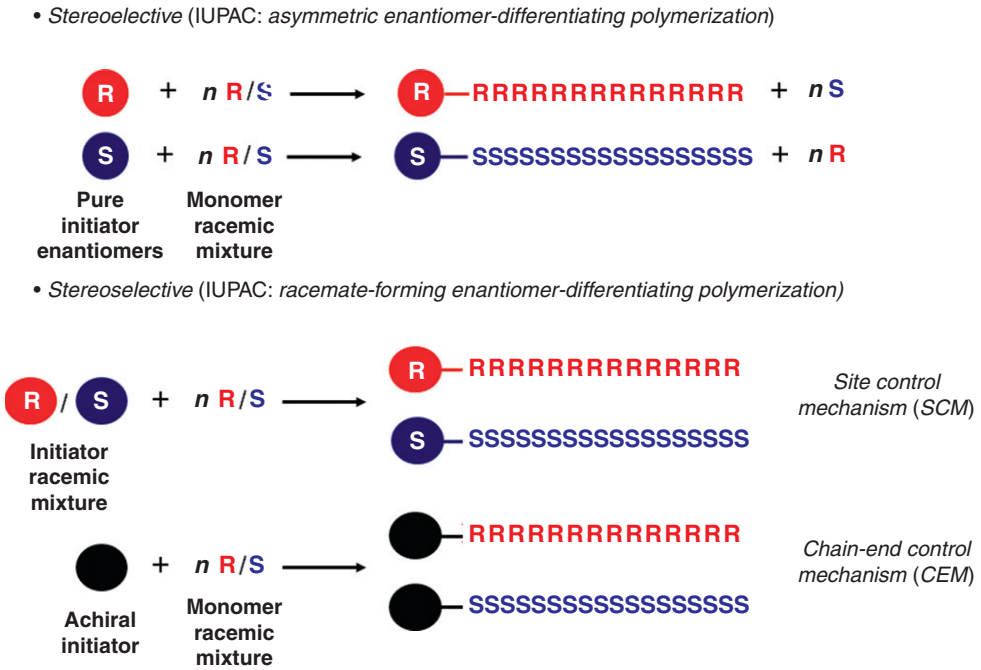


Figure 20 Classification of the stereocontrolled polymerization processes studied in the ROP of racemic cyclic esters and leading to isotactic (homochiral) macromolecules starting from racemic monomer.

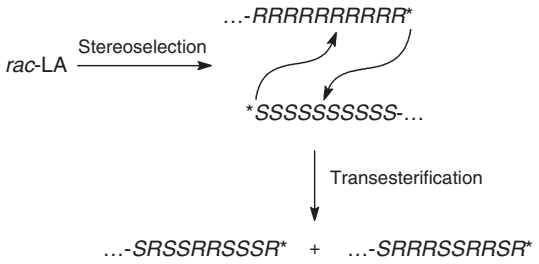
contain two centers of chirality, they can be present in a higher number of the stereochemical forms, namely, (*R*,*R*)-LA, (*S*,*S*)-LA, (*R*,*S*)-LA (*meso*-LA), and racemic equimolar (*R*,*R*)-LA/(*S*,*S*)-LA mixture (*rac*-LA).

The preparation of isotactic, enantiomerically pure polymers from the enantiomerically pure heterocyclic monomers is easy if the corresponding monomers are available. Typically, however, the optically pure monomers are not available in large quantities and their synthesis is much more complicated compared with their racemic counterparts. So far, the only exception has been (*S*,*S*)-LA, a monomer synthesized from (*S*)-lactic acid, which in turn is produced on industrial scale by fermentation from carbohydrates of agricultural origin.[82] The resultant high-molar-mass poly[(*S*,*S*)-lactide] is a crystalline (up to ≈70%) polymer melting at 180 °C, whereas poly[(*R*,*R*)-lactide-*co*-(*S*,*S*)-lactide], prepared from the racemic LA, with a random distribution of *R* and *S* repeating units is amorphous.[82,210] Similar difference in properties was observed for, for example, poly[(*R*)-β-BL] and poly[(*R*)-β-BL-*co*-(*S*)-β-BL] with a random distribution of *R* and *S* units. Therefore, stereocontrolled polymerization of *racemo* or *meso* monomers is of particular interest from the practical point of view, since polymer properties depend strongly on the distribution of chirality centers of opposite configuration along the macromolecular chain. This process also provides a useful tool in studies of the polymerization mechanisms of cyclic esters.

Figure 20 illustrates idealized classification of the stereocontrolled polymerizations of a racemic monomer that bears one center of chirality (β-BL case). For the sake of simplicity, only formation of isotactic (…–RRRRRRRR–… or …–SSSSSSSS–…) polymer formation is shown. In principle, this scheme conforms also to the *rac*-LA (containing two identical centers of chirality in one molecule) polymerization. In a more general case, formation of the syndiotactic (…–RSRSRSRS–…) and heterotactic (…–RRSSRRSS–…) polyester chains (see, e.g., structures 5) should additionally be considered (*vide infra*).



(*R* and *S* stand for (*R*)-and (*S*)-(C=O)CH(CH$_3$)O units, respectively)

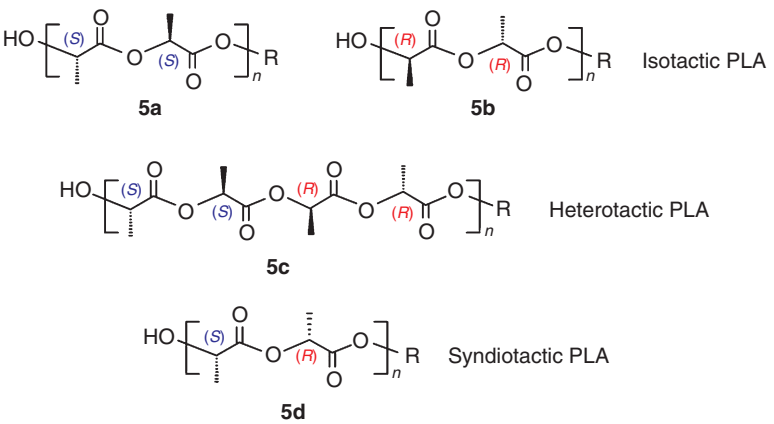
Scheme 15

transesterification will lead to the atactic stereocopolymer (Scheme 15).

It seems that the stereocontrolled ROP of chiral aliphatic cyclic esters became recently an emerging field of research in polymer science. Until the mid-1990s, the progress was rather modest. In a review on asymmetric polymerization,[211] only one paper on *rac*-β-BL polymerization has been cited reporting that the enantiomerically pure initiator [(–)-(*R*)-(CH$_3$)$_3$CC*H(OH)CH$_2$O]ZnEt$_2$ gave $k_p(R)/k_p(S)$ ratios not higher than 1.7.[212] Similar $k_p(R)/k_p(S)$ values were obtained in the polymerizations of other chiral β-lactones initiated with optically active phosphines.[106,107]

4.11.8.1 Stereocontrolled ROP of LA

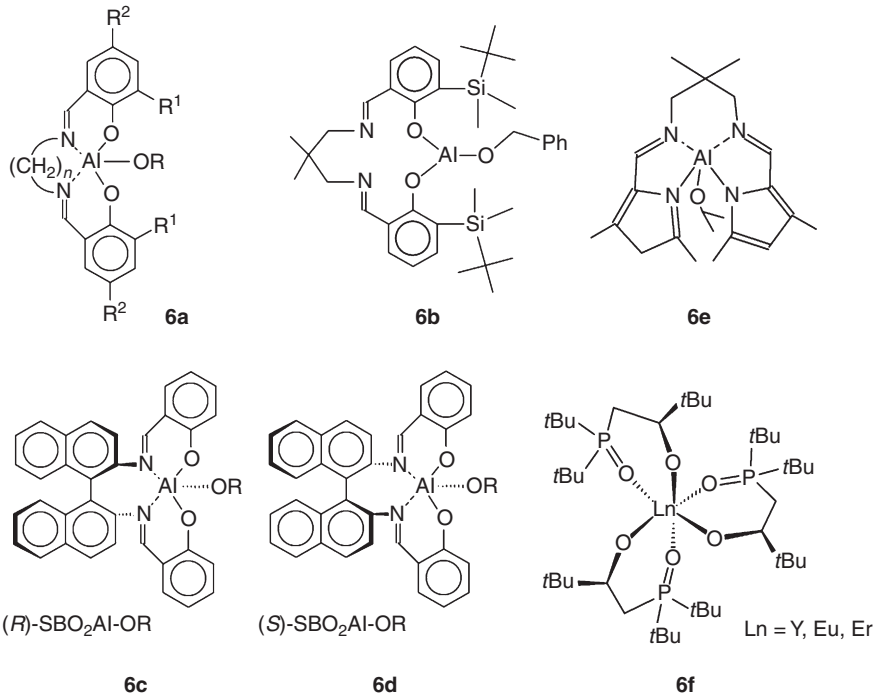
Research on *rac*-LA polymerization has been much more dynamic and successful, especially in the past decade. Suppression or even elimination of the segmental exchange turned out to be possible by applying metal alkoxide initiators with bulky ligands. Steric hindrance at the active center decreases the transesterification rate due to an increase in entropy of activation, while the propagation rate remains constant.[53]



Stereocontrolled polymerization requires elimination of the intermolecular transfer (segmental exchange) between the homochiral chains containing repeating units of opposite configuration. Otherwise, even if initially stereoselective polymerization proceeds giving the homochiral chains,

An efficient enantioelective or enantioselective polymerization, based on single-site initiators of *rac*-LA, has been realized by Spassky and co-workers, who applied achiral and chiral aluminum alkoxides of general structure O$_2$Al–OR, bearing Schiff base ligands.[70,71,213]

The chirality of (*R*)- and (*S*)-SBO_2Al–OR (structures **6c** and **6d**) derivatives has its origin in the hindered rotation of the 2- and 2′-substituted 1,1′-binaphthalene moieties.

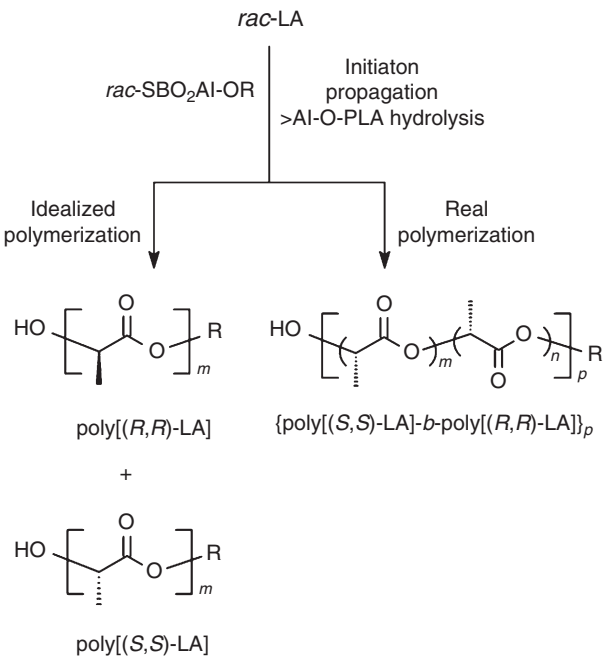


This method, originally developed by Spassky and co-workers, was then followed up by the groups of Radano *et al.*,[214] Ovitt and Coates,[215,216] Zhong *et al.*,[217,218] and Nomura *et al.*[219,220] It was revealed that polymerization of *rac*-LA mediated with either achiral or chiral but racemic initiators led to the multiblock copolymers {poly[(*S*,*S*)-LA]-*b*-poly[(*R*,*R*)-LA]}$_p$, resulting from a CEM or an enantiomorphic SCM of the monomer addition, respectively. Initially, formation of the isotactic polymer composed of an equimolar mixture of (*R*)- and (*S*)-PLA macromolecules was expected.[214]

However, Ovitt and Coates,[215,216] after repeating these experiments, came to the conclusion that the polymer obtained cannot be a mixture of the exclusively homochiral (*R*)- and (*S*)-PLA macromolecules (**Scheme 16**).

Comparison of the recorded and simulated ^{1}H NMR spectra and the assumption that polyester chain growth is accompanied by exchange of chiral macromolecules on alien active centers indicated that the resulting macromolecules were composed of stereoblocks with 11 repeating units derived from LA monomer of a given kind (toluene, 70 °C). Enantiomerically pure (*R*)- or (*S*)-SBO_2Al–OR initiators have been shown to polymerize preferentially one of the enantiomers of *rac*-LA, that is, (*R*,*R*)- or (*S*,*S*)-LA, respectively.[71,221] This enantiospecific preference was indicated by the stereoselectivity ratio $k_p(R/RR)/k_p(R/SS)$ (or $k_p(S/SS)/k_p(S/RR)$) equal to 28, what corresponds to $P_m = 0.96$ (i.e., probability of isotactic enchainment formation, equal to *m* diad content in the resulting polymer).

One of the most important practical consequences of the results described above, with regard to mechanical and thermal properties of PLA, is the possibility of stereocomplex formation by sufficiently long stereoblocks of the opposite configuration. The T_m of the (*R*)-PLA/(*S*)-PLA stereocomplex composed of an equimolar mixture of high-molar-mass *R*- and *S*-macromolecules is 230 °C,[210] whereas the highest T_m of the stereocomplex prepared initially by the stereoselective polymerization with achiral initiator was 192 °C,[219] and later on

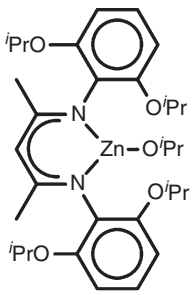


Scheme 16

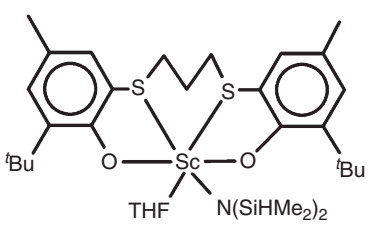
it was upgraded up to 210 °C by Nomura *et al.*, who applied achiral salen-Al complexes with (*tert*-BuMe$_2$Si)phenoxide ligands (structure **6b**).[220]

In another approach, a combination of the stereoelective polymerization and chiral ligand exchange resulted in the formation of a stereocomplex showing also $T_m = 210$ °C.[221] This was realized by two-step polymerization of *rac*-LA initiated by a (+)-(*S*)-2,2′-[1,1′-binaphthalene-2,2′-diylbis(nitrilomethylidyne)] diphenol [(*S*)-SB(OH)$_2$]–Al(O^{i}Pr)$_3$ trimer mixture, in which the actual initiator (SBO$_2$Al–O^{i}Pr) was formed *in situ* (**Scheme 17**).

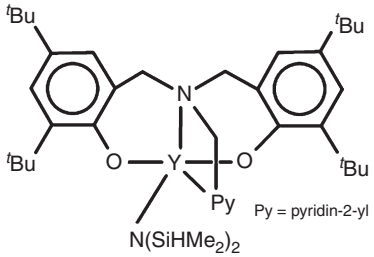
First, an (*S*)-SB(OH)$_2$–Al(O^{i}Pr)$_3$ mixture was reacted in THF at 80 °C and then *rac*-LA was introduced. Progress of the polymerization was followed using polarimetry and by GPC.



7a



7b



7c

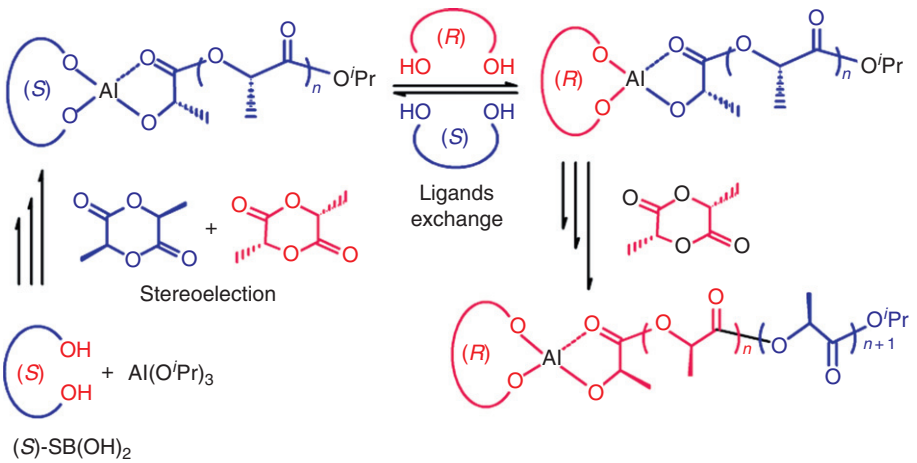
Optical rotation (OR) readings increased with polymerization time and eventually leveled off. GPC measurement showed approximately 50 mol.% consumption of *rac*-LA. In the second step, an equimolar quantity of (*R*)-SB(OH)$_2$ (with respect to the *S* enantiomer) was introduced. In subsequent polymerization, a gradual decrease in OR was observed. Taking into account the determined stereoelectivity coefficient, $P_m = 0.96$, for the final poly(*rac*-LA), the gradient poly[(*S*,*S*)-LA-*grad*-(*R*,*R*)-LA] rather than the block copolymer structure was expected. Indeed, homodecoupled ^{1}H NMR spectra showed, apart from the strong signal of the isotactic *mmm* tetrad, also peaks of lower intensity, which can be ascribed to the *mmr*, *rmm*, and *rmr* tetrads.[223]

Thus, in stereoelective or stereoselective polymerizations of *rac*-LA initiated with salen-Al (e.g., structures **6a–6d**) or Al-pyrrole Schiff base complexes **6e**,[222] predominantly isotactic PLA has been formed. Similar results were obtained with lanthanide L3 complexes of a chiral alkoxides (e.g., structure **6f**).[223]

Surprisingly, different behavior has been observed more recently for other metals and other type of ligands complexing the metal-alkoxide moiety, such as β-diimidate-Zn complex **7a**,[193,224–226] or diphenolate complexes of group III metals **7b**[227] and **7c**.[228] For these initiators, the chain-end-controlled ROP of *rac*-LA afforded highly heterotactic PLA characterized by P_r (i.e., probability of syndiotactic linkages formation, equal to *mr* or *rm* triad content in the resulting polymer) reaching 0.99.

It is worth noting that ROP of *rac*-LA initiated with lithium *tert*-butoxide, as it was reported by Kasperczyk and co-workers,[229,230] gives syndiotactic PLA, thus also with retention of configuration.

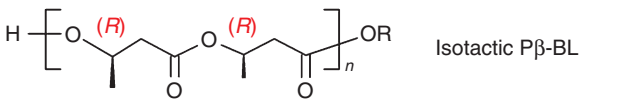
Some of the results reported for site-controlled ROP of *meso*-LA initiated with chiral initiators are also striking. For example, enantiomerically pure salen-Al complex **6d** led to syndiotactic chains ($P_r = 0.99$), whereas a **6c**/**6d** racemic mixture afforded heterotactic chains.[216] On the other hand, in the chain-end-controlled ROP initiated with imidozinc complex **7a**, formation of predominantly syndiotactic PLA was observed.[193]



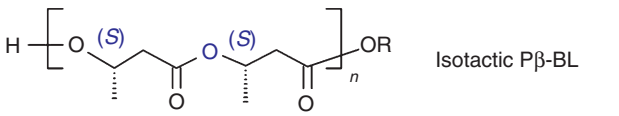
Scheme 17

The determination of the PLA chains microstructure is based mostly on ^{13}C or ^{1}H NMR spectral analysis: for the former in the carbonyl ($\delta \approx 169–170$ ppm) or methine region ($\delta \approx 68.5–69.5$ ppm), whereas for the latter in the region of methine protons ($\delta \approx 5.1–5.25$ ppm) with selective decoupling of methyl protons (chemical shifts are given for $CDCl_3$ as a solvent at room temperature). Systematic studies in this area have been initiated in the mid-1970s[231,232] and subsequently continued by several research groups (Chabot and Vert,[233] Schindler and Gaetano,[234] Bero *et al.*,[235] Dubois *et al.*,[236] Kricheldorf *et al.*,[237] Kasperczyk and co-workers,[229,230,238] Spassky and co-workers,[71,213,239] Stevels *et al.*,[240] Coudane *et al.*,[241] Kricheldorf and Lossin,[242] Thakur *et al.*,[243,244] Ovitt and Coates,[215,216] and Radano *et al.*[214]). Heteronuclear correlated {^{1}H,^{13}C} (HETCOR) two-dimensional spectroscopy was also employed in the analysis of the methine region.[245–247]

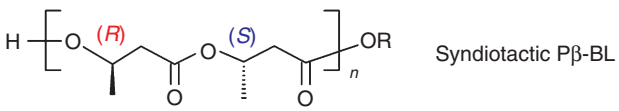
Attempts of β-BL polymerization with the multi-site metal alkoxides (e.g., $Al(O^{i}Pr)_3$[201]) were rather unsuccessful since the process was extremely slow (see, e.g., discussion in Section 4.11.3.1). Due to the impressively intensive research, carried out mostly by Coates[200] and Carpentier[81] and their co-workers on new effective ligands combined with properly chosen metals for β-BL ROP catalysis, considerable progress has been made in this area in the 2000–10 decade. Moreover, the new catalysts/initiators lead to remarkable stereochemical effects. In the stereocontrolled polymerization of *rac*-β-BL, two kinds of effects regarding the polymer structure can be expected: either isotactic or syndiotactic poly[(*R*)-β-BL] or poly[(*S*)-β-BL] formation (structures **8**)



8a Isotactic Pβ-BL



8b Isotactic Pβ-BL

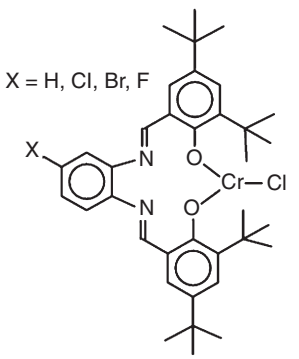


8c Syndiotactic Pβ-BL

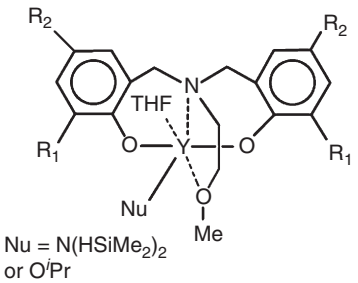
4.11.8.2 Stereocontrolled ROP of β-BL

As mentioned in the Introduction, controlled ROP of β-substituted β-lactones is still a serious challenge. Their relatively fast ionic polymerization suffers from chain transfer to monomer and, due to the carboxylic chain-end formation (eqn [20]) followed by carboxylic acid complexation, the polymerization slows down and complete monomer conversion could hardly be achieved.[45,46]

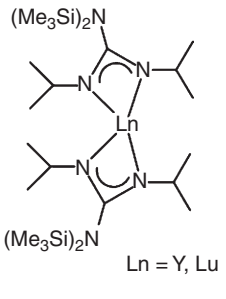
Stereocontrolled ROP of *rac*-β-BL, leading to the homochiral polymer and – which is also important – to the monomer of opposite configuration or to an equimolar mixture of chains with opposite configurations (poly[(*R*)-β-BL] or poly[(*S*)-β-BL]), is still a problem. For example, Rieger and co-workers[248] reported application of highly active achiral Cr(III) salophen complexes, **9a**, giving high-molar-mass Pβ-BLs but with high dispersities ($M_w/M_n = 5.2–9.6$) and with only modest isotacticities (P_r up to 0.66).



9a



9b



9c

On the contrary, the synthesis leading to a syndiotactic polymer and the corresponding studies of the polymerization mechanism are substantially advanced. Structures **9b** and **9c** are typical examples of catalysts, which afford poly[(*R*,*S*)-β-BL],

predominantly syndiotactic polymers (P_r up to 0.94). R^1 *ortho*-substituents in phenoxide ring in complex **9b** can finely tune the stereocontrol, but the electronic effects (e.g., R^1 in the substituent in the repeating unit C–H…π interactions) can also be important. Thus, depending on the monomer (e.g., *rac*-LA vs. β-BL), the influence of the R^1 bulkiness on the polyester stereoregularity (heterotacticity or syndiotacticity) can act in the opposite direction.[249] For larger substituents, ^{13}C NMR studies of the syndiotactic Pβ-BLs led to the conclusion that in this system the CEM operates.[250,251] Similar results have been obtained with guanidine complexes with group III metals.[252] In addition to high polymerization rates ('complete' monomer consumption in minutes or hours at room temperature!), these systems show typical features of living polymerization (e.g., it was revealed that one molecule of initiator starts, the growth of exactly one macromolecule and the linear dependences M_n vs. monomer conversion were observed).

More detailed information on the stereocontrolled polymerizations of racemic LA and β-BL monomers has been collected in the recently published review papers.[81,253–255]

Microstructure of the *rac*-β-BL polymerization products was resolved in a similar way as in the LAs polymerization case. However, the detailed analysis of the NMR spectra of PLAs and Pβ-BLs is out of the scope of this chapter.

4.11.8.3 Stereocontrolled Copolymerization of L,L-LA with CL

Homopolymerization rates of CL and LA are substantially different. For instance, the ratio of the absolute rate constants of propagation k_p(CL)/k_p(LA) proceeding on aluminum trialkoxide active species is as high as 6.7×10^3 (THF, 20 °C).[60] Surprisingly, in the CL/LA copolymerization, the LA comonomer with this initiating system is consumed first and, typically, block PLA-*b*-PCL or gradient poly(LA-*grad*-CL) copolymers are obtained (see **Figure 21(a)** and References 256–260). Thus, the net reactivities of CL and LA in copolymerization are reversed compared with those in the homopolymerizations. Despite the fact that the first reports describing this puzzling phenomenon were published in the mid-1980s,[256,257] its plausible explanation, on the molecular level, is still under debate.

However, there is at least one report[261] showing that in the CL/LA copolymerization the net reactivities of CL and LA comonomers can be reversed by altering the active center configuration to such an extent that the CL comonomer is consumed first. This new and striking phenomenon is of general importance, since it provides a useful tool for tuning the resultant copolymer microstructure and properties. This concept is depicted in **Scheme 18**.

The described kinetic behavior can be expressed quantitatively in terms of the corresponding reactivity ratios ($r_{CL} = k_{clCL}/k_{clLA}$ and $r_{LA} = k_{laLA}/k_{laCL}$) determined using the numerical integration method; $r_{CL} = 7.2$ and $r_{LA} = 112$ were obtained. Reactivity ratios $r_{CL} = 0.58$ and $r_{LA} = 17.9$ in the copolymerization initiated with neat Al(O^iPr)$_3$ were determined some time ago in the Liege laboratory.[256] Both sets of data, although showing different values, reflect favorable incorporation in the copolymer chain of the repeating units derived from the LA comonomer. A difference between r_{CL}'s and r_{LA}'s obtained for Al(O^iPr)$_3$ and **6d**/Al(O^iPr)$_3$ initiators is not only due to different methods used for their determinations (Mayo–Lewis and numerical integration, respectively) but also, more probably, due to the fact that only with the metal alkoxides that bear bulky substituents can the segmental exchange, modifying the …–cl* and …–la* active species proportions, be avoided.

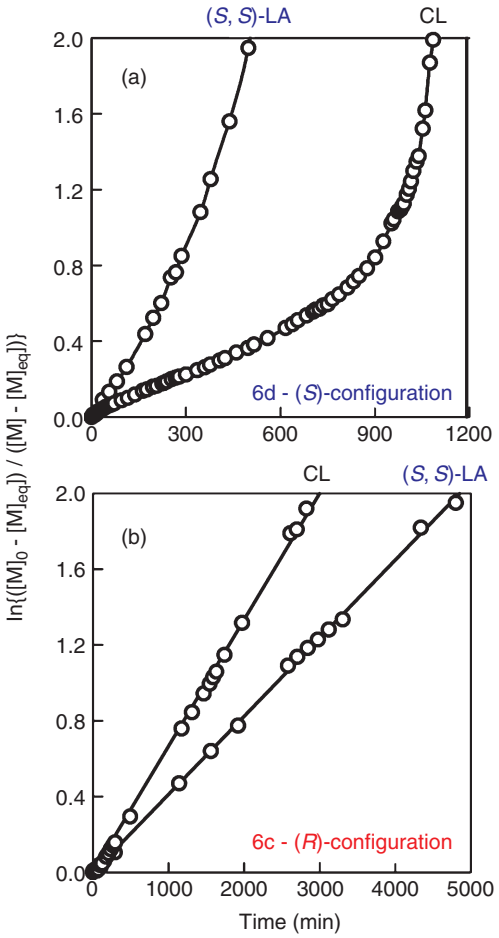


Figure 21 Kinetics of ε-caprolactone (CL)/L,L-lactide [(*S*,*S*)-LA] copolymerization initiated with structure **6d** (a) and structure **6c** (b). Polymerization conditions (concentrations in mol l^{-1}): $[CL]_0 = 2.0$, $[(S,S)\text{-LA}]_0 = 1.0$, $[\mathbf{6c}]_0 = 2 \times 10^{-3}$, $[\mathbf{6d}]_0 = 2.5 \times 10^{-3}$; THF solvent, 80 °C.[261]

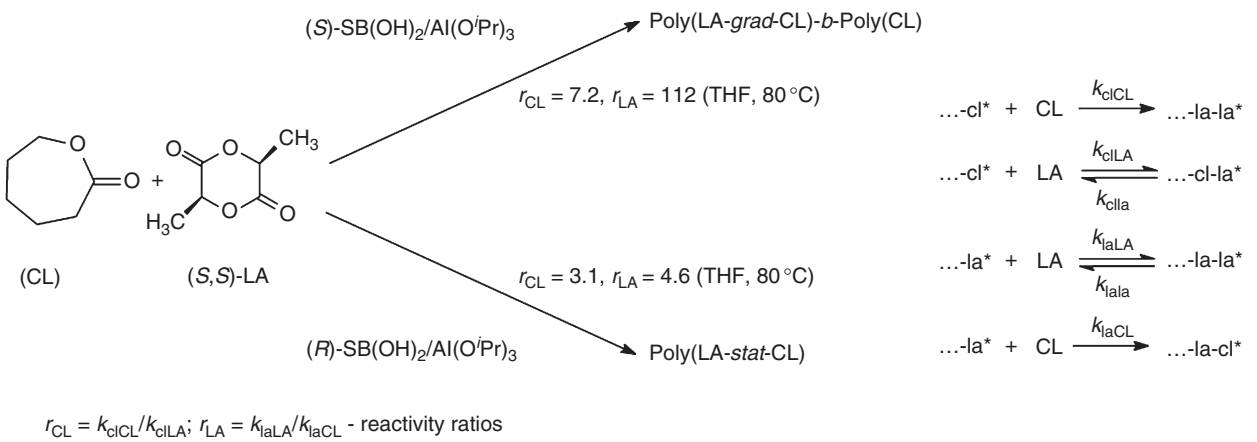
Then, kinetic measurements performed for the LA/CL copolymerization initiated with structure **6c** (**Figure 21(b)**) reveal that CL is consumed slightly faster compared with the LA comonomer under the applied polymerization conditions. The determined reactivity ratios are close to each other within the calculated experimental error, namely, $r_{CL} = 3.1$ and $r_{LA} = 4.6$.

According to the ^{13}C NMR spectra, microstructures of the CL/LA copolymers prepared with **6d** and **6c** initiators were substantially different. The corresponding kinetic measurements allow to predict the poly(LA-*grad*-CL)-*b*-poly(CL) or poly(CL-*stat*-LA) copolymer structures obtained with the initiating system of (*S*)- or (*R*)-configuration, respectively.

Finally, it has to be mentioned that later Nomura *et al.*[262] observed a similar copolymer randomization effect in the copolymerization of *rac*-LA and CL initiated with an achiral salen Al-alkoxide complex **6b**, thus by the CEM in contrast to the SECM operating in the **6c**/L,L-LA/CL system.



$r_{CL} = k_{clCL}/k_{clLA}$; $r_{LA} = k_{laLA}/k_{laCL}$ - reactivity ratios

Scheme 18

4.11.9 Conclusions

ROP of aliphatic cyclic esters is a continuously and dynamically developing research field. Initially, fundamental aspects of polymerization, such as thermodynamics, kinetics, and mechanisms of the elementary reactions, were explored. The best understood systems encompass polymerization of lactones and LAs. Determination of the standard thermodynamics parameters of polymerization for a majority of the most important monomers now allows the estimation of the equilibrium monomer concentration at given polymerization conditions. For a few polymerizing systems, such as anionic polymerization of PL, CL, or coordinated (proceeding on polarized covalent bonds) polymerizations of CL and LAs, the absolute rate constants have been determined. However, in a majority of the polymerizations, only the net reactivities have usually been determined which does not provide direct access to absolute rate constants of propagation. Nonetheless, the ROP of cyclic esters seems to be a convenient model system for studies of mechanism of cyclic monomers, in general.

Studies leading to depression of even practical elimination of the transfer to monomer or to macromolecule side reactions were also undertaken. Two important factors were recognized that increase the selectivity (i.e., favoritizing propagation over the side reactions): lowering the active species reactivity and increasing the steric hindrance created by ligands located at the active species. Later, precise stereochemical tools were also developed, allowing polylactides and poly(β-substituted β-lactone)s of various stereostructures to be prepared at will.

On that fundamental studies basis, the most convenient conditions for synthesis of aliphatic polyesters were elaborated, controlled with regard to their molar masses, molar mass dispersities, end groups structure, macromolecular architecture, and chain microstructure. One of the most important parameters allowing determination of the polymerization control is the prepared polyester molar mass, theoretically predicted on the starting monomer and initiator concentrations and that measured, most often by GPC. Fortunately, there are numerous examples that can be found in the literature showing the astonishing agreement between M_n determined by GPC employing RI detector and polystyrene standards and that predicted by the starting monomer and initiator concentrations. In parallel, more practical works that aimed to afford either (bio)degradable thermoplastic polyester for high-tonnage applications or specialty polymers for biomedicine or (opto)electronics were carried out. Typically, these are nonsolvent bulk processes, performed at elevated temperatures, above the resultant polyester melting point – under these conditions chain-breaking, transfer, racemization, and transesterification side reaction are particularly advanced. On the contrary, a majority of the mechanistic and stereospecific polymerization studies were carried out in solvent at moderate or low temperatures. Thus, some hopes of transferring results of these studies into the technological polymerization conditions seem to be exaggerated at present.

It can be concluded that studies of a subtle elements of propagation, particularly in the coordinated processes, are still needed. Perhaps the advanced quantum mechanical calculations methods would be very helpful for this purpose. The β-substituted β-lactones are still waiting for the stereospecific initiator allowing the stereoelective and/or stereoselective polymerizations to be carried out. Finally, initiators of the stereocontrolled polymerization operating in bulk, high-temperature processes are also wanted.

Biographical Sketch

Andrzej Duda is head of the Department of Polymer Chemistry at the Center of Molecular and Macromolecular Studies of the Polish Academy of Sciences in Lodz, Poland and currently chairman of the Polymer Section of the Polish Chemical Society as well as a member of the Polish National Science Center. He received his MSc degree from Lodz University of Technology (1975), his PhD (1984, under the supervision of Stanislaw Penczek), and his DSc (1997) from the Polish Academy of Sciences. Since 2004, he has been a full professor in chemistry with the title conferred by the President of Republic of Poland. His research interests focus on thermodynamics, kinetics, and mechanisms of the ring-opening and ionic polymerizations, reactivity–selectivity relationships in polymerization, methods of controlled/living polymerization, macromolecular engineering, and polymers and monomers available from renewable resources. He is the author and coauthor of more than 100 scientific papers (including 5 book chapters).

4.12 ROP of Cyclic Carbonates and ROP of Macrocycles

G Rokicki and PG Parzuchowski, Warsaw University of Technology, Warsaw, Poland

4.12.1 Introduction

Polycarbonates (PCs) are polyesters of diols or diphenols and carbonic acid containing –OC(O)O– groups in their backbone chains and, therefore, can be divided into aliphatic and aromatic ones. Taking into account the low stability and reactivity of carbonic acid, such polymers cannot be obtained by the polycondensation reaction of H_2CO_3 with diols or diphenols, and therefore, more reactive derivatives of carbonic acid such as phosgene are usually used as starting materials. However, due to the phosgene high toxicity and formation of stoichiometric amounts of sodium chloride as an environmentally burdensome by-product, alternative methods have been developed in which carbon dioxide or low-molecular linear or cyclic carbonate esters are applied.

An alternative method for PC synthesis is ring-opening polymerization (ROP) of cyclic carbonates, both aliphatic and aromatic. The chemistry of PCs is extensive and well developed. A comprehensive study of PCs was reported by Brunelle in 1993, 1997, and 2005.[1–3] A review of aliphatic cyclic carbonate synthesis and chemistry was presented by Rokicki.[4]

Nowadays, aromatic and aliphatic PCs are used in a broad range of applications, for example, as elastomers, sealants, elastoplastics, foams, coatings, and adhesives.[1,5–8] Global consumption of aromatic PC has risen by 9% annually on average over the past decade, and producers see this trend as set to continue along the same lines over the next several years. The outstanding properties of PC include transparency, heat resistance up to 130 °C, high toughness, and excellent dimensional stability. It can be sterilized, welded, or glued and is self-extinguishing. PC is easily blended with other polymers. Some 15% of consumption is for blends – especially popular are blends with styrene-based polymers such as acrylonitrile-butadiene-styrene terpolymer (ABS) or styrene-acrylonitrile copolymer (SAN). Electrical engineering is the most important market for PC, taking 30% of production for housings and covers for products such as distribution boxes, lights, and household appliances, among other applications. Optical storage media such as CDs and DVDs continue to be fast-growing

applications for PC. The main applications are solid and hollow chamber sheeting for canopies and greenhouses, as well as conservatory and swimming pool roofing.

Aliphatic PCs and copolycarbonates, due to their biocompatibility and biodegradability, are valuable biomaterials and stimulate intensive efforts to develop new synthetic methods. Incorporation of the carbonate structure provides flexibility and toughness to the otherwise rigid and brittle polyesters.

4.12.2 Synthesis of Cyclic Carbonates

4.12.2.1 Synthesis of Aliphatic Cyclic Carbonates

The first information concerning the synthesis of cyclic carbonates was revealed by Carothers *et al.* in the early 1930s.[9–11] Cyclic carbonates were obtained by the depolymerization of respective linear oligocarbonates at high temperature in the presence of various catalysts combined with distillation under reduced pressure. The products (yields of 40–80%) consisted of a mixture of volatile cycles (mostly monomeric and dimeric cyclic carbonates).[12–14] The most effective catalysts in this process were Sn(II), Mn(II), Fe(II), and Mg(II) chlorides, carbonates, and oxides. This method is still applied in the synthesis of six- and seven-membered and of larger size aliphatic cyclic carbonates.

4.12.2.1.1 Synthesis of five-membered cyclic carbonates

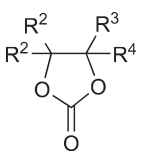
The synthesis of five-membered alkylene carbonates (1,3-dioxolan-2-ones) of the structure presented in Scheme 1 has been the subject of considerable research. Two of them, ethylene carbonate (EC) ($R^{1-4} = H$) and propylene carbonate (PC) ($R^{1-3} = H$, $R^4 = CH_3$), have been available commercially for over 45 years.[15,16]

Recently, it has been found that five-membered cyclic carbonate exists in nature. Rosselli and co-workers[17] have presented the first example of natural origin cyclic carbonate terpenoid. They isolated a new guaiane sesquiterpene (Scheme 2), carrying a carbonate ring, from the aerial parts of the *Centaurea hololeuca* (Boiss) plant.

There are two main synthetic routes leading to five-membered cyclic carbonates: the reaction of a respective oxirane with carbon dioxide or 1,2-diol with dialkyl or diphenyl carbonate. Instead of carbonic acid esters, phosgene or its derivatives can also be used.[18]

The alkylene carbonates are easily available through transesterification of dialkyl carbonates (usually dimethyl or diethyl carbonate) or diphenyl carbonate with appropriate 1,2-diols in the presence of alkaline catalysts.[19] This approach for the preparation of five-membered cyclic carbonates also was described in the 1950s by Ludwig and Piech[20] and Sarel *et al.*[18]

Venturello and D'Aloisio[21] also proposed a nonphosgene method for the five-membered synthesis of disubstituted cyclic



Scheme 1 Chemical structure of five-membered cyclic carbonates.

carbonates. In this method tetraalkylammonium hydrogen carbonate salt is reacted with disubstituted halohydrins such as $R^1CH(OH)CH(Cl)R^2$ ($R^1 = CH_3$ or Ph; $R^2 = H$, CH_3, or Ph) at 20 °C to give the corresponding disubstituted cyclic carbonates (Scheme 3).

Soga *et al.*[22,23] used alkali metal carbonates activated by crown ethers as an alternative source of carbonate linkages in the reaction with dihalo compounds. When epihalohydrin is used instead of the dihalo compound in the reaction with K_2CO_3, corresponding five-membered cyclic carbonates containing an epoxy group are formed.[24,25] In contrast, potassium bicarbonate reacts with epihalohydrin yielding 4-hydroxymethyl-1,3-dioxolan-2-one (glycerol carbonate, GC) (Scheme 4).[24]

Pd(0)-catalyzed arylation of the aryl-substituted α-allenic alcohols with hypervalent iodonium salts afforded substituted *trans*-epoxides.[26] Alternatively, arylation of the alkyl-substituted α-allenic alcohols in the presence of K_2CO_3 afforded *syn*-diol cyclic carbonates and *trans*-epoxides in the presence of Cs_2CO_3 (Scheme 5).

The treatment of carbonyl compounds with SmI_2 and methyl chloroformate in the presence of molecular sieves affords the cyclic carbonates or biscarbonates of pinacols. This one-pot reaction proceeds rapidly even with aliphatic ketones. The stereochemistry of the reaction run by this procedure is different from that of conventional pinacolic couplings.[27]

Trifluoromethylated five-membered cyclic carbonates were prepared through the palladium-promoted reaction of tertiary trifluoromethylated propargylic alcohols and sodium carbonate (Scheme 6).[28]

Tomishige *et al.*[29,30] found that cyclic carbonates such as EC and PC could be selectively synthesized over CeO_2–ZrO_2 catalysts, via the reactions of CO_2 with the respective glycol. No PC or dipropylene glycol was detected under the optimum reaction conditions. The 1,2-propylene glycol conversion was 2% and was much dependent on the composition and calcination temperature of the catalysts.

Organic bases were also used as effective catalysts for the synthesis of PC from propylene glycol and carbon dioxide in the presence of acetonitrile. With 1,5,7-triazabicyclo[4.4.0]dec-5-ene (TBD) as the catalyst, the yield of PC could reach 15.3% with the selectivity of 100% under optimal conditions.[31]

A much more convenient method of obtaining five-membered cyclic carbonates is the insertion of gaseous carbon dioxide into the appropriate oxirane ring (Scheme 7).[32–46]

The catalyst development and the reaction mechanisms over alkali metal halides,[37,39,47,48] organic bases,[49–51] metal oxides,[36,43,35,52] zeolite,[42,53] titanosilicates,[54] and metal complexes[44,55–64] have been reported for the synthesis of cyclic carbonates from CO_2 and epoxides.

Transition metal complexes are effective in the fixation of CO_2. Organotin compounds such as methyltin tribromide and

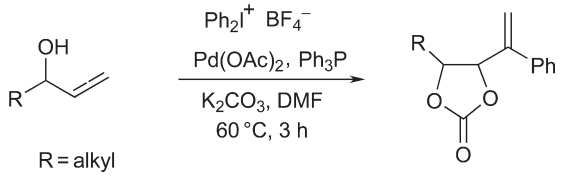

Scheme 5 Synthesis of five-membered cyclic carbonates by Pd(0)-catalyzed arylation of the α-allenic alcohols with hypervalent iodium salts in the presence of K_2CO_3.

butanestannoic acid have a good catalytic effect for EC formation under mild conditions.[65] It was found that pentavalent organoantimony compounds such as Ph_nSbX_{5-n} catalyze the reaction more effectively than tin compounds.[32,66] Additionally, in contrast to tin compounds, the pentavalent organoantimony compounds do not initiate oxirane polymerization. In the case of nickel(0) phosphine complexes cyclic carbonates are produced in high yields. The rate of carbonate formation is dependent on the structure of the epoxide and decreases in the order epichlorohydrin > ethylene oxide (EO) > propylene oxide (PO) > 2,3-epoxybutane.[55]

Quaternary ammonium salts,[67] as well as an anion exchange resin containing those groups, are used in the industrial-scale preparation of five-membered cyclic carbonates.[68,69]

Polyfluoroalkyl phosphonium iodides, Rf_3RPI (Rf = $C_4F_9C_2H_4$, $C_6F_{13}C_2H_4$, and $C_8F_{17}C_2H_4$; R = Me, Rf), catalyzed PC synthesis from PO and carbon dioxide under supercritical carbon dioxide ($scCO_2$) conditions, where PC was spontaneously separated out of the $scCO_2$ phase. The Rf_3RPI catalyst could be recycled with maintaining a high CO_2 pressure and temperature by separating the PC from the bottom of the reactor followed by supplying PO and CO_2 to the upper $scCO_2$ phase in which the Rf_3RPI remained.[70]

Although alkali metal salts appeared to be active catalysts for the CO_2–epoxide reaction, the introduction of crown ethers or phase-transfer agents to the system enhanced their catalytic activities.[71] In the presence of a crown ether, the respective nucleophilic anion is activated to such an extent that the cyclic carbonate is produced in a high yield under mild conditions. In the system studied the intermediate product of the reaction of the halide anion with the oxirane ring – alkoxide ion – does not undergo further reaction with oxirane and no poly(alkylene oxide) is formed. This results from the greater stability of the alkyl carbonate anion than that of the initial alkoxide one. Under these conditions no poly(alkylene carbonate) was formed. Due to anchimeric assistance (kinetic factor) and relatively high thermodynamic stability, the five-membered 1,3-dioxolan-2-one ring is more easily formed from the cyclization of that anion with respect to linear poly(alkylene carbonate) when no coordination catalyst is present. Relatively high pressures of CO_2 (> 8 bar) and temperatures above 100 °C are needed for an acceptable reaction rate. Nevertheless, it was

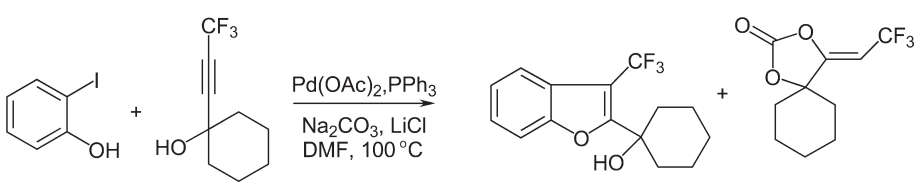
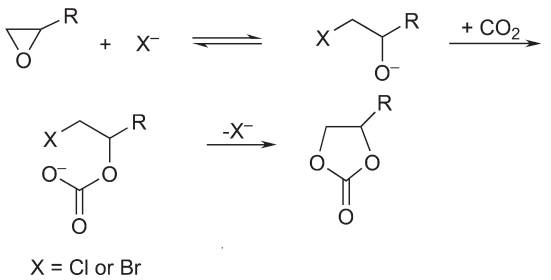


Scheme 6 Synthesis of trifluoromethylated five-membered cyclic carbonate from appropriate propargylic alcohol and Na_2CO_3.



Scheme 8 Synthesis of five-membered cyclic carbonates from CO_2 and oxiranes containing ammonium group in β-position.

found that oxiranes with ammonium groups at the β-position to the oxirane ring, due to the lowering of the activation energy of nucleophilic substitution, are able to fix carbon dioxide at room temperature and low CO_2 pressures (**Scheme 8**, R = CH_2–NR_3^+).[72–74]

The CO_2 insertion into the oxirane ring also proceeds under atmospheric pressure when the reaction is carried out in NMP as a solvent and catalyzed with LiBr at 100 °C.[75]

Cyclic carbonates can also be obtained in good yields under mild conditions from oxiranes and carbon dioxide using an electrochemical procedure.[76] The cyclic carbonate formation is catalyzed by Ni(cyclam)Br and is carried out in single-compartment cells fitted with a magnesium anode.

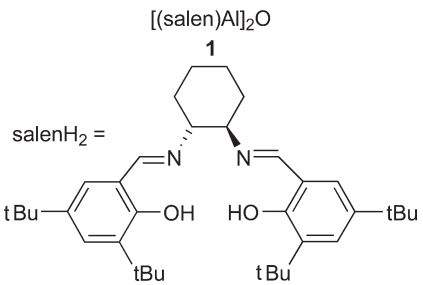
Chemical fixation of carbon dioxide with oxiranes to form cyclic carbonates proceeds very effectively under mild conditions using immobilized ionic liquid (IL) catalyst in conjunction with zinc chloride without any organic solvents. The optimum reaction conditions were 110 °C and 1.5 MPa, and the catalyst system was recycled and reused.[77] The reaction of carbon dioxide with oxiranes can be catalyzed by typical ILs (1-alkylmethylimidazolium salts).[78,79]

Very recently North's group revealed that the bimetallic aluminum(salen) complex **1** (**Scheme 9**) when used in conjunction with tetrabutylammonium bromide constitutes the only catalyst system capable of catalyzing the insertion of carbon dioxide into oxirane at 1 atm (760 mmHg) and at ambient temperature (25–30 °C).[80–82]

Another promising investigation was done by Li *et al.* They found that CO_2 and olefins can be directly converted into cyclic carbonates with water as solvent.[83]

4.12.2.1.2 Synthesis of six-membered cyclic carbonates

The synthesis of six-membered cyclic carbonates by transesterification of propane-1,3-diols (PPDs) with diethyl carbonate catalyzed with sodium ethanolate described by Carothers and Van Natta[19] gives a yield of 40%. Also Pohoryles and Sarel[18,84,85] reported on the synthesis of various six-membered cyclic carbonates from PPDs with different substituents (**Table 1**).



Scheme 9 Bimetallic aluminum(salen) complex.

Thus, when 2,2-dimethyl-, 2-methyl-2-*n*-propyl- and 2-methyl-2-*iso*-amylpropane-1,3-diol were treated with diethyl carbonate in the presence of catalytic amounts of sodium methoxide, only PCs were produced in high yield. On the other hand, six-membered cyclic carbonates are exclusively produced when 2,2-diethyl-, 2-ethyl-2-phenylpropane-1,3-diol, pentane-2,4-diol, 2-methylpentane-2,4-diol,[90] and butane-1,3-diol were subjected to the transesterification reaction (**Scheme 10**).

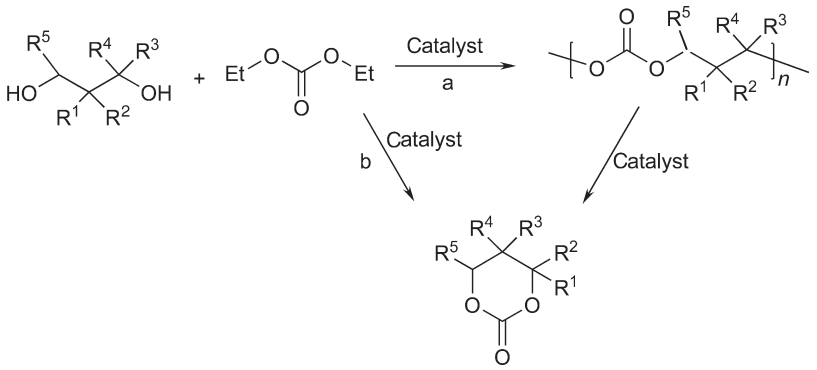


Scheme 10 Synthesis of six-membered cyclic carbonates from 1,3-diols and diethyl carbonate.

A similar method reported by Albertsson and Sjoeling[87] in which equimolar amounts of PPD and diethyl carbonate with stannous 2-ethylhexanoate as the transesterification catalyst were used afforded a yield of 53%. In this method reactants were refluxed for 8 h before ethanol was removed. It is postulated that stannous 2-ethylhexanoate can act both as a polymerization (at lower temperature) and as a depolymerization agent (at higher temperature).[96–99]

In the method proposed by Rokicki *et al.*, the synthesis of trimethylene carbonate (TMC) from PPD and dimethyl carbonate was carried out in three steps. First, bis(methylcarbonate) trimethylene was obtained using high excess of dimethyl carbonate and K_2CO_3 as a catalyst. In the second step bis (methylcarbonate)trimethylene was reacted with equimolar amounts of PPD to afford high-molecular-weight poly(trimethylene carbonate) (PTMC). The only volatile compound present in the reaction system in this step was methanol, easy to remove by distillation. Thus, it was possible to maintain an equimolar ratio of the monomers which resulted in a relatively high molecular weight of the PC. In the third step depolymerization combined with vacuum distillation was proceeded to afford TMC in 75% yield.[89]

Matsuo *et al.*[6] have revealed another universal method of cyclic carbonate synthesis from PPDs and ethyl chloroformate in the presence of a stoichiometric amount of triethylamine. The formation of a specific ammonium salt as an intermediate seems to be the driving force for the reaction proceeding at low temperatures favoring six-membered cycles (yields up to 60%) (**Scheme 11**).

Other phosgene derivatives (di- and triphosgene) also give cyclic products with good yields. The reaction of 2,2-disubstituted PPDs carried out with phosgene dimer affords the cyclic carbonate quantitatively in the reaction of 2-ethyl-2-phenylpropane-1,3-diol and 2,2-diphenylpropane-1,3-diol, while the corresponding oligocarbonates were formed in the reaction of 2,2-diethylpropane-1,3-diol in 24% yield, apart from the corresponding cyclic carbonate.[6]

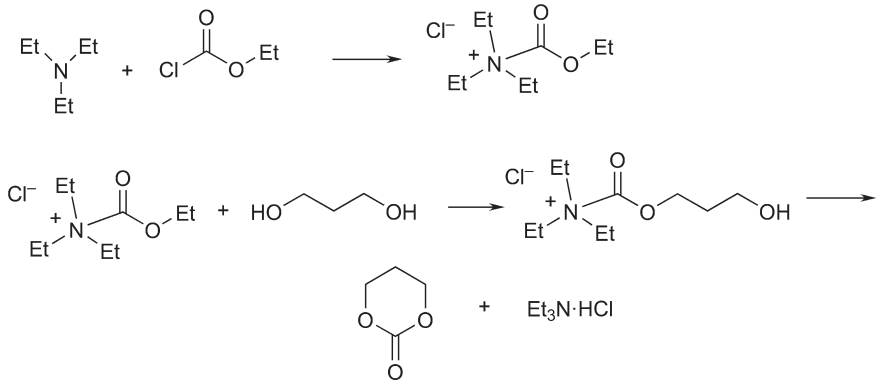
4.12.2.1.3 Synthesis of seven-membered and of larger ring size cyclic carbonates

Seven-membered and larger ring size cyclic carbonates can be synthesized according to the same transesterification reaction pathways as those leading to five- and six-membered rings[9,18] or in the reaction of appropriate diol with phosgene (or its derivative) in the presence of antipyrine.[100,101]

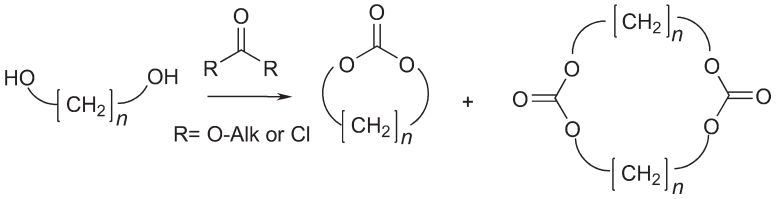
However, due to the low stability of seven-membered cyclic carbonates, the polymerization of its cyclic dimers (**Scheme 12**) is a better method for synthesis of the corresponding PCs.[102,103] The same concerns 8-, 9- and 13-membered cyclic carbonates.[102,104,105]

Dimers are also easier to obtain in larger quantities. In the transesterification-depolymerization method they are formed almost exclusively when the expected monomer cycle size is from 7 to 12; both monomer and dimer are formed when its size is 13 and 14 and monomers almost exclusively when the cycle size is more than 14.[9]

Typically, the transesterification is carried out at 120–130 °C in the presence of a catalyst (e.g., K_2CO_3, dibutyltin



Scheme 11 Synthesis of six-membered cyclic carbonate from 1,3-propanediol and ethyl chloroformate.



Scheme 12 Formation of monomeric and dimeric large ring size cyclic carbonates.

dimethoxide) under reduced pressure (0.07–11 mbar). The resultant PC subjected to ring-closing depolymerization at 260–300 °C affords cyclic products collected after distillation over a heated column.[102,106] Since 1,5-, 1,6-, and 1,10-diols have high boiling points, a more reactive diphenyl carbonate can be used instead of dimethyl- or diethyl carbonate for the transesterification and higher yields of the respective intermediate polymers can be obtained. The 18-membered cyclic carbonates cyclobis(hexamethylene carbonate) and its fluorinated analog representing the smallest ring carbonates based on hexane-1,6-diol were obtained in this way.[106]

Seven-membered cyclic carbonate – 1,3-dioxepan-2-one – can be obtained in its monomeric form in the reaction of butane-1,4-diol with triphosgene in the presence of antipyrine in anhydrous chloroform. This method does not involve polymerization. The product is purified by column chromatography.[100,101] It is a versatile method that allowed the synthesis of seven-membered cyclic carbonates bearing phenyl, methyl, or cyclic acetal side-groups.[107,108]

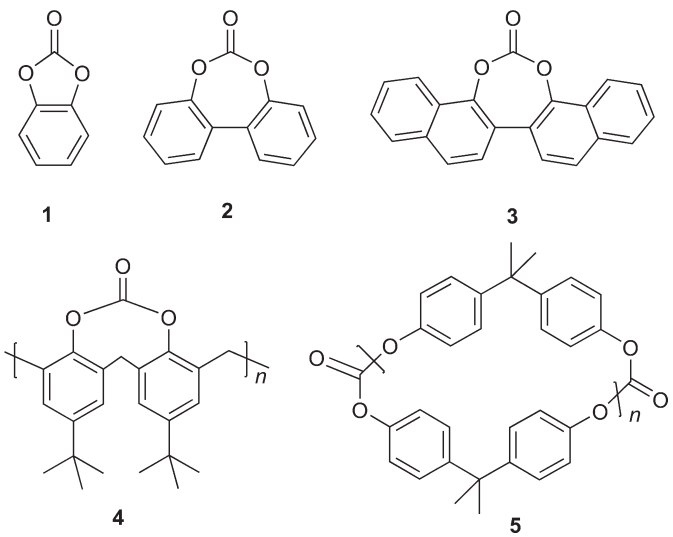
4.12.2.2 Synthesis of Aromatic Cyclic Carbonates

The smallest possible five-membered aromatic cyclic carbonate is a derivative of catechol: benzo-1,3-dioxolan-2-one (*o*-phenylene carbonate) (**1**, **Scheme 13**). It was synthesized using three different methods: the reaction of catechol with phosgene (or its dimer or trimer),[109] the reaction of catechol with chloroformate,[110] or by transesterification of catechol with diphenyl carbonate.[111]

The seven-membered aromatic cyclic carbonates were obtained from 2,20-biphenol and 1,10-bi(2-naphthol), *p*-nitrophenyl chloroformate, and a tertiary amine as a base.[112] They could be isolated with 80% yield (**2**, **3**, **Scheme 13**). As was shown by Kricheldorf and Jenssen,[113] disproportionation of 2,20-bis(methoxycarbonyloxy)biphenyl catalyzed by $Sn(Oct)_2$ can also be utilized for obtaining the seven-membered aromatic cyclic carbonate.

The possibility of obtaining aromatic polycyclic carbonates was also reported by Prochaska[114] from *o,o′*-bisphenols and Mandal and Hay[115] from novolac resin. A novolac-type phenol-formaldehyde resin (*ortho*-coupled through methylene group 4-*tert*-butylphenol resins) was reacted with an excess of triphosgene under high-dilution conditions. Because of the relatively low steric hindrance in these systems, the formation of cyclic carbonates was possible and oligomeric polycyclic carbonates were obtained (**4**, **Scheme 13**). The polycyclic carbonates were used for the modification of commercial aromatic PCs. They were mixed with the linear PC in different proportions and cured at different temperatures by using lithium stearate as a catalyst. The curing of a mixture which contained 10 wt.% of the polycyclic carbonates at 350 °C for 30 min resulted in a highly cross-linked system.

Besides the small ring size cyclic carbonates, cyclic oligocarbonates and PCs are known which are obtained in the reaction of bisphenol A (BPA) with phosgene (**5**, **Scheme 13**).[1] They were first found in the commercial condensation polymers such as PC, where they were present at levels of 0.25–2.0%.



Scheme 13 Aromatic cyclic carbonates.

The attraction of using this type of cyclic oligomers as precursors to engineering thermoplastics is based on the expectation that the oligomers would have significantly lower melt viscosity than the ultimate high-molecular-weight polymers and, therefore, be amenable to reactive processing techniques. Furthermore, since cyclic oligomers would contain no end-groups, very high molecular weights should be achievable without the formation of reaction by-products typically formed in melt polycondensation reactions.

The cyclic aromatic oligocarbonates have been separated from the polymers and characterized by several groups.[116] First attempts to synthesize cyclic BPA oligocarbonates were performed using classical high-dilution techniques.[117] For example, Schnell and Bottenbruch[15,118] reported that the cyclic tetrameric carbonate (**5**, $n = 3$, **Scheme 13**) of BPA could be formed in about 21% yield via slow addition of equimolar amounts of bisphenol and its bischloroformate to pyridine in dichloromethane at a final monomer concentration of 0.05 M.

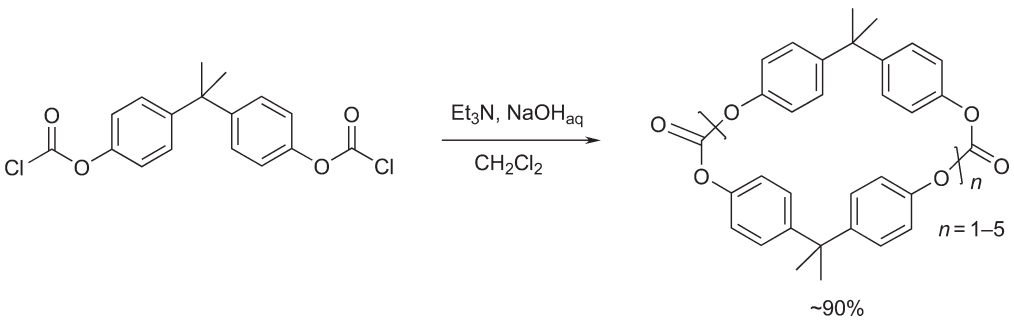
Currently it is possible to obtain low-molecular-weight cyclic oligomers completely selectively with respect to linear oligomers by applying pseudo-high-dilution conditions to a hydrolysis/condensation reaction of BPA bischloroformate, catalyzed by Et_3N in biphasic dichloromethane/$NaOH_{aq.}$ (**Scheme 14**).

After 1 h of reaction, the HPLC analysis of the crude product clearly shows a range of cyclic oligomers from dimer to docosamer (22 bisphenol units).[119] Selective formation of low-molecular-weight cyclic oligomers occurs even though the final product concentration is 0.2 M, much higher than usually used in cyclization reactions.

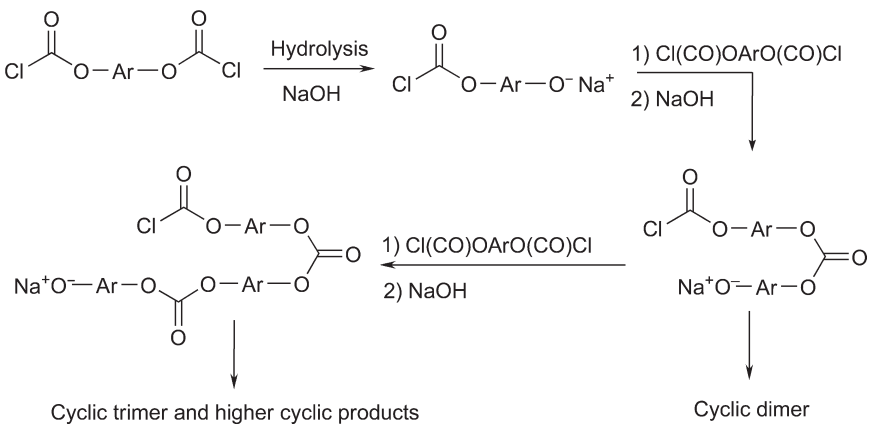
To form cyclic oligocarbonate from BPA–bischloroformate starting material, both hydrolysis and condensation reactions must occur (**Scheme 15**).[116] The selectivity of cyclic versus linear products and by-product polymer formation depends on the structure and concentration of the amine catalyst, reaction time and temperature, and pH of the interfacial medium.

In the hydrolysis–condensation reaction, the first step that must occur is the hydrolysis of at least one end of the bischloroformate molecule to form a phenoxide. Maintaining good pH control is important to ensure that highly reactive phenoxides, rather than protonated phenols, are present. Excessive pH can be destructive, since hydrolysis of the cyclic product could additionally occur. After chloroformate hydrolysis, the condensation with fresh bischloroformate entering the reaction can occur, leading to dimeric bischloroformate. As the dimeric bischloroformate itself undergoes hydrolysis, a key intermediate is formed, an oligomer with one phenoxide and one chloroformate end-group. This species can either form a cyclic oligomer or undergo further intermolecular reaction with incoming bischloroformate to form a trimer-bischloroformate which can undergo cyclization or be an intermediate in higher-molecular-weight oligomer formation.

The structure of the amine catalyst and its concentration proved to be critical to selective formation of cyclic carbonates. Application of Et_3N at 0.1 M concentration led to nearly exclusive formation of cyclic oligomers (90%). Examination of other



Scheme 14 Synthesis of low-molecular-weight cyclic oligocarbonates.



Scheme 15 Hydrolysis and condensation reactions leading to the formation of cyclic oligomers.

amines showed that amines less hindered than Et_3N (e.g., methyldiethylamine) led to mainly linear oligomer formation or mixtures of cyclics and linears. The use of very unhindered amines such as quinuclidine, 1,4-diazabicyclo[2.2.2]octane (DABCO), dimethylethylamine, or pyridine gave almost exclusively linear oligomers, or complete hydrolysis to BPA under more severe conditions. It is interesting to note that each of the five possible reaction outcomes is possible under the same reaction conditions, simply by changing the catalyst (cyclic and linear oligomers, polymer, complete hydrolysis, or no reactions).[116]

4.12.3 Polymerization of Aliphatic Cyclic Carbonates

The ability of cyclic monomers for ROP depends on both thermodynamic and kinetic factors. From the thermodynamic point of view the Gibbs energy (free enthalpy) change [ΔG_p] should be negative.[120–122] The Gibbs energy change in the polymerization is determined by the enthalpy and entropy changes (ΔH_p and ΔS_p) and temperature (T) according to the equation

$$\Delta G_p = \Delta H_p - T\Delta S_p$$

In this equation the monomer and polymer states and crystallinity should also be considered.

For most cyclic monomers of a small ring size ΔH_p and ΔS_p are both negative so they can polymerize only below a temperature known as the ceiling temperature (T_c).[122] The driving force for the polymerization of such monomers is their ring strain, which reflects the deviation from nondistorted bond angle values, bond stretching or compression, crowding repulsion between hydrogen atoms, and other substituents. The Gibbs energy of polymerization may also be expressed as

$$\Delta G_p = \Delta H_p^0 - T(\Delta S_p^0 + R \cdot \ln[M])$$

where ΔH_p^0 and ΔS_p^0 denote a standard polymerization enthalpy and entropy, respectively, [M] denotes monomer concentration, and R is the gas constant.

At equilibrium ($\Delta G_p = 0$) when polymerization is complete, the unreacted monomer concentration ($[M]_{eq}$) is determined by standard polymerization parameters ΔH_p^0 and ΔS_p^0 and polymerization temperature T. Thus, polymerization can occur only when $[M]_0 > [M]_{eq}$.

The angle and bond deformations are most pronounced for the three- and four-membered cyclic monomers and as a result $[M]_{eq}$ is very small. The five- and six-membered cyclic monomers are the least strained, and some of them are unable to polymerize. The introduction of a carbonyl group into the five-membered cycle makes the resultant compounds incapable of high polymer formation under normal conditions. This is caused by sp^2 hybridization of the carbon atom in the >C=O group. The six-membered cycloalkanes and cyclic ethers accept the most convenient chair conformation in which the energy of the conformational interactions is negligible and the hypothetical $[M]_{eq}$ is above any possible monomer concentration ($[M]_0$). In contrast, the presence of carbonate group in the six-membered cycle increases the strain, and cyclic carbonates can be easily polymerized. The carbonyl group introduces strain into six-membered rings due to the flat geometry of the carbonate moieties.

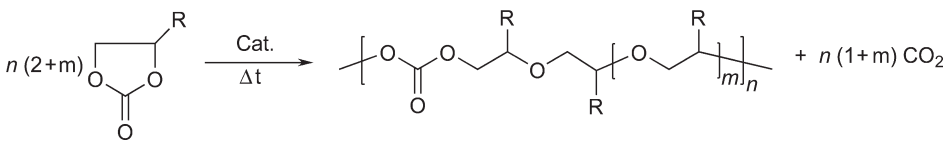
4.12.3.1 Polymerization of Five-Membered Cyclic Carbonates

Cyclic carbonates of the smallest ring size (aliphatic five-membered cyclic carbonates), such as EC (1,3-dioxolan-2-one) and PC (4-methyl-1,3-dioxolan-2-one), behave exceptionally in ROP. Their ceiling temperatures are below 25 °C and ΔH_p^0 is positive (above 120 kJ mol^{-1}), and so no ROP is possible leading to poly(alkylene carbonate), but they can be polymerized at high temperatures (above 150 °C) resulting in poly(ether-carbonate)s.[123] ΔH_{pd}^0 (standard enthalpy of polymerization with simultaneous decarboxylation) for EC becomes negative at 170 °C. The repeated units of the resultant polymers are a mixture of alkylene carbonate and the corresponding alkylene oxide units, which means that CO_2 is lost during the polymerization. Probably in this case the decarboxylation and small carbon dioxide molecules evolution make the ΔS_p^0 value positive and consequently, polymerization becomes thermodynamically possible at higher temperatures. Thus the polymerization of five-membered cyclic carbonates fails to produce thermodynamically disfavored poly(alkylene carbonate)s but leads to poly(alkylene ether-carbonate)s with contents of carbonate units lower than 50 mol.% (**Scheme 16**).[12,13,123–127]

Vogdanis and Heitz used a variety of catalysts for the polymerization of EC, ranging from dibutyltin dimethoxide to butyllithium and found that the retention of CO_2 decreased as the alkalinity of the catalyst increased. When a more basic catalyst was used, the resultant polymers contained 10–20 mol.% of EC units (reaction temperature was about 150 °C and reaction time was 72–98 h).[123,128]

Soga *et al.* proposed the mechanisms in which the polymerization of PC proceeded via spiroorthocarbonate species (2,7-dimethyl-1,4,6,9-tetraoxaspiro[4.4]nonane). To conform this mechanism the authors polymerized the spiroorthocarbonate in the presence of diethylzinc as a catalyst and obtained poly(propylene ether-carbonate) of similar chemical structure.[124] It means that in the first reaction step the monomer decarboxylation takes place. The decarboxylation involves most probably metal carbonate species formation due to the 1,3-dioxolan-2-one ring opening via the alkyl carbon–oxygen bond cleavage.[129]

Detailed investigations of the mechanism of five-membered cyclic carbonate polymerization initiated with tin and zirconium alkoxides were carried out by Kricheldorf *et al.*.[130,131]

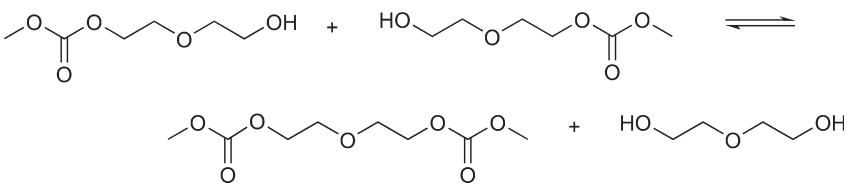


Scheme 16 Polymerization of five-membered cyclic carbonates.

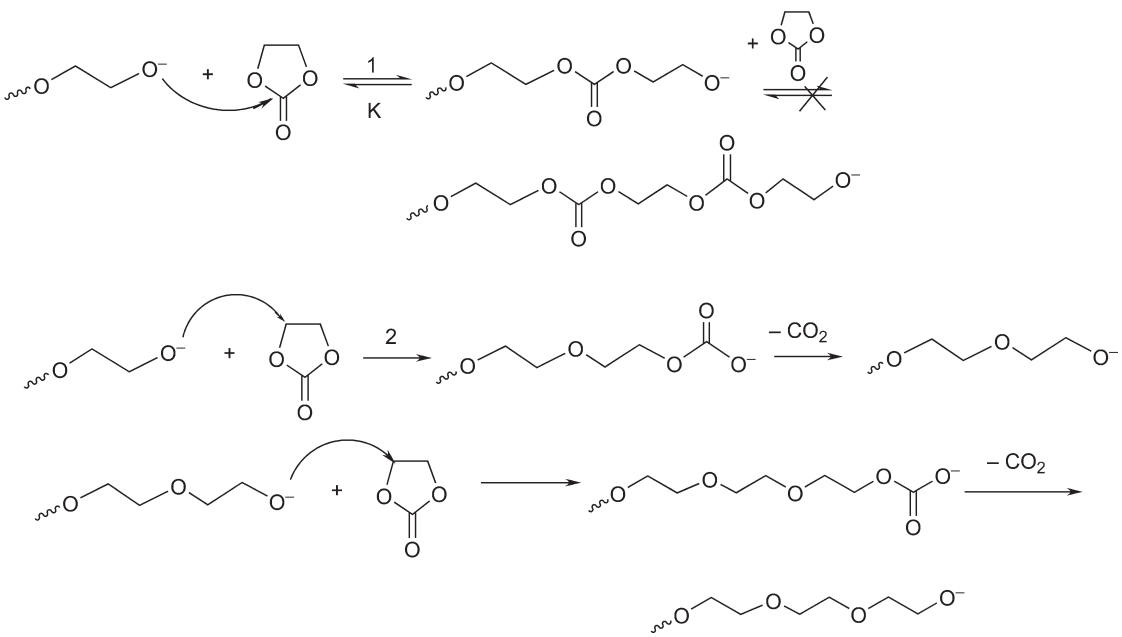
Harris has reported the use of sodium stannate trihydrate as a heterogeneous catalyst in EC polymerization.[125,132] The structures of obtained oligomers have been studied by alkaline degradation to the oligo(oxyethylene) glycols, which make up their backbone, followed by GC analysis. Based on the analytical techniques, it was possible to establish the composition of a given poly(ethylene ether-carbonate) diol. Harris and McDonald[126] have found that 2-hydroxyethyl carbonate and 2-hydroxyethyl ether end-groups are present at the beginning in the polymerization mixture. However, only 2-hydroxyethyl ether end-groups were present during the latter stages of polymerization. When poly(ethylene ether-carbonate) diols were heated at temperatures above 180 °C under reduced pressure, volatile by-product – diethylene glycol (DEG) – was removed, followed by molecular weight advancement. Under such conditions the transesterification process proceeds in which $-OC(O)OCH_2CH_2OCH_2CH_2OH$ end-groups of one molecule react with carbonate moieties of a second molecule with loss of DEG (**Scheme 17**).

Poly(ethylene ether-*co*-ethylene carbonate) diols obtained in this manner had a relatively low dispersion index.[133] Sodium stannate is a preferred catalyst for the preparation of poly(ethylene ether-carbonate) diols. The rate of advancement to 3000 molecular weight products increased together with CO_2 retention when the tin catalyst concentration level was 100–500 ppm. At higher catalyst concentration levels, the product decomposition to 1,4-dioxane became more intensive.[134,135] The same authors also applied dibutyltin diacetate, dilaureate, and dimethoxide as catalysts for EC polymerization.

The process of EC polymerization with an alkaline initiator was analyzed and discussed in more detail by Lee and Litt.[136] They polymerized EC in bulk at 150–200 °C using various amounts of KOH as the initiator. The products were analyzed by gel permeation chromatography (GPC) and NMR spectroscopy. Maximal molecular weights of the polymers did not exceed 7000 after about 3–5 h of heating at 200 °C for the EC/KOH molar ratio = 1000/1. It was shown that the ratio of the rate of polymerization to that of chain scission increased as temperature rose. The EO sequences in the polymer backbone were converted to oligo(oxyethylene) glycols by alkaline hydrolysis of the copolymer. Under such conditions the carbonate linkages easily and fully degrade. Taking the above results into account the authors suggested that in the early stage of the polymerization a major polymer structure comprises one EC unit per two EO units. For longer reaction times the content of EO units increases. The content of EC units, even in the earliest stage of the reaction, was not higher than 32 mol.%. They claimed that polymerization proceeds in two stages. During the first stage EC conversion takes place and molecular weight increases. In the second stage, when no EC is present in the reaction mixture, both the number of EC units and molecular weight decrease with time. The latter indicates that chain cleavage and decarboxylation take place. There are two possible reaction pathways between the alkoxide ion and EC monomer (**Scheme 18**).



Scheme 17 Homocondensation of 5-hydroxy-3-oxapentylcarbonate groups.



Scheme 18 Formation of poly(ethylene ether-carbonate)s.

According to pathway 1 (Scheme 18), the carbonyl carbon atom in EC is attacked by the alkoxide ion and 2-hydroxyethyl carbonate group is formed. On the other hand, the alkyl carbonyl atom is subjected to nucleophilic attack (2), resulting in decarboxylation and irreversible formation of a DEG unit. Rokicki *et al.*[137] reported the loss of CO_2 from alkyl-potassium carbonate such as 2-(1-phenoxy)propyl potassium carbonate above 150 °C. It should be mentioned that the reaction with carbonyl group (1) is reversible. Kinetically, the carbonyl attack is favored over the alkylene one.

Lee and Litt suggested that the most probable EC polymerization mechanism under basic conditions should be a combination of an alkylene carbon attack (2) and a carbonyl carbon attack (1). However, it should be underlined that the product of reaction (1) cannot react with another EC molecule in the same manner because the formation of the EC–EC sequence is thermodynamically forbidden. Rokicki and Pawlowski investigated the reaction of EC with different diols catalyzed by various alkali metal salts (NaCl, K_2CO_3). The reaction was carried out in xylene with azeotropic distillation of ethylene glycol formed as a side product. They found that to suppress the reaction proceeding according to pathway (2), the diol with long hydrocarbon chain (e.g., 1,6-hexanediol) and less basic catalyst such as NaCl should be used; the reaction temperature should be lower than 145 °C. The products were analyzed by MALDI-TOF mass spectrometry and NMR spectroscopy. The molecules of the resultant oligomer had no more than two EC units (as two terminal 2-hydroxyethylcarbonate groups). It means that terminal –O–(C=O)–OCH_2CH_2O– alkoxide groups cannot react with EC molecule according to pathway (1) (Scheme 19) as well as the transesterification reaction between two 2-hydroxyethylcarbonate groups is not possible (Scheme 20).

Thus, the most plausible reaction mechanism illustrating the formation of EC–EO–EO sequence comprises the formation of tri(ethylene oxide) fragments according to reaction pathway (2) and reaction with EC applying the carbonyl carbon atom attack (pathway 1) (Scheme 18).

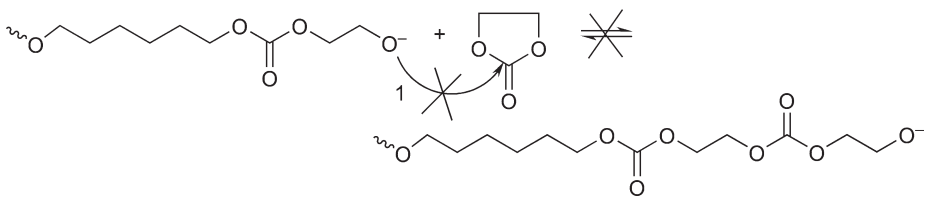
Lee and Litt have also observed that in the second stage (after 19 h heating at 180 °C) vinyl ether groups were formed. In the ^{1}H NMR spectra of the product characteristic signals at 6.47 ppm were present which could be assigned to methine protons of vinyl ether. Their intensity increased with the reaction time. The authors discussed two possible elimination reaction mechanisms: pyrolytic (Ei) and bimolecular (E2) eliminations (Scheme 21).

However, taking into account that Ei elimination is a first-order intramolecular reaction and vinyl ether groups formation started in the second stage, bimolecular elimination (E2) is more plausible. In this process proceeding in the presence of a strong base such as alkoxide, proton abstraction from EC unit may occur leading to the vinyl ether formation, chain scission, and decarboxylation. A relationship between carbonate content and degree of polymerization was derived using both decarboxylation and bimolecular elimination reactions for the kinetic equations. The authors indicated that this reaction sequences fit the experimental data.

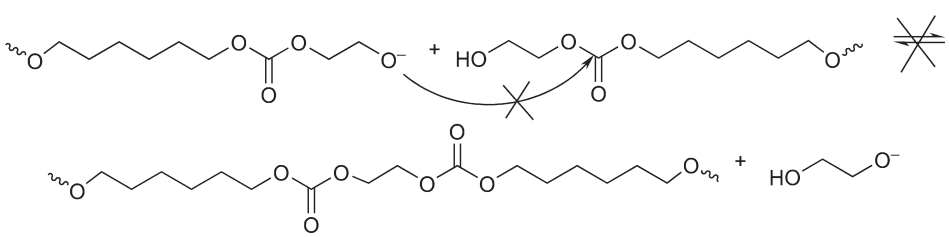
The process of PC oligomerization in the presence of less alkaline catalyst system was also investigated by Keki *et al.*[138,139] The ring-opening oligomerization of PC was initiated with *tert*-butylphenol/$KHCO_3$. The resultant oligomers were analyzed by means of MALDI-TOF and ESI-TOF mass spectrometries. It was found that in addition to the chain extension reaction with the PO units, the oligomers of all of the PO units and oligomers containing carbonate end-groups condensed. However, the proposed mechanism is less plausible. The alkyl carbonate anion is unstable under the reaction conditions, so fast decarboxylation should take place.

Elmer and Jannasch[140] prepared poly(ethylene oxide-*co*-ethylene carbonate)s by the anionic polymerization of EC with CH_3OK as an initiator. Reaction mixtures composed of EC and CH_3OK in the CH_3OK/EC molar ratio of 1:1000 containing 50 ppm of an antioxidant – triethylene glycol bis-3-(30-*tert*-butyl-40-hydroxy-50-methylphenyl)propionate – was heated at 180 °C. An oligomer having a number-average molecular weight of 2650 and an EC content of 28 mol.% was obtained. This cooligomer was used as a raw material for the preparation of solid polyelectrolyte in lithium batteries.

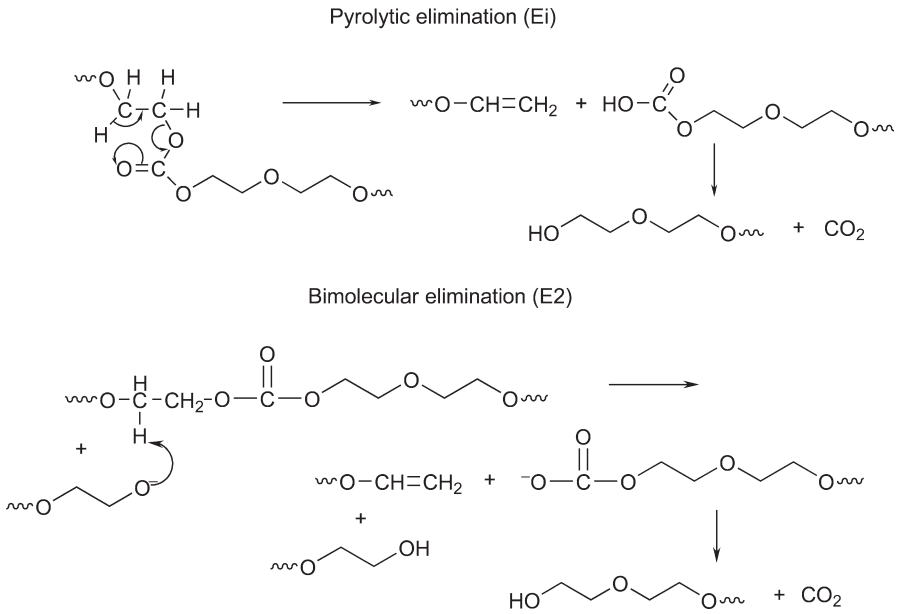
Recently, Wu *et al.* reported that the polymerization of PC carried out in the presence of BPA initiated with organic bases such as DABCO, 1,8-diazabicyclo[5.4.0]undec-7-ene



Scheme 19 Forbidden reaction of 2-hydroxyethylcarbonate groups with ethylene carbonate.



Scheme 20 Forbidden homocondensation of 2-hydroxyethylcarbonate groups.



Scheme 21 Formation of vinyl groups after heating poly(ethylene ether-carbonate) at 180 °C.

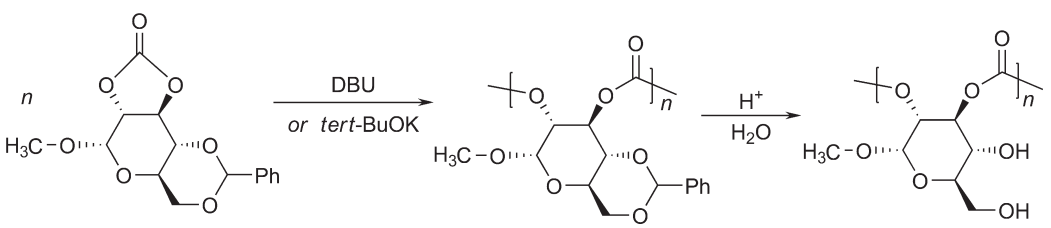
(DBU), 1,5-diazabicyclo[4.3.0]non-5-ene (DBN), and *N*, *N*-dimethylaminopyridine (DMAP) afforded polyether diols containing BPA moiety.[141] It was shown by MALDI-TOF spectrometry and ^{1}H and ^{13}C NMR spectroscopies that the product obtained from 4-*tert*-butylphenol and PC at 150 °C contained some amount of oligomers with carbonate linkages. The authors suggested that phenols were ionized by an organic base to form an active phenol anion which attacked cyclic carbonate monomer to generate intermediate ions that could further capture proton and react with phenol itself to yield polyether or poly(ether-carbonate).

Another approach was presented by Kadokawa *et al.*[142] They proceeded with the ROP of EC using two ILs, 1-butyl-3-methylimidazolium chloroaluminate ([bmim]Cl-$AlCl_3$) and 1-butyl-3-methylimidazolium chlorostannate ([bmim]Cl-$SnCl_2$), as polymerization catalysts. Although polymerization in the presence of [bmim]Cl-$AlCl_3$ took place even at temperatures below 100 °C, frequent decarboxylation occurred to give polymers with low content of EC units. When the polymerization was performed in the presence of [bmim]Cl-$SnCl_2$ higher reaction temperatures were required. In this case the maximal amount of carbonate units present in the copolymer was 33.9 mol.%.

4.12.3.1.1 Polymerization of five-membered cyclic carbonates with a strained ring

In contrast to typical five-membered cyclic carbonates, which polymerize at high temperatures ($T > 150$ °C) leading to poly(ether-carbonate)s, five-membered cyclic carbonates obtained from methyl 4,6-*O*-benzylidene-glucopyranoside can be polymerized at relatively low temperatures, without elimination of carbon dioxide, to produce homopolycarbonates.[143–145] The polymerization of such a monomer was carried out at 60 °C in tetrahydrofuran (THF) or dimethylformamide (DMF) yielding a polymer exclusively consisting of carbonate repeating units (Scheme 22). Two types of initiators were used: DBU and potassium *tert*-butoxide. It was shown that the polymerization proceeded smoothly even at 30 °C to give the PC of $M_n = 14\,000$ in 93% yield.

To confirm the homopolycarbonate structure, Haba *et al.* hydrolyzed the resulting polymer using KOH in ethanol. The hydrolysis product and the model compound prepared by them from methyl *R*-D-glucopyranoside and benzaldehyde dimethyl acetal were the same.[146] It means that no elimination of carbon dioxide during the anionic polymerization took place and no etherification occurred. The authors presumed that the ring strain was the driving force of ROP of this five-membered cyclic carbonate. The ring strain may result from the connection of two hydroxyl groups in E (*trans*) position by the carbonate linkage. In addition, the carbonate ring is connected on one side to the rigid bicyclic structure of methyl 4,6-*O*-benzylidene-glucopyranoside. The acetal groups in the resulting polymer can be removed by acidic hydrolysis. The presence of two hydroxyl groups in the monomeric units activates such PC to hydrolytic degradation (Scheme 22). Taking



Scheme 22 Polymerization of the five-membered cyclic carbonate with the strained ring.

into account that the monomer was obtained from natural sugar the resultant PC can find application in biomedicine, where fast hydrolityc decomposition is the most important factor.

As far as cationic polymerization concerns, it was shown by Kricheldorf and Jenssen that EC did not react with a cationic-type catalyst such as methyl triflate.[147] No polymer or oligomer was found after 48 h of reaction carried out in nitrobenzene at 100 °C.

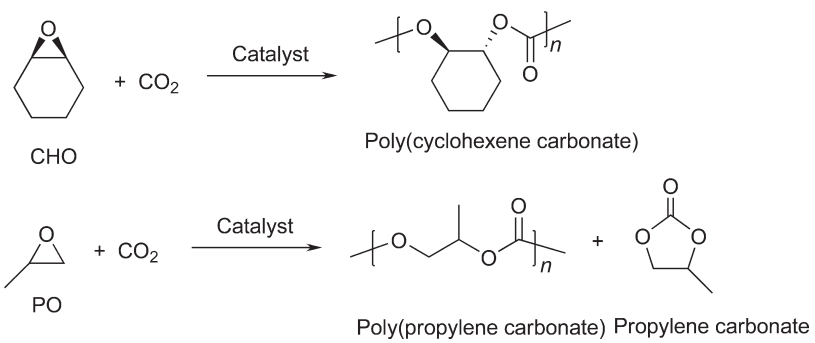
The aromatic five-membered cyclic carbonate (benzo-1,3-dioxolan-2-one) appeared inert in anionic polymerization initiated with *sec*-BuLi and potassium dihydronaphthalide.[111]

On the other hand, the high-molecular-weight aliphatic PC with an alternating sequence of the monomeric alkylene units can be obtained by copolymerization of oxiranes with CO_2 using coordination catalysts under appropriate reaction conditions. In 1969, Inoue and co-workers[148] made the remarkable discovery that a mixture of $ZnEt_2$ and H_2O was active as a catalyst system of the alternating copolymerization of PO and CO_2 (Scheme 23), initiating epoxide–CO_2 coupling chemistry. Since the 1970s, a great number of publications dealing with copolymerization of CO_2 with oxiranes and oxetanes have appeared. The reviews concerning CO_2 copolymerization and catalysts used are also available, especially prepared by Inoue, Kuran and Rokicki, Darensbourg and Holtcamp, Super and Beckman, Kuran, Coates and Moore, and very recently by Darensbourg.[33,143,149–153]

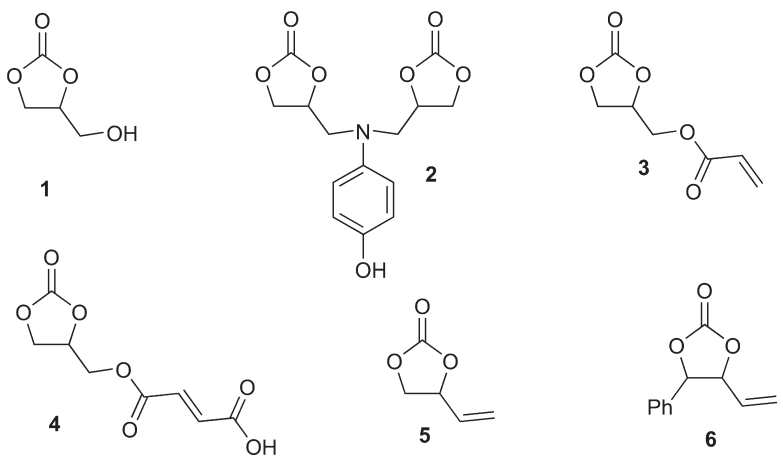
4.12.3.1.2 Polymerization of five-membered cyclic carbonates containing functional groups

Aside from the simple alkyl-substituted five-membered cyclic carbonates many derivatives of EC have been developed in recent years that contain added functionality, that is, derivatives bearing reactive groups in addition to the carbonate ring itself.[154] Among them, there are vinyl moieties, esters, ethers, and alcohols (Scheme 24).

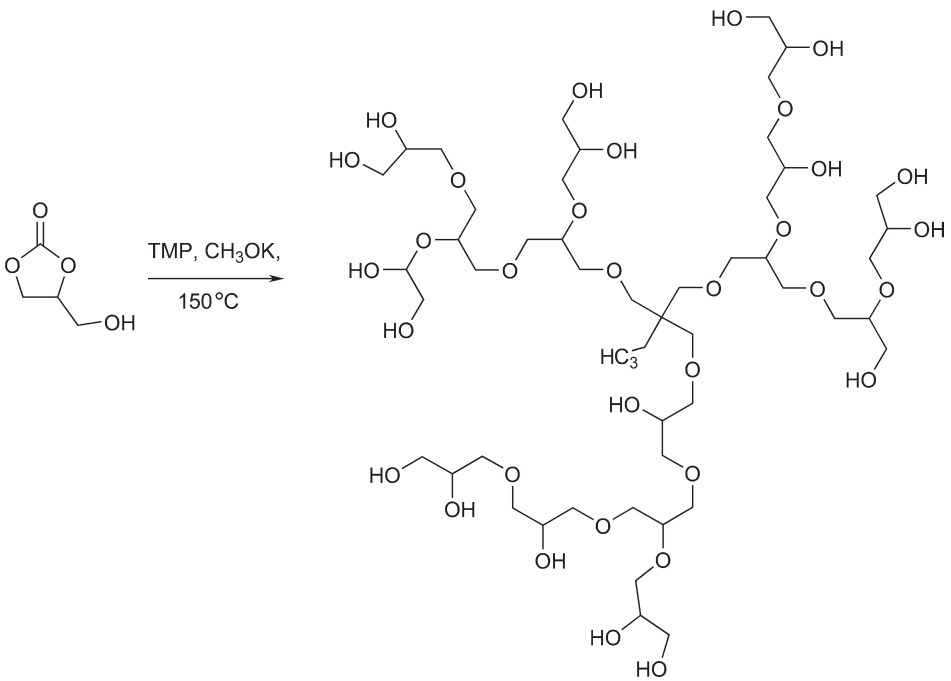
Of these, only GC (1, Scheme 24) has been commercialized so far. GC is a stable, colorless liquid that is used as a solvent, additive, and chemical intermediate. As a chemical intermediate it reacts readily with alcohols, phenols, and carboxylic acids with loss of CO_2 as well as with aliphatic amines with carbon dioxide recovery and β-hydroxyurethane bond formation. GC can be obtained according to various methods, using epoxy compounds as well as glycerol as raw materials.[155–158] It was reported that GC can be formed in the reaction of epichlorohydrin with $KHCO_3$ carried out at 80 °C in the presence of 18-crown ether.[24] Nevertheless, more attractive methods are those utilizing glycerol as a renewable and cheap raw material. A typical method of obtaining carbonate derivatives of glycerol is its transesterification with EC or dialkyl carbonate. In the reaction with EC carried out at 125 °C in the presence of sodium bicarbonate the product was formed in a yield of 81%.[159] Very promising methods of GC preparation comprise the reaction of glycerol with CO_2 or carbon monoxide and oxygen in the presence of Cu(I) catalysts.[160] The reaction of



Scheme 23 Copolymerization of cyclohexene oxide and propylene oxide with CO_2.



Scheme 24 Five-membered cyclic carbonates containing functional groups.



Scheme 25 Anionic polymerization of glycerol carbonate.

glycerol with carbon dioxide was carried out in a $scCO_2$ medium in the presence of zeolite and EC as a cosource of carbonate groups.[161] However, according to all the above-mentioned methods GC should be purified by distillation under reduced pressure at a relatively high temperature (125–150 °C).

Rokicki *et al.* showed that the GC synthesis can be carried out under mild conditions without any solvent, using glycerol and dimethyl carbonate as environmentally benign and renewable reagents.[162] Due to the almost quantitative reaction yield there was no need for the product purification by distillation at high temperature and recovery of unreacted glycerol.

GC alone can be a valuable monomer for the synthesis of hyperbranched poly(hydroxyether)s (**Scheme 25**).[158] In case of polymerization, GC, containing a 1,3-dioxolan-2-one ring and hydroxyl group in a single molecule, is considered a latent cyclic AB_2-type monomer. The anionic ROP of the GC, which proceeds with CO_2 liberation, leads to a branched polyether. 1,1,1-Tris(hydroxymethyl)propane or other multihydroxyl molecules are usually used as a initiator-starter and central core of the polyether. The hyperbranched polyglycerol structure is obtained by slow addition of the cyclic carbonate monomer at above 150 °C. Such polymers are characterized by a flexible polyether core and a multihydroxyl outer sphere. They are suitable for preparation of acrylic resins for dental applications or additives for polyurethane foams. Hyperbranched poly (hydroxyether)s from biscyclic carbonate with phenol group (**2**, **Scheme 24**) were also reported.[162,163]

Because it contains a hydroxy group, GC can be reacted with anhydrides,[164,165] acyl chlorides,[166] isocyanates,[167] and the like. For instance, GC reacted with the multifunctional isocyanate polymeric methylene diphenyl diisocyanate (MDI) in the presence of potassium acetate gave a multifunctional alkylene carbonate.[168] The reaction of GC with isocyanates occurs at room temperature or with slight heating and is generally accompanied by an exotherm such that the controlled addition of one component into the other is desired. The multifunctional carbonates prepared by means of the above process are useful as blow promoters in the preparation of polymeric foams,[168] or they can be reacted with aliphatic diamines to prepare polyurethane resins.

Five-membered cyclic carbonate rings can be also generated on existing polymeric species. For example, hyperbranched polyglycerol was reacted with dimethyl carbonate yielding multifunctional alkylene carbonate.[169] In contrary, soybean oil-based multifunctional alkylene carbonate was prepared via epoxidation of double bonds followed by a pressure reaction with CO_2 catalyzed with KI-crown ether system.[170] Such carbonate derivatives were applied as toughening agents for amine-cured epoxides. Although not yet commercially available, multialkylene carbonates can also be prepared from epoxy resins via CO_2 insertion.[171]

Vinyl-functional alkylene carbonates, useful in the preparation of polymers that contain alkylene carbonate pendant groups, can also be prepared from GC. Two examples are the reaction of GC with maleic anhydride and acryloyl chloride to produce the acrylate-functional cyclic carbonates (**3** and **4**, respectively, **Scheme 24**).[164] Although the transesterification of alkyl esters such as dimethyl maleate or methyl acrylate by reaction with GC represents an obvious means of obtaining the above materials, the temperatures required of such processes (> 100 °C) result in unwanted polymerization of both the reactant and product species, even in the presence of well-known radical inhibitors such as 2,6-di-*tert*-butyl-*p*-cresol or phenothiazine.[164] In addition, the synthesis of vinyl-functional alkylene carbonates is greatly complicated by the fact that such materials cannot be purified by distillation and must be stored at temperatures < 0 °C in the presence of a

polymerization inhibitor.[172] In fact, these and similar species are known to undergo polymerization much more readily than the analogous underivatized vinyl monomers.[173,174]

Vinyl-functional alkylene carbonates can also be prepared from the corresponding epoxides in a manner similar to the commercial manufacture of ethylene and PCs via CO_2 insertion. The most notable examples of this technology are the syntheses of 4-vinyl-1,3-dioxolan-2-one (vinyl ethylene carbonate, VEC) (**5**, Scheme 24) from 3,4-epoxy-1-butene[175] or 4-phenyl-5-vinyl-1,3-dioxolan-2-one[176] (**6**, Scheme 24) from analogous aromatic derivative 1-phenyl-2-vinyl oxirane. Although the homopolymerization of both vinyl monomers produced polymers in relatively low yield, copolymerizations effectively provided cyclic carbonate-containing copolymers. It was found that VEC can be copolymerized with readily available vinyl monomers, such as styrene, alkyl acrylates and methacrylates, and vinyl esters.[175] With the exception of styrene, the authors found that VEC will undergo free-radical solution or emulsion copolymerization to produce polymeric species with a pendant five-membered alkylene carbonate functionality that can be further cross-linked by reaction with amines. Polymerizations of 4-phenyl-5-vinyl-1,3-dioxolan-2-one also provided cyclic carbonate-containing copolymers.

4.12.3.2 Polymerization of Six-Membered Cyclic Carbonates

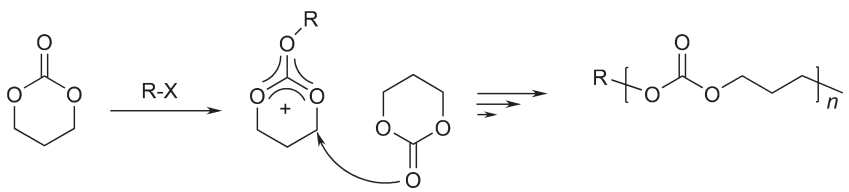
Six-membered cyclic carbonates such as TMC and neopentyl carbonate, in contrast to thermodynamically unfavorable five-membered cyclic carbonate, easily polymerize to afford PCs without ether sequences. Taking into consideration that the ROP of cyclic carbonates is an equilibrium reaction, six-membered cyclic carbonates show a strong substitution effect on the equilibrium monomer concentration. The anionic ROP of TMC and 5,5-disubstituted 1,3-dioxan-2-ones (dimethyl, methyl-phenyl, diethyl, ethyl-phenyl) in THF solution using potassium *tert*-butoxide initiator exhibited an increasing monomer concentration at equilibrium, with an increasing bulkiness of the substituents. This correlates with the yields obtained in monomer synthesis: the higher the steric effect of the substituents, the higher the selectivity toward the cyclic monomer in comparison to the linear oligomers. An estimation of the thermodynamic parameters reflected the polymerizability of the monomers ($\Delta H_p^0 = -26.37$ to $-5.02\ kJ\ mol^{-1}$); a decrease in the absolute value of ΔH_p^0 is observed for monomers with increased bulkiness of the substituents. The reason for the decrease in polymerizability of the six-membered cyclic carbonates with increased bulkiness of the substituents lies in the conformational distortion of the polymer backbone, rather than in the change of conformation of the monomer caused by the substituents.[6,145]

4.12.3.2.1 Cationic polymerization of six-membered cyclic carbonates

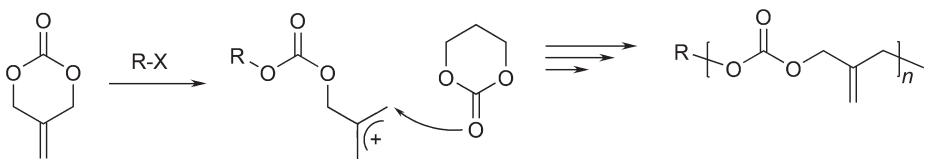
In ROP of aliphatic cyclic carbonates proceeding according to the cationic mechanism, electrophilic reagents are used as initiators. Brønsted and Lewis acids, as well as alkyl esters of strong organic acids (e.g., methyl trifluoromethanesulfonate) are most often involved. Cyclic carbonates contain polarized bonds (C=O)–O, in which carbonyl oxygen atom has a lone electron pair so that it can act as a Lewis base in reaction with an electrophilic initiator. As a result, an alkoxy-substituted carbon atom (trialkoxycarbenium cation) becomes a cationic center. In this mode the ring-opening reaction of the monomer will be caused by the nucleophilic attack of a lone electron pair of a carbonyl group oxygen toward the electrophilic initiator. The resulting cationic species of a cyclic structure can be attacked by another molecule of the monomer to undergo a ring-opening reaction according to S_N2 mechanism (Scheme 26).[6,177]

In contrast, cyclic carbonate with an *exo*-methylene substituent in the ring polymerizes via an S_N1 mechanism. Such a monomer can undergo ring-opening reaction spontaneously to produce a linear product with allyl cation that will be attacked by the carbonyl oxygen atom of the next monomer molecule according to the S_N1 mechanism (Scheme 27). It should be noticed that allyl carbocation is stabilized by an electron delocalization.

The stability of the cation, in this case trialkoxycarbenium cation versus allyl one, decides which of these two mechanisms predominates.[177–179] The selective ROP of 5-methylene-1,3-dioxan-2-one to the linear PC can be explained by assuming that the competitive vinyl polymerization is suppressed by neighboring electron-withdrawing carbonate group.[178]



Scheme 26 Cationic polymerization of six-membered cyclic carbonate in accordance with S_N2 mechanism.



Scheme 27 Cationic polymerization of six-membered cyclic carbonate in accordance with S_N1 mechanism.

It is well known that cationic polymerization of heterocyclic monomers such as oxiranes can proceed according to two mechanisms: activated monomer (AM) and active chain end (ACE) ones. In the polymerization proceeding according to an AM mechanism, the active centers are located on the monomer molecule, while the growing polymer chain is neutral. Taking into account that in the cationic AM mechanism there is no active species at the chain end, the backbiting is to a large extent reduced. In order to suppress the reaction proceeding according to ACE mechanism the instantaneous concentration of monomer in the reaction mixture should be kept very low (e.g., by continuous very slow monomer addition).[122,180,181]

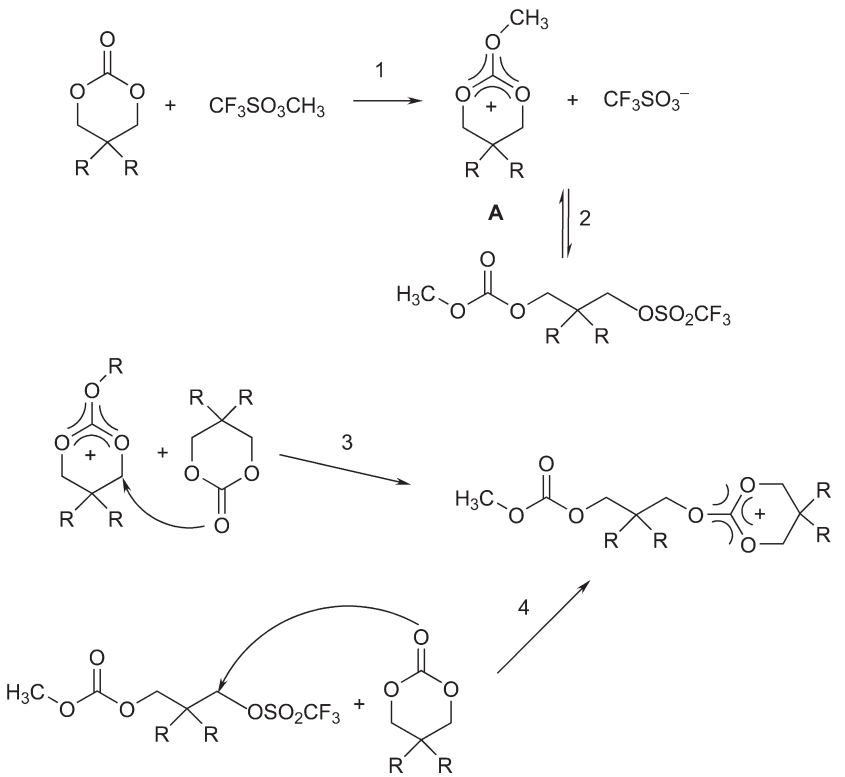
The ROP of TMC initiated with several alcohols was examined by Endo's group.[86] It was found that the reactions proceeded without acidic catalyst in low conversions. However, when the polymerization was carried out in the presence of alcohol/trifluoroacetic acid (ROH/TFA) catalyst system the corresponding PCs with $M_n = 2500–6800$ were formed. The molecular weights increased with an increase of the monomer conversion. Mechanistic aspects studied by NMR spectroscopy indicated that carbonate rings are activated by TFA. The signals of the methylene protons shifted to lower fields by 0.06–0.11 ppm in the ^{1}H NMR spectra after the addition of TFA. Downfield shifts of the carbonyl carbon atom signals in TMC were observed by 3.94–4.15 ppm in the ^{13}C NMR spectra.

Recently, Hyun *et al.*[182] have revealed that TMC can be polymerized according to the AM mechanism when a poly (oxyethylene) glycol/HCl · OEt_2 system was used as a cationic initiator. The polymerization of TMC in the presence of HCl · OEt_2 gave triblock or diblock copolymers composed of poly(ethylene glycol) (PEG) and PTMC units depending on the used PEG or monomethyl-PEG. The obtained PTMC had molecular weights close to the theoretical values calculated from TMC/PEG molar ratios (e.g., 920-2000-920) and exhibited a monomodal GPC curve without any trace of dead polymer. The terminal hydroxy group of PEG served as an initiator in this polymerization system.

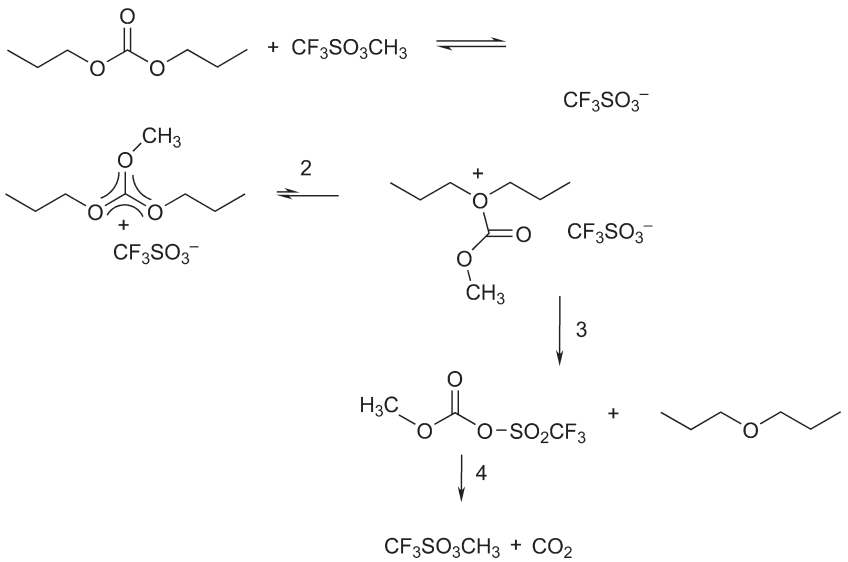
The mechanism of cationic polymerization of six-membered cyclic carbonates was also investigated and discussed by Kricheldorf *et al.*[183] Using IR and ^{1}H NMR spectroscopies it was shown that methyl triflate initiated the polymerization of six-membered cyclic carbonates by alkylation of the *exo*-cyclic oxygen atom of the carbonate linkage, generating a trialkoxycarbenium ion, **A** (**Scheme 28**). The reaction equilibrium is established after ring opening by the counterion (eqn [2]). Another molecule of cyclic carbonate can attack the trialkoxycarbenium ion leading to the alkyl–oxygen bond cleavage and the *exo*-cyclic oxygen atom of the nucleophile is alkylated (eqn [3]). The second possible propagation reaction is between the covalent triflate and monomer (eqn [4]).

When an excess of methyl triflate was used it was possible to establish that the covalent initiator is slightly more reactive than the trialkoxycarbenium ion.[147,183] Thus, the propagation reaction involves the cleavage of the alkyl–oxygen bond in the monomer. The active cationic chain end and the dead methyl-carbonate end-groups were identified by means of ^{1}H NMR spectroscopy.

However, the main disadvantage of the cationic polymerization of six-membered cyclic carbonates is the decarboxylation as a side reaction resulting in the formation of ether linkages. The



Scheme 28 Cationic polymerization of six-membered cyclic carbonates initiated with methyl triflate.



Scheme 29 Formation of ether linkages in cationic polymerization of six-membered cyclic carbonates.

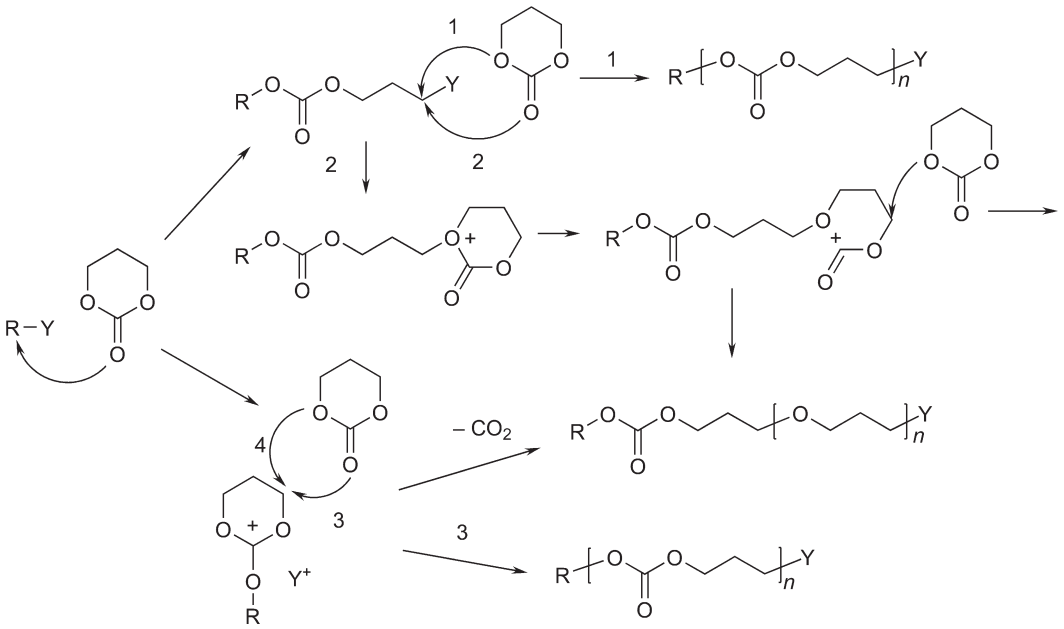
concentration of the ether groups, depending on the chemical structure of the monomer, cationic initiator, and temperature, is in the range of 3–10 mol.% relative to carbonate groups. Molecular weights of the polymers obtained according to this mechanism do not exceed 6000, owing to side reactions such as backbiting and formation of ether groups. The intramolecular migration of an alkyl group is proposed to explain the formation of ether linkages (Scheme 29). The equilibrium 2 is shifted to the trialkoxycarbenium ion due to its better stabilization. But still intramolecular migration is possible and the initiator can be regenerated as shown in eqn [4]. The decarboxylation of carbonates catalyzed by cationic initiators was confirmed by the reaction of diethyl carbonate with 5 mol.% of methyl triflate carried out under reflux. Slow CO_2 evolution and ether formation were observed. After 16 h, 30 mol.% conversion of carbonate groups was found. The ^{1}H NMR spectra of the reaction mixture also revealed the formation of methyl carbonate groups and ethyl triflate that support the proposed reaction mechanism illustrated by eqns [1–4] (Scheme 29).

Other Lewis acids such as $BF_3 \cdot OEt_2$, BCl_3, and BBr_3 were used by Kricheldorf and Weegen-Schulz for the polymerization of neopentyl carbonate and TMC under various conditions. It was found that the six-membered cyclic carbonates and boron halogenides formed crystalline complexes. Depending on the reaction conditions, BCl_3 and BBr_3 react with both cyclic carbonates by ring opening and halogen transfer without initiating polymerization. In contrast, $BF_3 \cdot OEt_2$ initiates polymerizations to give high yields (> 95%) and high molecular weights (M_w > 100 000). However, the resulting PCs contained ether linkages. The molar fraction of ether groups increased with the reaction temperature. Moreover, kinetic data and ^{1}H NMR end-group analyses suggested that a cationic polymerization mechanism involved cyclic trialkoxycarbenium ions in analogy to methyl triflate-initiated polymerizations of six-membered cyclic carbonates (Scheme 29). However, backbiting degradation is much more efficient in the case of the methyl triflate-initiated polymerizations presumably due to the reactivity of a covalent triflate end-group.[147]

Also tin(IV) halogenides ($SnCl_4$, $SnBr_4$, and SnI_4) afforded PCs by cationic ROP.[184] The highest molecular weight (M_w = 150 000) was obtained when the polymerization of six-membered cyclic carbonate (TMC) had been conducted in bulk at 60 °C in the presence of SnI_4. In contrast, $SnCl_4$ and $SnBr_4$ caused partial decarboxylation even at 60 °C (~ 2 mol.%). Both $SnCl_4$ and $SnBr_4$ can form crystalline 1:2 complexes with TMC.[185] IR and ^{1}H ^{13}C NMR spectroscopies indicated complexation at the carbonyl oxygen. Additionally, CH_2OH, CH_2Cl, and CH_2Br end-groups were detected by ^{1}H NMR spectroscopy. Kinetic measurements of polymerization in solvents of different polarity suggested cationic polymerization proceeding according to the AM mechanism.

Organotin(IV) compounds such as $BuSnCl_3$, Bu_2SnCl_2, and Bu_3SnCl were also used for polymerizations of TMC.[186] The polymer yields above 90% were obtained with all three compounds, but their reactivities decreased in the order $BuSnCl_3 > Bu_2SnCl_2 > Bu_3SnCl$. The maximum molecular weights decreased in the same order. The PC of the highest molecular weight (M_w = 250 000) was obtained for $BuSnCl_3$. By means of ^{1}H and ^{13}C NMR spectroscopies the authors revealed that $BuSnCl_3$ forms complexes with the carbonyl group of TMC. In the ^{1}H NMR spectra signals corresponding to CH_2OH and CH_2Cl polymer end-groups were present regardless of the used initiator. Kinetic studies and a comparison with Bu_3SnOMe suggest that at least $BuSnCl_3$ initiates the polymerization proceeding according to a cationic mechanism. It should be noticed that, in contrast to $SnCl_4$, $BuSnCl_3$ did not cause decarboxylation.

Also Albertsson and Sjoeling[87] have reported that bulk polymerization of TMC, especially at higher temperatures (80–100 °C), and preferably when using $BF_3 \cdot OEt_2$ as initiator, afforded PTMC with high molecular weight (~ 100 000). At higher reaction temperatures higher molecular weight could be obtained, but thermal degradation of PTMC and ether group formation were observed. The polymer obtained with this cationic initiator contained about 3 mol.% of ether linkages. Other cationic initiators such as $AlCl_3$ gave a polymer



Scheme 30 Polymerization of six-membered cyclic carbonate with alkyl halide – possible reaction pathways.

of much lower molecular weight. Polymerization in solution gave mostly oligomers.

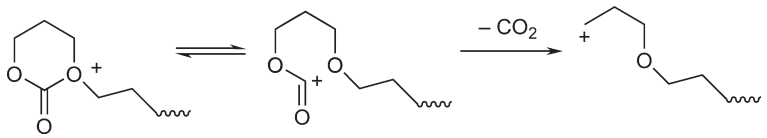
Ariga *et al.*[88,187] have revealed that when alkyl halides were used as cationic initiators for six-membered cyclic carbonates the ROP proceeded without decarboxylation and the corresponding homopolycarbonates, but of rather low molecular weights, were formed. The reactions of PTMC with several cationic initiators including methyl iodide were monitored by ^{1}H NMR and GPC. Both a decrease in the polymer molecular weight and the ether units content strongly depended on the kind of initiator. PM3 molecular orbital calculations using model compounds confirmed that the decarboxylation occurred mainly in the propagation step (**Scheme 30**).

The reaction of TMC with an excess of alkyl halide such as methyl iodide and benzyl bromide at 120 °C afforded the corresponding 1:1 adducts. The yield of the adduct from methyl iodide was only 10%, while the yield of that from benzyl bromide was 78%. The cationic polymerizations of different cyclic carbonates with alkyl halides such as methyl iodide (RY = CH_3I), benzyl bromide (RY = $C_6H_5CH_2Br$), and allyl iodide (RY = $CH_2=CHCH_2I$) carried out under various conditions led to the corresponding PCs without any ether units (pathway 1 in **Scheme 30**). The polymerization with ethyl 3-iodopropyl carbonate as a model compound was examined to prove the structure of the propagation active site. The decarboxylation seems to occur by the attack of the monomer at the propagating end more preferably than that of the polymer at the propagating end. This is because of the better nucleophilic properties of a monomer than those of a polymer, as was postulated from PM3 molecular orbital calculation. The comparison of the HOMO level of cyclic carbonate (TMC) and linear carbonate (dimethyl carbonate) indicates that a cyclic carbonate is more nucleophilic than a linear one. On the other hand, the heat of the formation of cationic intermediates suggests that the stabilization energy of the formation of the cyclic oxonium cation is 7.4 kcal mol^{-1} greater than that of the linear oxonium cation. Therefore, Endo *et al.* suggested that decarboxylation from the monomer should be thermodynamically and kinetically predominant over that from the linear carbonate. Taking into consideration that decarboxylation competes with the propagation process, to suppress the decarboxylation Endo *et al.* proposed to use propagating species of lower reactivity. It is well known that less reactive compounds give products with higher selectivity.[88] Thus, the authors used a less reactive halide ion instead of the triflate one. Less reactive neopentyl carbonate did not polymerize in the presence of alkyl halides, due to unfavorable nucleophilic substitution at the sterically hindered neopentyl position. In contrast to methyl triflate-initiated polymerization (RY = $CH_3OSO_2CF_3$ in **Scheme 30**), in which the resultant polymer contained hydroxyl end-groups, the PC molecules obtained using alkyl halides as a cationic initiator were terminated by haloalkyl groups.

A haloalkyl carbonate structure is formed by the initial ring-opening reaction of the monomer with alkyl halide, which was shown by using ethyl 3-iodopropyl carbonate as the initiator for cyclic carbonate polymerization. The obtained polymer contained both ethyl and iodopropyl end-groups.

According to this mechanism, alkyl halopropylcarbonate is attacked by cyclic carbonate at the carbon atom neighboring the carbonate linkage to afford biscarbonate via ring opening and PC with alkyl and iodopropyl end-groups is formed (Y = I; **Scheme 30**). Since the polymerization initiated by ethyl 3-iodopropyl carbonate is faster than that initiated by methyl iodide, it is suggested that ethyl 3-iodopropyl carbonate is more reactive than methyl iodide and the halopropyl carbonates are the actual propagating species.

The polymerization of cyclic carbonate with alkyl halide proceeds according to pathway 1 (**Scheme 30**) and owing to the higher nucleophilicity of the halide anion, the covalent macrohalide is more favored than the trioalkxycarbenium ion. However, when a solvent of higher polarity is used as the reaction medium, partial decarboxylation takes place due to



Scheme 31 Mechanism of decarboxylation of terminal oxonium groups.

the shifting of the balance to the carbenium ion species, and a nucleophilic attack along pathway 4 (Scheme 30), causing the decarboxylation, is more probable.

The reaction pathways of TMC during cationic ROP have been explored by Holder and Liu[188,189] applying Austin Model 1 (a semi-empirical method for the quantum calculation) (AM1) semiempirical calculations. They established a species evolution diagram, and the propagation chain ends on the ether oxygen atom have been identified as the species that ultimately lead to decarboxylation (Scheme 31).

Three factors were proposed and evaluated to reduce the degree of decarboxylation based on theoretical calculations: increasing the monomer concentration; decreasing the solvent polarity; and introduction of such ring substituents to bypass the decarboxylation route.

Rare earth halogenides, such as neodymium bromide or iodide, can catalyze TMC and ε-caprolactone (CL) bulk polymerization quickly with small amounts of catalyst ([TMC]/[Ln] = 3000 molar ratio) at 80 °C. The reason why the catalytic activity of TMC polymerization is higher than that of CL polymerization has been studied and it is shown that the difference arises from different polymerization mechanisms of TMC and CL with rare earth halides.[190] Rare earth halogenide single component also can catalyze the copolymerization of TMC and D,L-lactide (LA) and the catalytic activity sequence of various rare earth chlorides is as follows: $LaCl_3 > YCl_3$, $PrCl_3 > NdCl_3 \gg DyCl_3$.[191]

Agarwal *et al.*[192] reported the polymerization of TMC and its copolymerization with L-LA using the SmI_2/Sm initiator system. SmI_2 was prepared by reacting Sm powder with diiodoethane. The reactions proceeded at 70 °C without significant decarboxylation during polymerization.

4.12.3.2.2 Anionic polymerization of six-membered cyclic carbonates

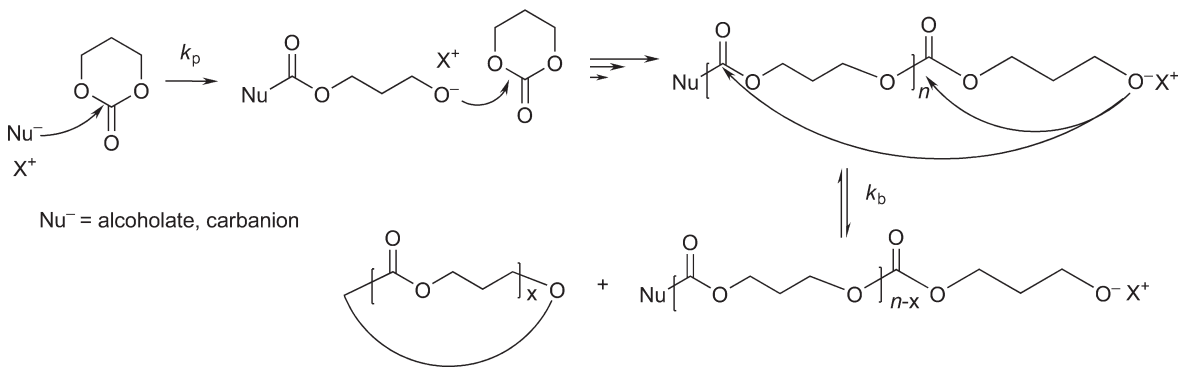
The anionic polymerization of six-membered cyclic carbonates was first reported in the 1930s by Carothers and Van Natta.[19,193] The PCs were obtained by heating TMC in the presence of K_2CO_3.

Generally, six-membered cyclic carbonates easily polymerize with anionic initiators affording high-molecular-weight polymers. In contrast to cationic ROP of cyclic carbonates, these polymers do not contain ether linkages. This feature is especially important when the PCs or their derivatives are utilized in biomedical practice. The presence of ether linkages make such polymers susceptible for oxidation and loss of good mechanical properties.

The ROP of six-membered cyclic carbonates with nucleophilic initiators is a chain reaction in which, besides initiation and propagation reactions, transesterification reactions can also take place (Scheme 32).[194,195] Intramolecular nucleophile (e.g., alkoxide) attacks on carbonyl carbon atom (backbiting) lead to cyclic oligomers, while intermolecular transesterification leads to a change of the macromolecule length with the consequence that, at equilibrium, the most probable distribution of the molecular weight is obtained (Scheme 32).

The initiation reaction comprises the nucleophilic attack of the initiator on the carbonyl carbon atom, followed by an acyl-oxygen cleavage and formation of the active species, an alkoxide.[196] The initiation process depends on the nucleophilicity of the initiator and on the electron affinity of the monomer. A slow initiation in comparison to the propagation process leads to a broadening of the molecular weight distribution and a loss of molecular weight control.[197]

The stereochemistry and mechanism of reversible polymerization of 2,2-disubstituted TMCs were discussed in the 1950s by Sarel and Pohoryles.[84] The anionic mechanism was discussed by Kühling *et al.*[196,198] According to them, a good control of the reaction course can be attained when the ratio of the rate constants of propagation (k_p) and of backbiting (k_b) and transesterification (k_{te}) are large, and there are no termination and transfer reactions. Thus, a high polymer yield and a narrow molecular weight distribution are obtained. The polymerization conditions such as temperature, reaction medium



Scheme 32 Anionic polymerization of six-membered cyclic carbonate with nucleophilic initiators.

(solvent polarity), monomer concentration, and the nature of the active site also are important for the polymerization control.

The homopolymerization of the most popular six-membered cyclic carbonates (TMC and neopentyl carbonate) using nucleophilic initiators based on Li-, K-, Mg-, Al-, Zn-, and Sn-containing compounds were also studied. The systems containing alkali metals, Mg and Sn, were found to afford during polymerization, besides linear, also cyclic oligomers.[195,199,200] This shows that for this group of initiators the rate of backbiting reaction (k_b) is of the same order of magnitude as the rate of propagation (k_p).[201] For Al- and Zn-based catalysts no oligomers were detected, so the backbiting reaction is much slower than the chain-growth reaction.[199] With former mentioned initiators the intramolecular and intermolecular transesterification reactions take place. High-molecular-weight polymer is formed when the reaction is kinetically controlled. In the regime of thermodynamic control ring-chain equilibrium takes place.[195]

It is known that the anionic polymerization of dimethyl trimethylene carbonate (DTC) in toluene with lithium cation as a counterion proceeds slower than that with potassium one due to the more covalent character of the lithium–oxygen bond compared with the potassium-oxygen bond; this leads to a lower nucleophilicity of the lithium alkoxide and also the low tendency for complexation with PEG favors lithium as counterion.[91]

Other initiators based on alkali metals such as *sec*-butyllithium (*sec*-BuLi) as well as sodium and potassium naphthalene were also surveyed.[195] Sodium and potassium naphthalene, when used as electron-transfer reagents for the initiation of styrene polymerization, react with neopentyl carbonate as a nucleophile. The investigation of oligomers obtained in the initial stages of the polymerization by means of GPC using a UV-detector revealed naphthalene to be incorporated into the growing chain.

Rokicki and Jezewski[202] showed that when potassium naphthalene reacts with cyclic carbonate (1:2 molar ratio) dialkoxide species are formed. After reaction with α,ω-dibromo-*p*-xylene the resultant product containing aromatic-aliphatic ester and aliphatic linkages was confirmed by ^{1}H NMR spectroscopic analysis.

Macroinitiators such as polymeric Li, Na, and K alkoxides can also be used for the initiation of the six-membered cyclic carbonate polymerization. Thus, besides living vinyl polymers,[203] hydroxyl group-terminated polymers of poly (tetrahydrofuran) (PTHF),[204] poly(oxyethylene),[205] and poly(dimethylsiloxane) (PDMS)[206] were transformed to alkoxides by treatment with *sec*-BuLi or K-naphthalene and used as initiators. The use of these macroinitiators enables the identification of side reactions, as shown by Keul and Höcker for polystyrene lithium (PS^-Li^+).[203] The addition of the macroinitiator to the monomer, to maintain a high excess of monomer, minimizes side reactions. Transformation of the polystyryl carbanion to a less nucleophilic alkoxide to avoid the side reaction was another approach proposed by the authors. They used EO as a reagent for lowering the nucleophilicity of the macroinitiator. Polymerization of neopentyl carbonate initiated by such macroalkoxide ($PS\text{-}CH_2CH_2O^-Li^+$) led to high yields of AB-block-copolymers (**Scheme 33**).

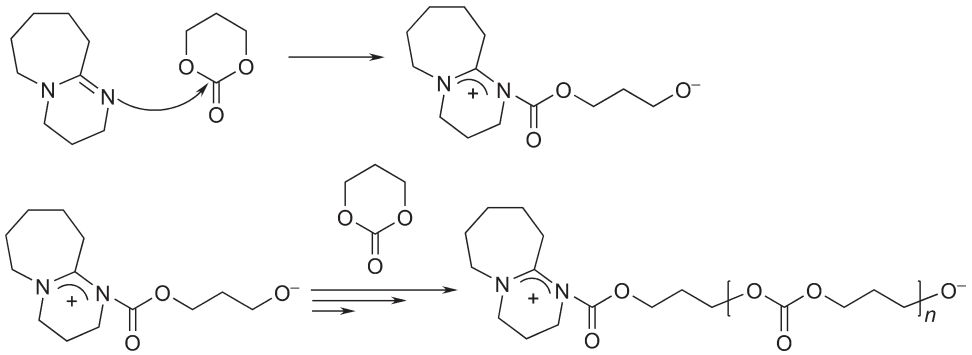
It was found that the polymerization of neopentyl carbonate initiated by PTHF alkoxides with different counterions such as Li^+, K^+, and Bu_4N^+ proceeds slower than that initiated by poly(ethylene oxide) (PEO) alkoxides, which can be explained by the lower solvation ability of PTHF. It was also shown that the nucleophilicity of the active species is significantly reduced by exchanging potassium counterion with lithium one. As a result, high PC yields were obtained after several minutes. The lower nucleophilicity of the lithium alkoxide was ascribed to the more covalent character of the lithium–oxygen bond, compared with the potassium–oxygen one. Moreover, Li^+ exhibits lower tendency for complexation withPEO; self-association prevails, compared with the corresponding potassium alcoholates.[207]

When lithium alkoxide of hydroxyl telechelic PDMS of different molecular weights (M_n = 900–46 000) was used as initiator for the neopentyl carbonate polymerization, the time needed for the complete monomer conversion was significantly longer than that with initiators based on polyethers with the Li^+ counterion.[206] Moreover, a dependence of the polymerization rate on the PDMS molecular weight was observed. For a given concentration of the active species the polymerization rate decreased with increasing molecular weight of the initiating macroinitiator. The low polymerization rate of neopentyl carbonate with PDMS-based macroinitiators has its origins in a decrease of the nucleophilicity of the active species being complexed by the PDMS chain. Such complexation of an alkoxide has been reported, for example, in the reaction of diphenyl-diethoxy silane with potassium ethoxide. The dependence of the polymerization rate of neopentyl carbonate on the molecular weight of the initiator might be explained by the locally larger concentration of complexing $(CH_3)_2SiO$ units.

Anionic metal-free initiation was successfully applied to both aliphatic and aromatic cyclic carbonates.[208] This method is based on the reaction of a silyl ether with fluoride anions, for example, tetrabutyl ammonium fluoride (Bu_4NF) or tris (dimethylamino)sulfonium trimethylsilyl difluoride (TASF, $[(CH_3)_2N]_3\ SSi(CH_3)_3F_2$), to produce an anion with a tetrabutyl ammonium or tris(dimethylamino)sulfonium counterion. The metal-free system is an efficient initiator for neopentyl carbonate polymerization.[209]

An important aspect for materials with applications in the biomedical field is the use of nontoxic catalysts. Biologically nontoxic magnesium and calcium complexes have been successfully employed for the ROP of TMC; however, the toxicity of the salen ligands has not been assessed, and polymerization

Scheme 33 Transformation of the polystyryl carbanion to alkoxide.



Scheme 34 Anionic polymerization of six-membered cyclic carbonate initiated with DBU.

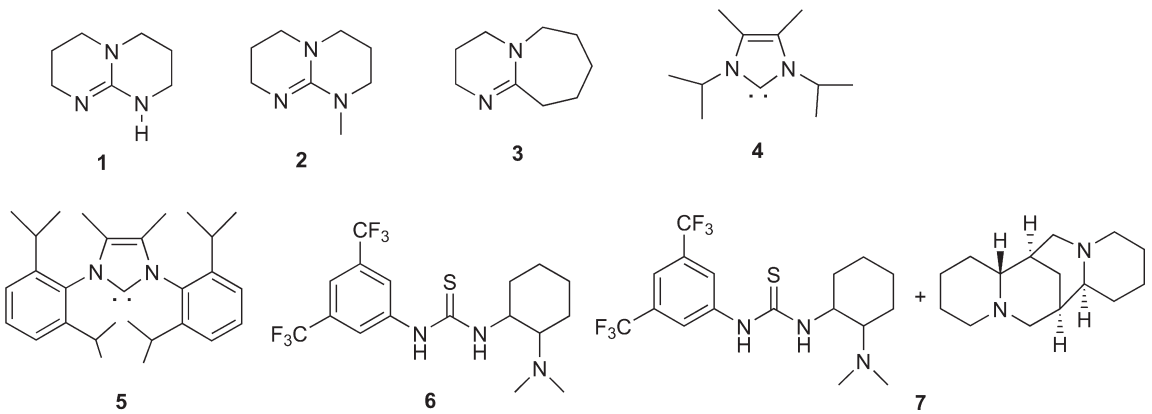
control was limited as judged from the dispersities of the polymers (~ 1.6).[210]

Thus, instead of using ionic and coordination initiators it is possible to use organic initiators for the polymerization of six-membered cyclic carbonates. Murayama *et al.*[211] have found that polymerization carried out in the presence of tertiary amines such as DBU, DABCO, and DMAP afforded the corresponding PC (Scheme 34). A cyclic carbonate of a norbornene (5,5-(bicyclo[2.2.1]hept-2-en-5,5-ylidene)-1,3-dioxan-2-one) (NBC) initiated by DBU at 120 °C yielded in short time (1 h) a polymer with relatively low molecular weight (6400). However, no polymer was obtained when triethylamine, aniline, *N*,*N*-dimethylaniline, or pyridine were used for the polymerization. The much lower activity of triethylamine than that of DABCO might be caused by the steric hindrance around the nitrogen atom, while aromatic amines showed low activities due to the aromatic resonance effect decreasing their nucleophilicities. The authors proposed the zwitterionic polymerization mechanism (Scheme 34), which was confirmed by FD-MS mass spectrum analysis of the polymerization products. In the spectrum the signals which can be assigned to cyclic oligomers and a linear polymer with DBU end-group were found. Thus, the reaction between DBU and cyclic carbonate to form an alkoxide anion is the initiating step of the polymerization. In the propagation reaction the alkoxide anion attacks the carbonyl group of cyclic carbonate to yield the corresponding PC.

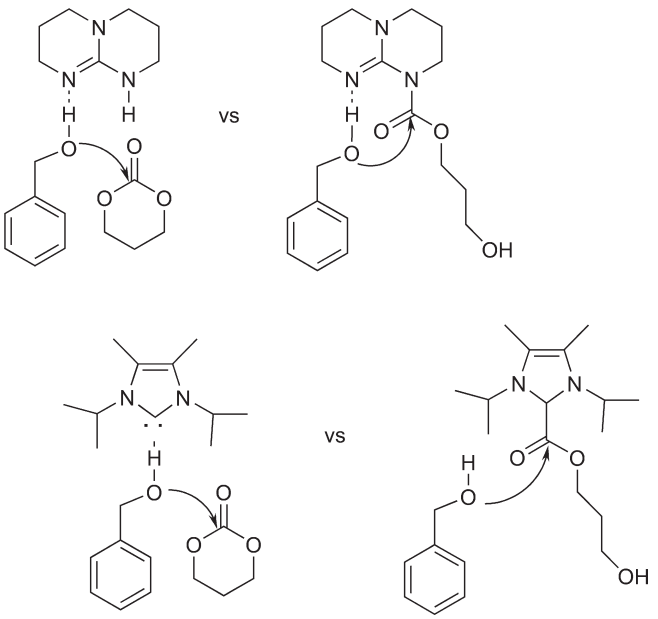
A similar mechanism comprising the formation of the zwitterion intermediate was proposed by Kricheldorf *et al.*[212]

Recently, Nederberg *et al.*[213] reported results on the ROP of TMC using several organocatalysts such as N-heterocyclic carbenes (NHC), guanidine and amidine bases, and the bifunctional thiourea–tertiary amine system. Good polymerization control was found for several of these catalysts yielding well-defined PCs with molecular weights up to 50 000, dispersity index below 1.08, and high end-group fidelity. The authors surveyed the following catalysts: guanidines (TBD, **1**, $pK_a = 26.0$ and 7-methyl-1.5.7-triazabicyclo-[4.4.0]dec-5-ene, MTBD, **2**, $pK_a = 25.5$), amidine base (DBU, **3**, $pK_a = 24.3$), NHCs with either alkyl or aryl substituents (1,3–diisopropyl-4,5-dimethyl-imidazol-2-ylidene, **4**, $pK_a = 30.4$; 1,3-bis(2,6-diisopropylphenyl)-imidazol-2-ylidene, **5**, $pK_a = 22.0$), bifunctional thiourea-tertiary amine catalyst (**6**) and catalyst mixture (**7**) (Scheme 35).

To avoid autoinitiation, the bulk polymerization was carried out at 65 °C. When DBU was used as a catalyst in the presence of benzyl alcohol, TMC was polymerized within minutes, yielding polymers with controlled molecular weight and small dyspersity index (1.09–1.15). To demonstrate the living nature of the polymerization carried out under bulk conditions, the chain extension experiment was conducted. Resultant polymer growth proceeded in a linear fashion. It was demonstrated that the intermediate chains can be employed for further growth, by the addition of more



Scheme 35 Organocatalysts for anionic polymerization of six-membered cyclic carbonates.



Scheme 36 Hydrogen bond activation of cyclic carbonate monomer and initiator/propagating species.

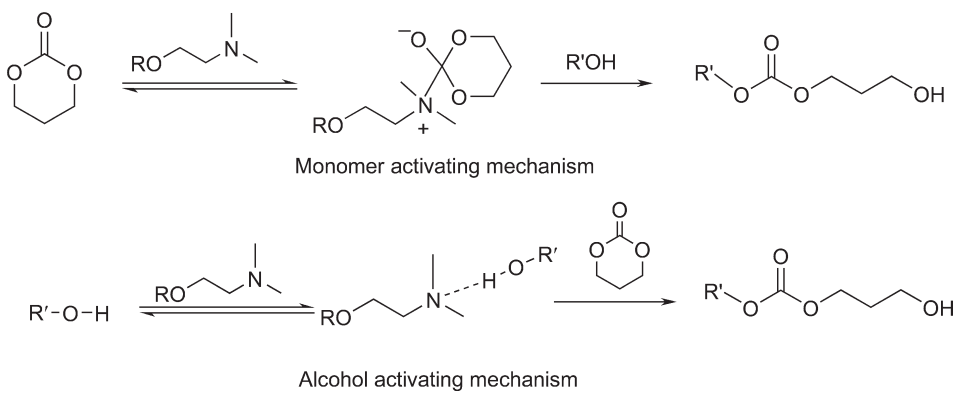
monomer. The molecular weight distribution remained narrow and monomodal.

These catalysts were used for random ester-carbonate bulk copolymerizations. Furthermore, by combining sequential polymerization techniques using bifunctional initiators, the mild polymerization conditions allow for the preparation of block copolymers. Hydrogen bond activation of monomer and initiator/propagating species was proposed as the underlying mechanism, which can be tuned to mitigate adverse side reactions (Scheme 36).

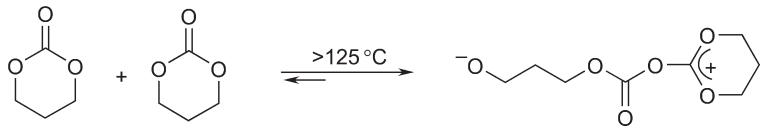
Liu *et al.*[214] used natural amino acids such as L-alanine, L-valine, L-proline, L-leucine, and L-phenylalanine as initiators of the ROP of DTC and TMC. PTMC and poly(dimethyl trimethylene carbonate) (PDTC) with different M_n were obtained at 80 and 120 °C, respectively, in bulk by changing the molar ratio of [monomer]/[amino acid]. Among these polymers, the maximum values of M_n of the PCs reached 17 800–18 900 and the dispersity index was 1.67 for [monomer]/[L-phenylalanine] molar ratio of 200. ^{1}H NMR spectroscopic analysis demonstrated that amino acid was incorporated into the polymer chain.

A similar approach was presented by Mindemark and coworkers.[215] According to this novel concept a controlled self-catalyzed polymerization reaction yields well-defined α,ω-heterotelechelic polymer chains and at the same time the elimination of low-molecular-weight catalyst residues in the final polymer product. The tertiary amine 2-(dimethylamino) ethanol (DMAE) was used as an efficient initiator/catalyst for the ROP of TMC. The catalytic behavior of DMAE was investigated in bulk polymerizations of TMC at temperatures of 46–48 °C. By carrying a tertiary amine as well as an alcohol functionality, in the initiating step DMAE is bifunctional, acting both as the catalyst and as the initiator (Scheme 37). There are two possible reaction pathways for the initiation step: a monomer-activating and an alcohol-end-group-activating mechanism (Scheme 37).

By ^{1}H NMR spectroscopy the authors have confirmed that the DMAE catalyst is attached to the growing polymer chain. The ROP of TMC catalyzed and initiated by DMAE yields the polymer chains bearing the same functional end-groups as the DMAE initiator molecule. This provides a good opportunity for creating new functional macromolecular architectures.



Scheme 37 Two possible reaction pathways for the initiation step of six-membered cyclic carbonate.



Scheme 38 Thermal spontaneous polymerization of TMC.

It should be noticed that pure TMC undergoes spontaneous polymerization in bulk at above 100 °C. In the plausible formulation of a TMC cleavage, a zwitterion intermediate with the trialkoxycarbenium ion, well stabilized by delocalization, and an alkoxide ion are formed (Scheme 38).[212] The alkoxide ion can initiate chain growth according to the anionic mechanism.

However, less reactive neopentyl carbonate did not undergo spontaneous polymerization. A similar observation concerning thermal ROP of substituted six-membered cyclic carbonate 5-benzyloxy-1,3-dioxan-2-one (BTMC) in bulk in the absence of any catalyst was reported by Feng *et al.*[216] Polymerization carried out at 150 °C for 6 h yielded high-molecular-weight poly (BTMC) (PBTMC) ($M_n = 80\,300$) and subsequent catalytic hydrogenolysis resulted in functional PTMC with pending OH groups (PHTMC). Similar spontaneous polymerization of BTMC in the presence of PEG ($M_n = 2000$) as a macroinitiator provided amphiphilic block polymers. An evaluation of the degradation and cytotoxicity of PHTMC demonstrated enhanced degradability compared with PTMC and similar toxicity compared with poly[(d,l-lactide)-*co*-glycolide] (PLGA), showing PHTMC to be a promising biomaterial.

Pawlowski *et al.* demonstrated that TMC can be polymerized using various diols as initiators but without any catalyst at moderate high temperatures (110–120 °C). The oligocarbonate diols were obtained by the thermal polymerization of TMC using PPD and the reaction products of aliphatic diamines with EC [1,2-bis(2-hydroxyethoxycarbonylamino)ethane and 1,6-bis(2-hydroxyethoxycarbonylamino)hexane] as the initiators.[217] The authors also applied microwave radiation for TMC polymerization in the presence of the alcohol initiator to afford oligocarbonates in a very short time (10–15 min).

Recently, Liao *et al.*[218] have used the same procedure, namely microwave radiation, for the ROP of TMC. The polymerizations were carried out in a single-mode microwave oven using ethylene glycol as an initiator. It was shown that the molecular weight of the resulting PTMC and TMC monomer conversion by the microwave method is higher than those by the conventional method.

Very recently, Okada and co-workers[219] revealed that the polymerization reaction of TMC proceeded rapidly in the aqueous solution and high conversion was achieved in a relatively short time. PPD formed by hydrolysis of TMC played the role of an initiator. The TMC oligomer obtained by ROP had a TMC unit backbone with terminal 3-hydroxypropyl groups at both chains ends. The oligomer underwent transesterification reaction with elimination of PPD, resulting in a gradual increase in the molecular weight of the product. Polymerization of the homogeneous TMC aqueous solution was then performed for up to 16 h at 145 °C with nitrogen bubbling through the solution. The molecular weight was affected by the concentration of TMC.

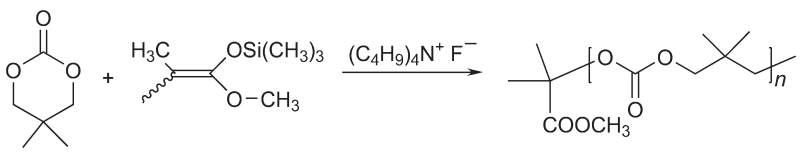
4.12.3.2.2(i) Site transformation from group transfer polymerization to anionic metal-free polymerization

'Living' poly(methyl methacrylate) (PMMA) prepared by group transfer polymerization (GTP) can be used as a macroinitiator for the ROP of cyclic carbonates. For this purpose the silyl ketene acetal was transformed into an alkoxide (anionic ROP mechanism) with a metal-free counterion (Scheme 39).[220] Hovestadt *et al.*[201] reported that the polymerization of DTC took place under GTP conditions: 1-methoxy-2-methyl-1-trimethylsiloxypropene used as initiator and tetrabutylammonium fluoride as catalyst. A quaternary ammonium alkoxide seems to be the likely propagating species for DTC polymerization.[221] In this way, good yields of the respective block copolymers were obtained.

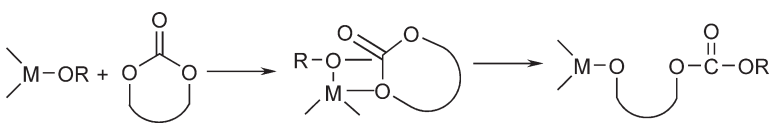
The fluoride anion promotes desilylation of the silyl ketene acetal with formation of an enolate, which reacts as a carbon-centered nucleophile with the carbonyl carbon of DTC.[222]

4.12.3.2.3 Coordination-insertion ROP of six-membered cyclic carbonates

The pseudo-anionic ROP is often referred to as coordination-insertion ROP, since the propagation is thought to proceed by coordination of the monomer to the active species, followed by insertion of the monomer into the metal–oxygen bond by rearrangement of the electrons (Scheme 40).



Scheme 39 Polymerization of DTC initiated with 1-methoxy-2-methyl-1-trimethylsiloxypropene in the presence of tetrabutylammonium fluoride.



Scheme 40 Coordination-insertion ROP of six-membered cyclic carbonate.

The growing chain remains attached to the metal through an alkoxide bond during the propagation. The covalent metal alkoxides with free p- or d-orbitals react as coordination initiators and not as anionic or cationic initiators. The ring cleavage during the polymerization of the cyclic carbonates in the presence of typical coordination catalysts was found to occur at the C(O)–O bond, resulting in the formation of metal alkoxide propagating species. The reaction is terminated by hydrolysis forming a hydroxy end-group. With functional alkoxy-substituted initiators, macromonomers with end-groups active in postpolymerization reactions are produced.

4.12.3.2.3(i) Tin-based catalysts

Tin(II) 2-ethylhexanoate, commonly referred to as stannous octoate ($Sn(Oct)_2$), is the most frequently used catalyst in the ROP and copolymerization of cyclic heterocyclic monomers including cyclic carbonates due to a high activity as well as an approval by the American Food and Drug Administration (FDA) as a food additive. The mechanism of polymerization with its contribution has been widely discussed. $Sn(Oct)_2$ is not thought to be the actual initiator since the molecular weight does not depend on the monomer/$Sn(Oct)_2$ molar ratio.

Investigations of the coordination-insertion mechanism have resulted in two slightly different reaction pathways. Kricheldorf and co-workers[223,224] have proposed a mechanism in which the initiating alcohol functionality and the monomer are both coordinated to the $Sn(Oct)_2$ complex during propagation (**Scheme 41**, eqn [1]). Penczek and Duda groups have presented a mechanism in which the $Sn(Oct)_2$ is converted into a tin alkoxide before complexation and ring-opening of the monomer (**Scheme 41**, eqn [2]).[122,225–227]

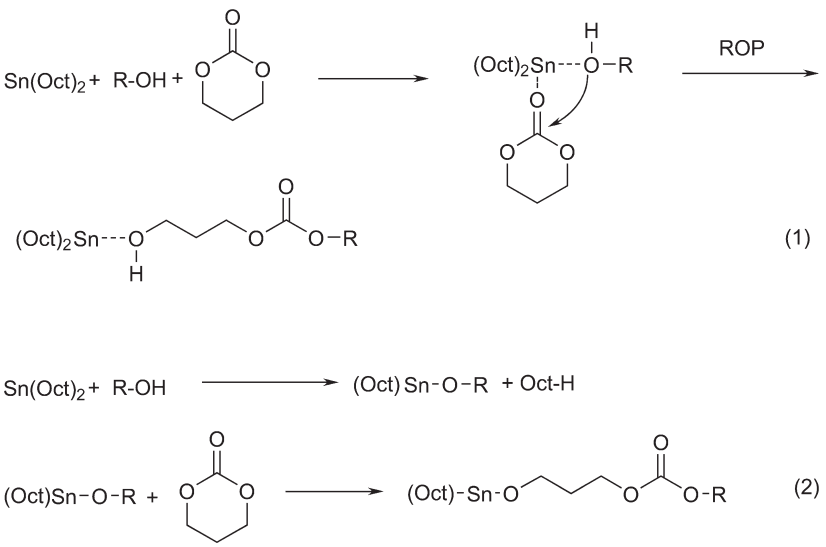
The $Sn(Oct)_2$ catalyst is an active transesterification agent, especially at high temperatures, and the resulting copolymers usually have a randomized microstructure.[228] An increase in reaction temperature or reaction time increases the extent of transesterification reactions.

Kricheldorf and Stricker[229] presented results of ROP of TMC catalyzed with $Sn(Oct)_2$ which enabled understanding the mechanistic aspects of the TMC polymerizations. The temperature range of 100–120 °C seems to play an important role as a borderline for the polymerization mechanism. At lower temperatures an alcohol-type initiator is needed for sufficiently rapid polymerizations. This initiator is incorporated into the chain and formed alkyl carbonate end-groups. Both initiation and propagation follow the pattern of the normal coordination-insertion mechanism (**Scheme 42**). At above 120 °C the TMC can obviously undergo direct insertion into the Sn-O(O)CR bond. The consequences are PTMC chains having one octanoate ester end-group per chain. Furthermore, the molecular weight can be controlled via the M/I ratio and high-molecular-weight PTMC can be obtained with short reaction times at 160 °C.

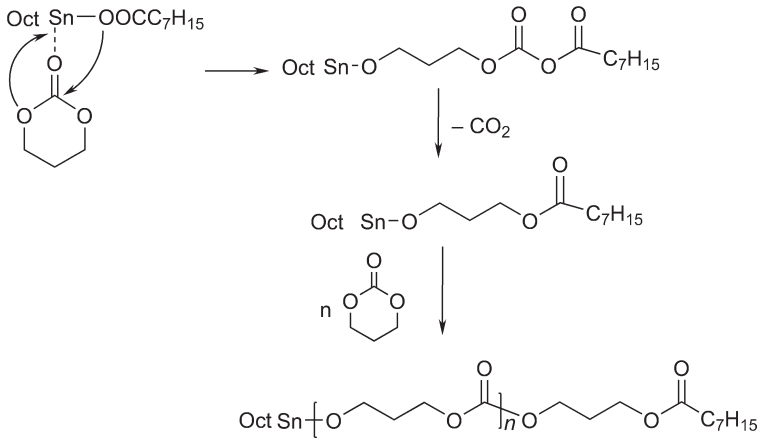
Applying $Sn(Oct)_2$ as a catalyst, PTMC of exceptionally high molecular weight ($M_n = 450\,000$) can be obtained by TMC polymerization at 130 °C for 3 days.[230] To regulate the molecular weight of PTMC appropriate amounts of alcohol should be added as initiator (e.g., hexanol).

Liao *et al.*[231] applied microwave irradiation for ROP of TMC carried out in the presence of IL (1-*n*-butyl-3-methylimidazolium tetrafluoroborate, [bmim]BF_4) using $Sn(Oct)_2$ as a catalyst. In the presence of 5 wt.% of [bmim]BF_4, PTMC with a molecular weight $M_n = 36\,400$ was obtained after only 60 min. The M_n of PTMC synthesized in the presence of [bmim]BF_4 was much higher than that obtained in bulk for the same reaction time.

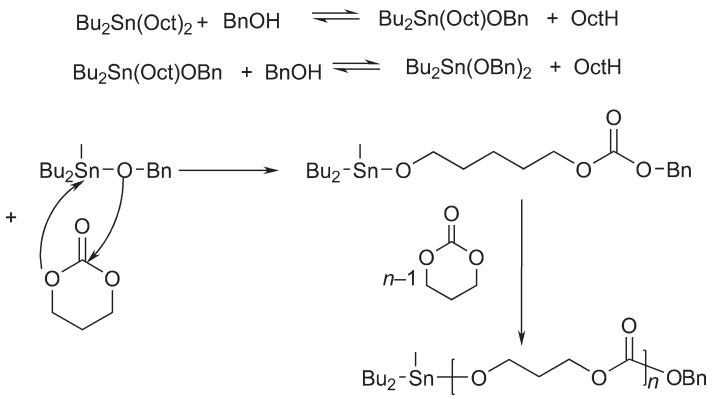
Other tin-based catalysts can also be applied for the polymerization of six-membered cyclic carbonates. Kricheldorf and Stricker[232] showed that $Bu_2Sn(Oct)_2$ could be used for the ROP of TMC. Its reactivity was comparable with that of $Sn(Oct)_2$, but details of the initiation process and of the kinetic course of the polymerization were quite different. Polymerizations carried out below 100 °C were initiated by alcohols that accelerated the entire polymerization process and allowed for a control of the molecular weights. The resulting PCs contained alkyl carbonate end-groups derived from the initiator, but no octanoate end-groups. Above 120 °C the polymerizations proceeded with rapid esterification of octanoate residues yielding PCs containing nearly stoichiometric amounts of octanoate



Scheme 41 Mechanisms of coordination-insertion polymerization of six-membered cyclic carbonates.



Scheme 42 Polymerization of TMC initiated with $Sn(Oct)_2$.

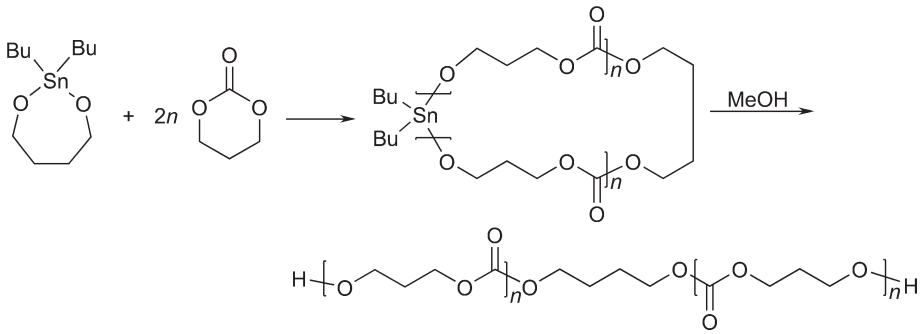


Scheme 43 Polymerization of TMC initiated with $Bu_2Sn(Oct)_2$ in the presence of benzyl alcohol.

end-groups. Model reactions between $Bu_2Sn(Oct)_2$ and benzyl alcohol suggested that no exchange occurs at temperatures below 60 °C. However, at 100 °C a slow esterification process yielding benzyl octanoate and Sn–OH groups takes place (Scheme 43). $Bu_2Sn(Oct)_2$ is a little less reactive than $Sn(Oct)_2$, but polymerization of TMC can be carried out even at 80 °C.

Kricheldorf's group demonstrated that 2,2-dibutyl-2-stanna-1,3-dioxepane (DSDOP) could be used as cyclic initiator for the polymerization of TMC (Scheme 44).[233,234] The polymerizations were either conducted in concentrated chlorobenzene solution at 50 and 80 °C or in bulk at 60 and 120 °C. With monomer/initiator ratios < 100 the conversion was complete within 2 h at 80 °C and within 12 h at 50 °C.

Variation of the reaction time revealed that the rapid polymerization was followed by a relatively rapid (backbiting) degradation even at 80 °C. With optimized reaction time the molecular weight (M_n) roughly paralleled the monomer/initiator ratio and M_ns up to 100 000 were obtained. In contrast to a classical living polymerization broader dispersity indexes (1.5–1.7) were found. In the case of neopentyl carbonate, rapid degradation and chain transfer reactions prevented the formation of high-molecular-weight polymers.



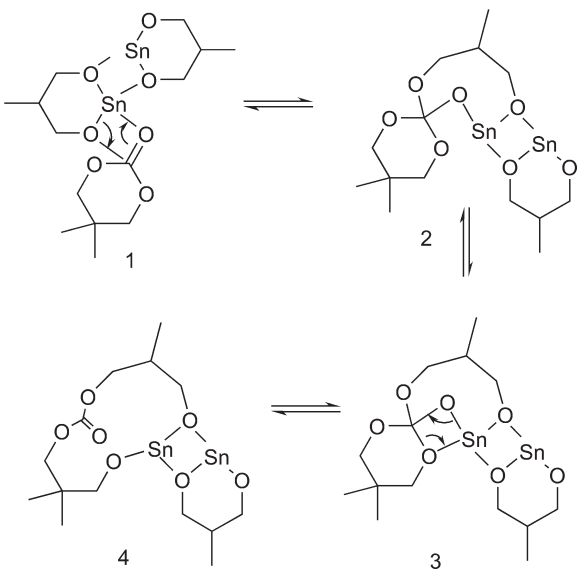
Scheme 44 Polymerization of TMC initiated with 2,2-dibutyl-2-stanna-1,3-dioxepane.

Kricheldorf's group reported that macrocyclic crystalline dibutyltin dicarboxylates (dibutyltin succinate (Bu_2SnSuc) and adipate (Bu_2SnAd)) could be prepared in high yields from Bu_2SnO and respective dicarboxylic acid.[235] It was found that these macrocycles initiated polymerization of TMC at 80 °C which proceeded faster than for $Sn(Oct)_2$ or $Bu_2Sn(Oct)_2$. The resulting PTMC did not contain succinate or adipate groups, and the molecular weight (M_n) was independent of the monomer to initiator ratio (M/I). A complete esterification and incorporation of the dicarboxylic acids took place above 120 °C, and the identification of CH_2OH end-groups suggests that a ring-expansion polymerization proceeded via the insertion of TMC into the Sn–OCH_2 bonds.

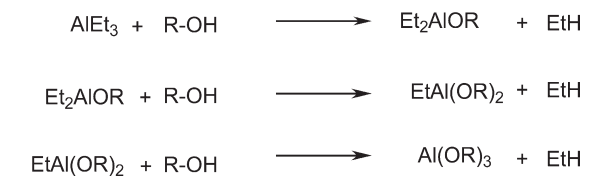
The mechanistic aspects of the coordination-insertion polymerization of six-membered neopentyl carbonate (DTC) initiated by tin(II) alkoxide-based catalysts were discussed by Rokicki *et al.*[236] ^{1}H NMR and MALDI-TOF mass spectrometric analyses of the DTC polymerization products revealed that in the presence of the stannane catalyst macrocyclic oligocarbonates are formed predominantly (**Scheme 45**). It was found that the addition of a small amount of water or diol suppresses the macrocyclization and linear PCs could be obtained. The authors suggested a plausible mechanism of macrocyclization in which the reaction proceeds via orthocarbonate species. The reaction pathway involves monomer coordination through the oxygen atom of the carbonyl group (1), cleavage of the C(O)–O bond leading to orthocarbonate species (2), and then after the rearrangement, the formation of a new tin–alkoxide bond (3) (**Scheme 45**).

4.12.3.2.3(ii) Al-based catalysts

Due to high selectivity aluminum alkoxides are frequently used for obtaining well-defined PCs. The propagation reaction is much faster than transesterification in the ROP and molecular weight is very well controlled. There are a number of aluminum alkoxides which can be prepared by reaction of triethylaluminum with selected alcohol ROH (**Scheme 46**). Thus, the choice of the end-group is very flexible. Usually an excess of triethylaluminum is used to form the monoalkoxide catalyst since the di- and trialkoxides aggregate and are less useful in the aliphatic PC or polyester synthesis. The groups involved in coordinative aggregation are not active in propagation. Significant advances in the understanding of the coordination-insertion ROP mechanism have been made through the kinetic studies by Duda and Penczek.[237,238]



Scheme 45 Formation of cyclic oligocarbonates in the polymerization of DTC initiated with a tin(II) alkoxide-based catalyst.



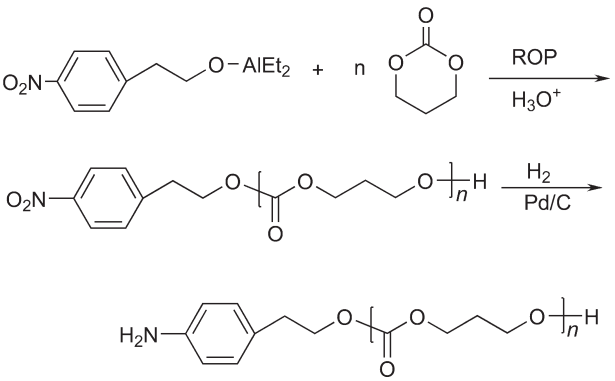
Scheme 46 Reaction of $AlEt_3$ with alcohols.

For safety reasons, residual aluminum must be removed from the material before use in food or biomedical applications. Aluminum can be efficiently extracted by ethylenediaminetetraacetic acid (EDTA) complexation.

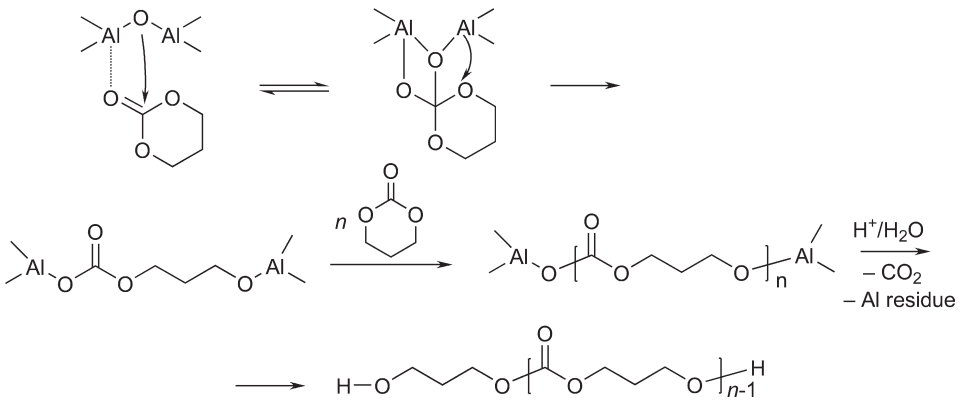
The polymerization of neopentyl carbonate with tri-*sec*-butoxyaluminum ($Al(O\textit{sec}\text{-}Bu)_3$), diethyl zinc ($ZnEt_2$), and dibutyldimethoxytin ($Bu_2Sn(OMe)_2$) in toluene as a solvent revealed a clear distinction between the aluminum- and zinc-based catalysts on the one hand and the tin-based catalysts on the other. For the tin-based catalyst, the rates of backbiting reactions (intramolecular transesterification) and intermolecular transesterification reactions are as high as the rate of the propagation reaction, while for aluminum- and zinc-based catalysts, the rate of the propagation reaction is much higher than that of transesterification.[200] Hence, within the scope of a kinetic treatment of the polymerization of DTC with $Al(O\textit{sec}\text{-}Bu)_3$ as a catalyst, only propagation reaction must be considered.[239]

An interesting example of using an Al-based catalyst in ROP was reported by Carter *et al.*[240] Catalysts of the formula $AlEt_{3-x}(OR)_x$, where $x = 1–2$; $R = (CH_2)_2PhNO_2$, were efficient for the solution polymerization of TMC, and it was possible to obtain polymers with each chain terminated by a single nitrophenyl group ($M_n = 9500$) (**Scheme 47**). These nitro groups after reduction under mild conditions afforded amino-terminated PCs.

Florjanczyk *et al.*[241] applied a commercially available methylaluminoxane/$AlMe_3$ system for ROP of cyclic carbonates, ethers, and esters. The analysis of the end-groups by means of MALDI-TOF indicated that the polymerization was



Scheme 47 Formation of amine-terminated poly(trimethylene carbonate).



Scheme 48 Polymerization of six-membered cyclic carbonates in the presence of methylaluminoxane/$AlMe_3$ system.

initiated by insertion of a monomer into the Al–O–Al bond, generating alkoxide species, which were active sites in the coordination-insertion polymerization. The final hydrolysis of Al–O bonds was accompanied by elimination of CO_2 from the terminal carbonate units (Scheme 48). The polymerization of six-membered carbonates proceeded selectively, forming linear PC diols with high yields at moderate temperatures.

It is worth mentioning that the interaction of oxiranes with aluminoxane electrophilic sites caused also the formation of cationic species, which initiated the polymerization of THF. To prove the formation of cationic species in those systems, triphenylphosphine was used for their trapping and identification by means of ^{31}P NMR spectroscopy.

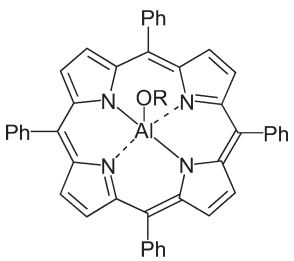
Kuran and co-workers[242] used catalysts prepared in the reaction of water with triethylaluminum or diethylzinc for the polymerization of DTC and TMC. The ROP of six-membered cyclic carbonates catalyzed with the above-mentioned compounds was an efficient method for the synthesis of low-molecular-weight PCs terminated from both sides by hydroxyl groups. The very low ether linkage content in the obtained macrodiols indicated that the propagation step occurred practically without any decarboxylation.

Darensbourg's group and Yang *et al.* have reported the use of effective salen complexes of aluminum as catalysts for six-membered cyclic carbonate polymerization.[243,244]

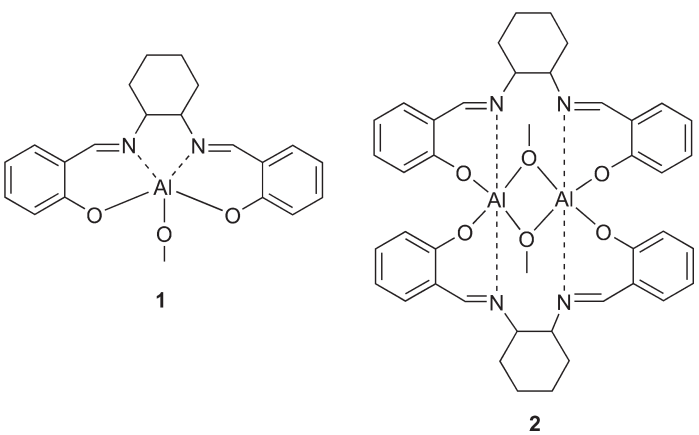
Yang *et al.*[244] tested two aluminum complexes with salen ligands prepared from trimethyl aluminum ($AlMe_3$), methanol, and (*R,R*)-*N,N'*-bis(salicylidene)-1,2-diaminocyclohexane as catalysts for the ROP of TMC and DTC as well as cyclic esters (Scheme 49).

The synthetic results indicated that both metal complexes efficiently catalyzed ROP at 100 °C in an anisole solution, and **2** showed much better controlled characteristics of ROP than **1** (Scheme 49).

Hovestadt *et al.*[201] indicated that the polymerization of six-membered cyclic carbonates catalyzed with porphinatoaluminum compounds like (TPP)AlOR (Scheme 50) exhibited a living character.



Scheme 50 Porphinatoaluminium (TPP)AlOR) catalyst used for polymerization of six-membered cyclic carbonates.



Scheme 49 Aluminum complexes with salen ligands used for polymerization of six-membered cyclic carbonates.

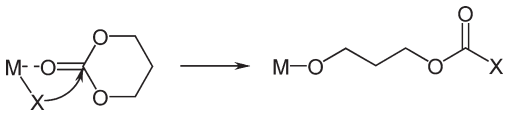
4.12.3.2.3(iii) Biocompatible metal-based catalysts

Taking into account that materials prepared from PTMC are mainly directed for use in medicine (tissue scaffolds, nerve regeneration) the catalyst applied for their preparation must not be toxic and harmful for a human being. Recently, special attention has been given to develop biocompatible metal-based catalysts, for example, calcium-based complexes for the ROP of cyclic carbonates or cyclic esters.[210,245]

Darensbourg *et al.*[246,247] reported that calcium, zinc, and magnesium complexes with tridentate Schiff base ligands showed good catalytic activity for ROP of TMC to produce high-molecular-weight polymers with narrow dispersity index (**Scheme 51**). In addition, these catalysts can be used for effective copolymerization of TMC with L-LA.

It is worth noticing that in these processes a cocatalyst must be present in the reaction system since these M(II) salen derivatives do not possess internal nucleophiles for the chain initiation step as is present in the M(III) derivatives, for example, (salen)AlCl.[243] For this purpose the authors applied anions (e.g., N_3^-) derived from μ-nitrido-bis(triphenylphosphine)$^+$ (PPN^+) or n-Bu_4N^+ salts. It was shown that the catalytic activity depends on a metal used in the order $Ca^{2+} \gg Mg^{2+} > C_2H_5Al^{2+} > Zn^{2+}$. The optimal appeared to be a system containing a calcium(II) salen ligand with *tert*-butyl substituents in the 3,5-positions of the phenolate rings and an ethylene backbone for the diimine grouped together with $PPN^+N_3^-$ (**Scheme 52**).

The kinetic studies revealed the polymerization reaction to be quasi-living. The activation parameters for the ROP of TMC catalyzed by (salen)Ca(II)/n-$Bu_4N^+Cl^-$ in TCE were found to be $\Delta H_p^0 = 20.1 \pm 1.0\ kJ\ mol^{-1}$ and $\Delta S_p^0 = 128 \pm 3\ J\ mol^{-1}\ K$. The ΔG_p^0 value of $58.2\ kJ\ mol^{-1}$ observed for the calcium-catalyzed process was $24.5\ kJ\ mol^{-1}$ lower in energy than that for the reaction catalyzed by an aluminum derivative ($82.7\ kJ\ mol^{-1}$).[243] This is consistent with the latter process occurring much slower under similar reaction conditions. In both instances, these activation parameters are in accordance with a reaction mechanism involving the addition of a nucleophile to a metal-bound cyclic carbonate. The mechanism involves insertion of the monomer into the growing polymer chain by breaking the acyl–oxygen bond instead of the alkyl–oxygen bond (**Scheme 53**).



Scheme 53 Insertion of the monomer into the growing polymer chain by breaking the acyl-oxygen bond.

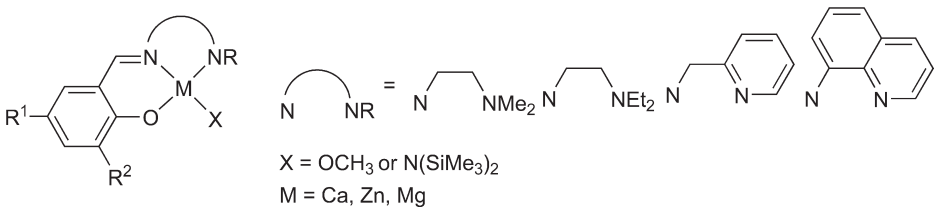
Also zinc lactates can be used as catalysts for ROP of TMC.[248] To shorten the reaction time the polymerization was carried out under microwave radiation and afforded PTMC of high molecular weight ($M_n = 75\,400$) after 30 min at 120 °C.

4.12.3.2.3(iv) Immortal polymerization of cyclic carbonates

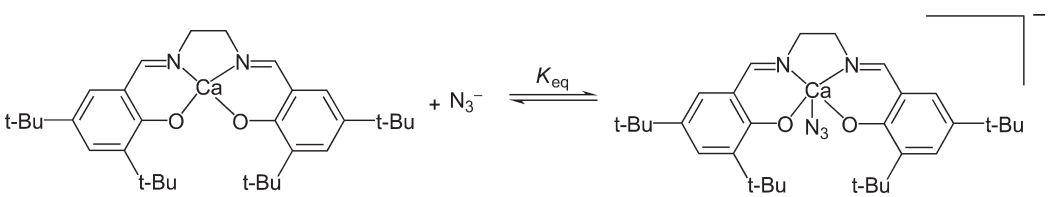
Interesting results concerning ROP of TMC have been recently presented by Helou *et al.*[249] The polymerization of six-membered cyclic carbonate carried out in the presence of binary catalyst system based on Coates' zinc complex supported by a β-diiminate ligand and benzyl alcohol as a transfer agent indicated an immortal character. It was shown that this catalytic system is extremely effective; high amounts of TMC can be fully converted into PC in a controlled manner from very small catalytic amounts of the zinc complex combined with large quantities of benzyl alcohol under mild reaction conditions.

The concept of immortal polymerization was first proposed and developed in the 1980s by Inoue for the ROP of oxiranes by an Al-porphyrin/alcohol system.[250,251] In this type of polymerization, the resulting polymers are characterized by a narrow molecular distribution, even in the presence of a chain transfer reaction, because of the reversibility, which leads to the revival of the polymers once dead. As a result, immortal polymerization can afford polymers with a controlled molecular weight. The compound that plays a leading role, in the case of Inoue's system, is metalloporphyrin, in which the metal–axial ligand bond shows unusually high reactivity. Immortal polymerization was carried out in the ROP of oxiranes, by using an appropriate metalloporphyrin as the initiator and a protic compound acting as the chain transfer agent.

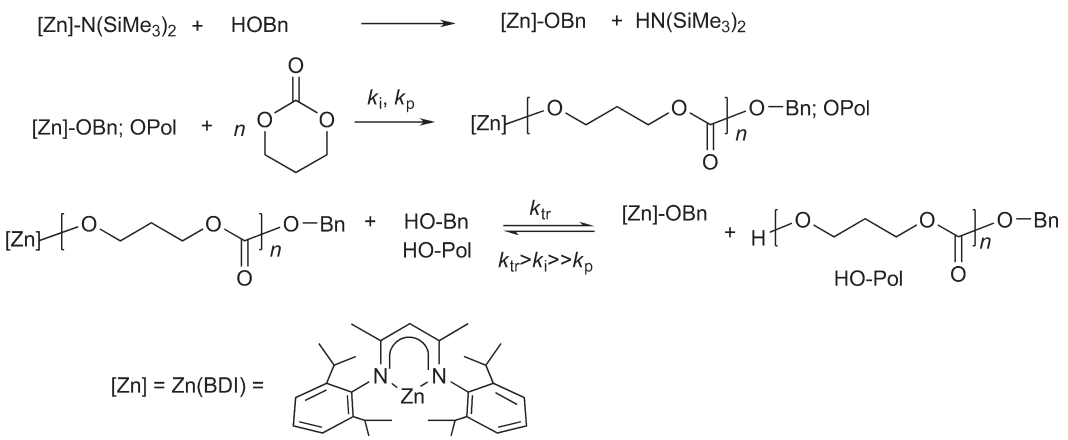
Helou *et al.* revealed that TMC can be efficiently polymerized in bulk at 60–110 °C in the presence of [Zn(BDI){$(SiMe_3)_2$}] (BDI = CH($CMeNC_6H_3$-2,6-iPr$_2$)$_2$) as the catalyst precursor and



Scheme 51 Calcium, zinc, and magnesium complexes with tridentate Schiff base ligands used for polymerization of six-membered cyclic carbonates.



Scheme 52 Formation of the complex of calcium(II) with the salen ligand in the presence of N_3^- cocatalyst.



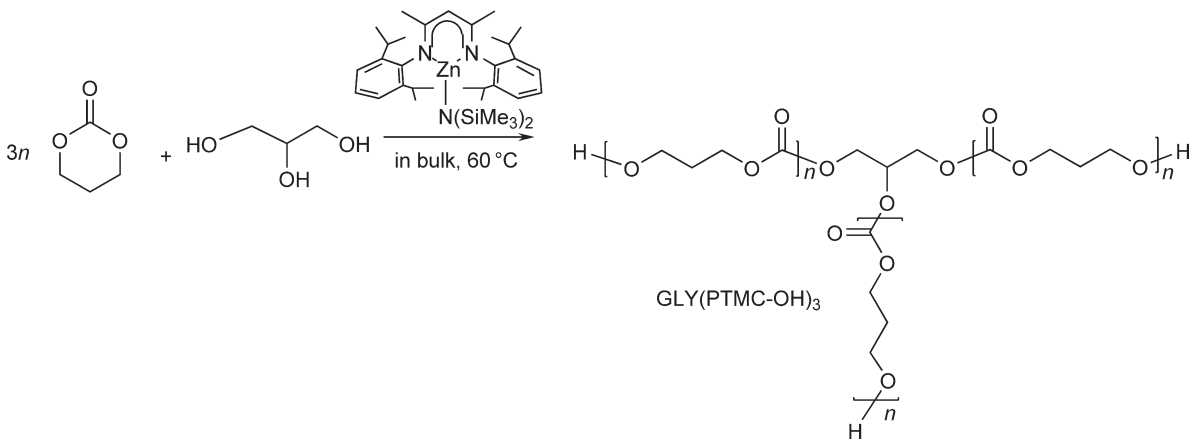
Scheme 54 Mechanism of immortal polymerization of TMC in the presence of the zinc-based binary catalyst.

benzyl alcohol (BnOH) as the transfer agent, with an initial alcohol/zinc ratio varying from 0 to 50 and a monomer/zinc loading ranging from 500 up to 50 000.[249,252,253] It was shown that this binary catalyst system was generated *in situ*, within 15 min, and there was no need for the prior synthesis of this derivative, which is a significant advantage of this method (Scheme 54).

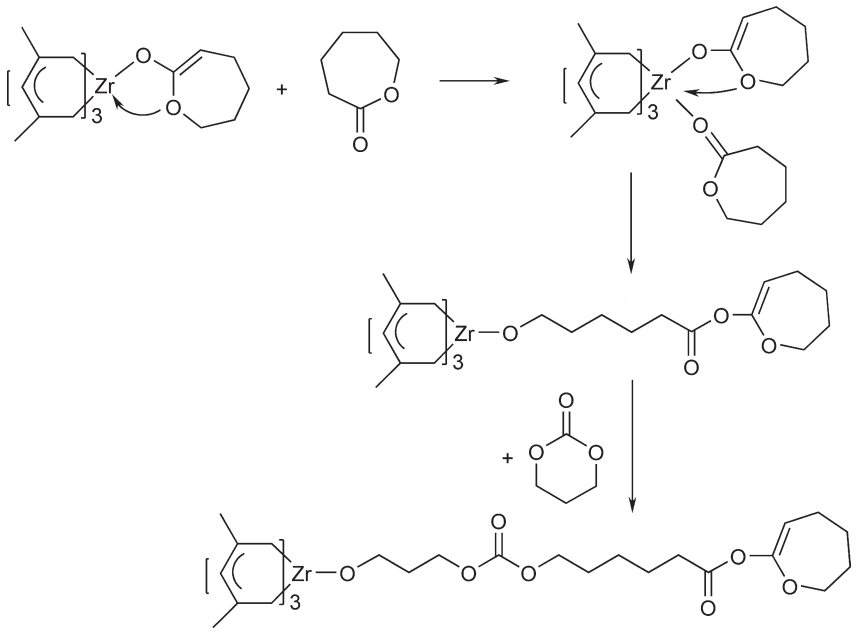
The molecular weights determined by size exclusion chromatography (SEC) were in quite good agreement with the calculated ones, assuming that all the added alcohol molecules contribute to the immortal polymerization.

PTMC terminated with hydroxyl groups (HO-PTMC-OH) was synthesized according to the controlled immortal ROP of TMC under mild conditions (in bulk, 60 °C), using $ZnEt_2$ or $[(BDI)Zn(N(SiMe_3)_2)]$ (BDI = $CH(CMeNC_6H_3$-2,6-$iPr_2)_2$) as a catalyst precursor, in the presence of a diol HO-R-OH (R = $(CH_2)_2$ or $CH_2C_6H_4CH_2$; 0.5–10 equiv. vs. Zn) acting both as coinitiator and as chain transfer agent.[253] The versatility of this immortal ROP also allowed the preparation of star polymers such as the glycerol-based PTMC$(OH)_3$ (Scheme 55). Due to the renewable character of PPD or glycerol used as starting materials, and biometal zinc catalyst used in very small amounts, PTMC obtained according to this method can be considered a 'green' PC.

Dobrzynski *et al.*[254] tested less toxic metal acetylacetonates (Zn(II), Fe(III), and Zr(IV)) as efficient catalysts of trimethylene and neopentyl carbonate polymerization. The reaction carried out at 110 °C with the use of these catalysts was very rapid and of high yield. Using both zinc(II) and iron(III) acetylacetonates, as well as the zirconium(IV) one, at high temperatures it was possible to obtain PC of high molecular weight (M_n = 190 000). It should be underlined that zirconium derivatives are 10 times less toxic than their tin counterparts and Zr-containing drugs and cosmetics are accepted by the FDA.[255] A disadvantage of this method may be a strong influence of thermal degradation on the course of the reaction, particularly at 160 °C. The DTC polymerization proceeded much slower when catalyzed by iron and zinc acetylacetonates. The relation between the molecular weight of the PC and the conversion of the monomer is directly proportional, indicating the living polymerization mode. Dobrzynski explained the reason for low-molecular-weight PTMC formation at 110 °C when $Zr(Acac)_4$ was used as a catalyst. In contrast to cyclic carbonates, at the stage of the initiation of lactide polymerization, the reaction of deprotonation of the monomer and charge transfer of the proton to the acetylacetonate ligand take place. As a result, the exchange of ligands with the release of free acetylacetone occurs. The complex obtained in this way is the



Scheme 55 Preparation of glycerol-based poly(trimethylene carbonate) star polymer by the immortal polymerization of TMC.



Scheme 56 ε-CL acting as coinitiator in ROP of TMC in the presence of $Zr(Acac)_4$.

actual initiator of the polymerization. In the case of polymerization of TMC, the deprotonation of the monomer does not occur as easily as it does during the polymerization of lactide or glycolide (GL). The author indicated that when CL was added to the system containing TMC and $Zr(Acac)_4$ CL monomer acted as a coinitiator in ROP of TMC and high-molecular-weight PTMC could be obtained at 120 °C (Scheme 56).[256,257]

As was presented by Darensbourg *et al.*,[258] chromium(III) Schiff base catalyst was also active in TMC polymerization. Moreover, chromium(III) salen derivatives in the presence of anionic initiators have been shown to be very effective catalytic systems for the alternating copolymerization of oxetane and carbon dioxide to provide the corresponding PC with a minimal amount of ether linkages. The best results were achieved for the salen ligand with *tert*-butyl groups in the 3,5-positions of the phenolate rings and a cyclohexylene backbone for the diimine along with an azide ion initiator (Scheme 57).

For the reaction catalyzed by (salen)CrCl in the presence of $n\text{-}Bu_4N^+N_3^-$ as the initiator, both MALDI-TOF spectrometry and infrared spectroscopy revealed an azide end-group in the copolymer.[259,260] The formation of the copolymer is shown to proceed in part by way of the intermediacy of TMC (pathway 2, Scheme 58), which was observed as a minor product of the coupling reaction, and by the direct enchainment of oxetane and CO_2.

The determined free energies of activation for these two reactions, namely 101.9 kJ mol^{-1} for ROP of TMC and 107.6 kJ mol^{-1} for copolymerization of oxetane and carbon dioxide, support this conclusion.

4.12.3.2.3(v) Rare earth catalysts

A large variety of rare earth derivatives have been used to initiate ROP of cyclic carbonates. Their usually high reactivity must be emphasized, as exemplified by the polymerization of TMC with $Ln(OAr)_3$ (Ln = Lanthanide = f-block elements) under mild conditions, in contrast to the long reaction time and high temperature required when tin-based or aluminum-based catalysts were used. As rare earth metals La (lanthanum), Ce (cerium), Nd (neodymium), Sm (samarium), Gd (gadolinium), Dy (dysprosium), Er (erbium), Yb (ytterbium), Sc (scandium), and Y (yttrium) are most often applied.[261]

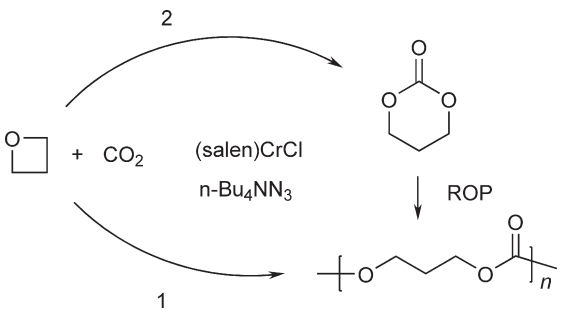
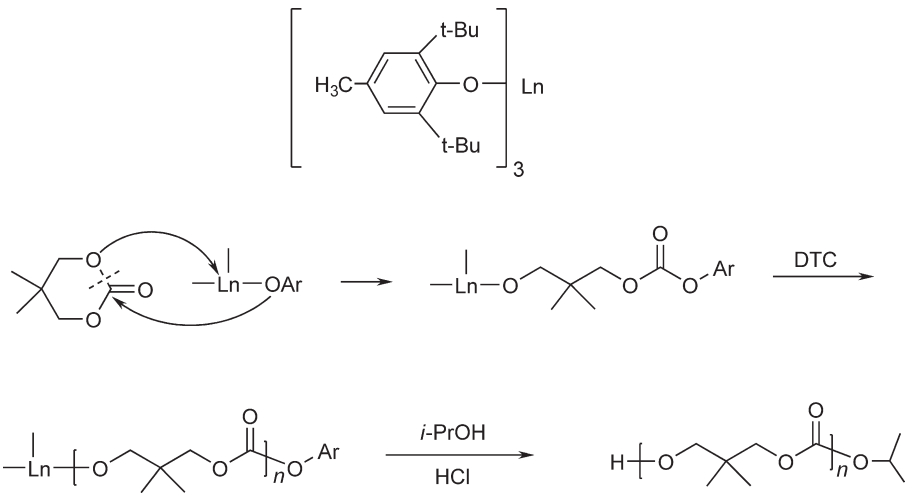


Scheme 58 Copolymerization of an oxetane and CO_2 catalyzed by a (salen)CrCl catalyst.



Scheme 59 Polymerization of DTC via an acyl–oxygen bond cleavage in the presence of a lanthanide catalyst.

ROP of cyclic carbonates using lanthanide alkoxide-based initiators is a relatively recent discovery. The first example of lactone polymerization by lanthanide alkoxide complexes was reported in a DuPont patent written by McLain and Drysdale in 1991.[118] Polymers of relatively high molecular weight and narrow dispersity index were formed. However, the disadvantage of these catalysts is the formation of macrocycles.

Shen *et al.*[262] first used lanthanide catalyst for the polymerization of TMC in 1996. Most often rare earth tris(2,6-di-*tert*-butyl-4-methylphenolate)s [$Ln(OAr)_3$] isopropoxide [$Ln(OiPr)_3$] were used as single-component catalysts for the cyclic carbonate and lactone polymerization (**Scheme 59**).[263–265]

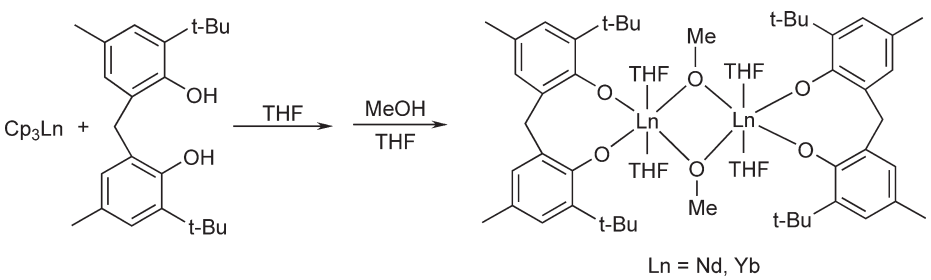
The catalysts were highly active in both homopolymerizations of DTC, TMC, and CL and random copolymerizations of DTC with CL and TMC. The polymerization of these monomers proceeded via the same route of an acyl–oxygen bond cleavage in heterocyclic rings (**Scheme 59**). The catalytic activities of various $Ln(OAr)_3$ systems decreased in the following order: La > Nd > Dy ≈ Y.

Very recently, Zhang *et al.*[266,267] investigated single-component rare earth aryl oxides substituted by various alkyl groups such as methyl, isopropyl, and *tert*-butyl used to initiate the ROP of neopentyl carbonate. The experimental results revealed that the catalytic activity of $Ln(OAr)_3$ changes in good concordance with variation of ligands' structure and number of alkyl groups on benzene ring. The greater the ability of electron donation of alkyl groups, the greater the catalytic activity. Moreover, the greater the number of substituted alkyls on benzene ring, the greater the catalytic activity. Thus, the rare earth tris(2,4,6-tri-*tert*-butylphenolate)s [$Ln(OTTBP)_3$] exhibits greatest activity in all lanthanide aryl oxides. The catalytic activity was in the order La > Sm > Gd > Dy > Er, which is in accordance with the results obtained for one-component rare earth metal catalysts.

Bisphenolate lanthanide (Ln = Nd or Yb) methoxide complexes (**Scheme 60**) were also active in ROP of cyclic carbonates as was revealed by Xu *et al.*[268]

In polymer synthesis, calixarenes – cyclic phenol–formaldehyde oligomers – are rarely studied and reported. There are two main applications of calixarenes in polymer synthesis: use of metal calixarene complexes as catalysts for polymerization and star-shaped polymers with a calixarene core.

Calixarene complexes with lanthanides have been developed to catalyze the homopolymerization of TMC and DTC. The complexes were synthesized from lanthanide isopropoxide and appropriate *p-tert*-butylcalix[*n*]arene (*n* = 4, 6, and 8). Based on the polar solvent effect, the end-group examination of the polymers, and NMR analyses of the growing chain, it could be concluded that the polymerizations of TMC and DTC initiated by p-*tert*-butylcalix[*n*]arene (*n* = 4, 6, and 8) complexes of Nd, La, and Y proceeded by a coordination-insertion mechanism.[269–271] Gou *et al.*[272] used scandium p-*tert*-butylcalix[6]arene complex as a single-component catalyst for ROP of cyclic carbonates. The polymerization of neopentyl carbonate using this complex proceeded under mild



Scheme 60 Structure of bisphenolate lanthanide methoxide complexes active in ROP of cyclic carbonates.

conditions. Poly(neopentyl carbonate) with $M_w = 33\,700$ and dispersity index of 1.21 was prepared. Kinetics study indicated that the polymerization rate was of first order with respect to both monomer and initiator concentrations, and the apparent activation energy of the polymerization was 22.7 kJ mol^{-1}. Instead of phenolate, Li *et al.*[273] applied samarium thiolate derivatives as catalysts for neopentyl carbonate polymerization.

Sheng *et al.*[274] proposed to use the anionic lanthanide-sodium-2,6-di-*tert*-butylphenoxide complexes $[Ln(OAr)_4][Na(DME)_3]\cdot DME$ (Ln = Nd, Sm, or Gd; DME = dimethoxyethane) for the polymerization of cyclic carbonate (TMC) and lactone (CL). The anionic lanthanide complexes were synthesized by the reaction of anhydrous $LnCl_3$ with 4 equiv. of sodium-2,6-di-*tert*-butylphenoxide in high yields. These complexes showed high catalytic activity in the ROPs of TMC and CL. The catalytic activity significantly depended on the lanthanide metals. The active order of Nd > Sm > Gd for the polymerization of TMC was observed. It is worth noting that the anionic complex was more efficient than the corresponding neutral complex, $Ln(OAr)_3(THF)_2$.

Also other alkoxide clusters of lanthanide and sodium, $Ln_2Na_8(OCH_2CF_3)_{14}(THF)_6$, $LnNa_8[OC(CH_3)_3]_{10}(OH)$, and $[Ln_2Na_8(OCH_2CH_2NMe_2)_{12}(OH)_2]$ (Ln = Sm, Y, Nd, Yb), were found to be highly active single-component catalysts for the ROP of TMC.[275–277] These cluster activities were much higher than monometallic alkoxide lanthanides. Homoleptic lanthanide amidinate complexes also indicated high activity for the ROP of TMC, giving polymers with $M_w/M_n = 1.41–1.73$.[278–280] There are two methods of obtaining a homoleptic guanidinate lanthanide complex. The samarium guanidinate complex $[Sm\{Ph_2NC(NCy)_2\}_3]\cdot 2C_7H_8$ was synthesized by the metathesis reaction of lithium guanidinate with anhydrous samarium trichloride in a 3:1 molar ratio. The analogous complexes $[Ln\{Ph_2NC(NCy)_2\}_3]\cdot 2C_7H_8$ [Ln = Yb, Nd] were synthesized by the insertion reaction of *N,N′*-dicyclohexylcarbodiimide into the Ln–N bond of $[(THF)_4Li][Ln(NPh_2)_4]$ in a 3:1 molar ratio in good yield.

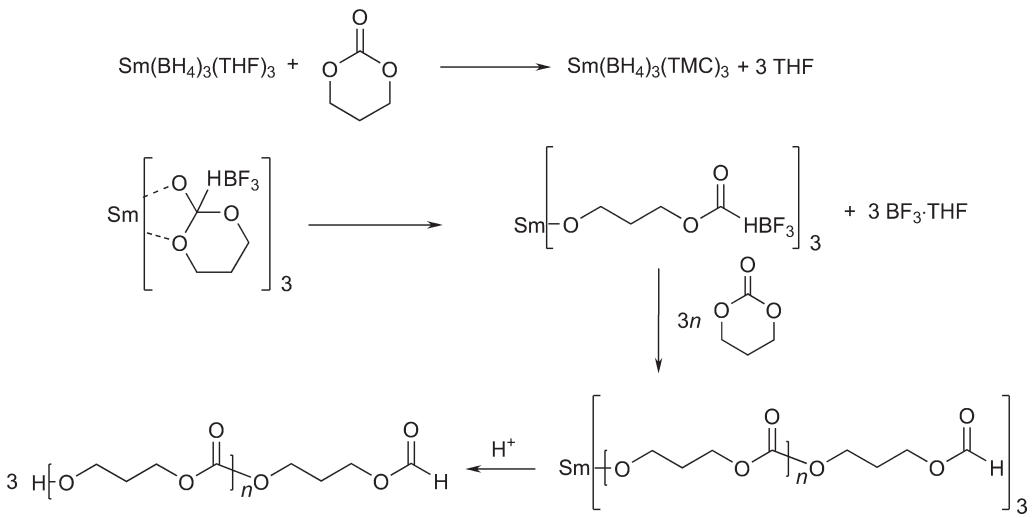
Palard *et al.*[281] used samarium borohydride complexes $[Sm(BH_4)_3(THF)_3]$ for the ROP of TMC. This catalyst showed high activity to give high-molecular-weight PTMC with M_w/M_n ranging from 1.2 to 1.4 and with a regular structure without ether linkages (Scheme 61). The rare earth borohydride complex $[Sm(BH_4)_3(THF)_3]$ was an efficient initiator for the controlled ROP of TMC at ambient temperature to form α-formate-ω-hydroxy telechelic PTMC. ^{1}H and ^{13}C NMR analyses, especially of the PC chain ends, idicated that the synthesis of such a formate end-functionalized polymer relies on the intrinsic reactivity of the samarium-bound borohydride ligand, which does not reduce the –O–C(O) – carbonyl and which is eliminated as $BH_3\cdot THF$ (Scheme 61).

Agarwal and Puchner[282] used commercially available, easy to synthesize rare earth cyclopentadiene (CP_3) complexes as catalysts for TMC and cyclic ester polymerization to afford high-molecular-weight polymers. Using these catalysts the PC was obtained in a quantitative yield with moderate dispersity index (1.6–2.1). Rare earth metal cyclopentadienyl complexes ($LnCp_3$; Ln = Ce, Pr, Sm, Gd, and Er) irrespective of their size acted as ROP catalysts for TMC polymerization giving high-molecular-weight PTMC ($M_n \approx 20\,000$) at 78 °C for 1 h. The ^{1}H NMR spectrum of PTMC showed the presence of only two peaks at 4.2 and 1.95 ppm. The absence of peaks between 3.1 and 3.3 ppm clearly indicated the absence of ether units which are generally formed as defects in the polymer structure by cationic polymerization of TMC by elimination of CO_2.

4.12.3.2.4 Enzymatic polymerization of aliphatic cyclic carbonates

Many bacteria synthesize, accumulate, and deposit aliphatic polyesters in their cells. The high stereoselectivity of the enzymatic synthesis produces as a rule polyesters with high crystallinity which have attracted a great deal of attention during the last few years.[81,283,284] The enzymatic ROP of δ-valerolactone (VL) and CL was first conducted using lipase as a catalyst.[285]

On the other hand, it is known that the introduction of carbonate groups into the polymer chain leads to improving the mechanical properties of biodegradable polyesters.[286] The carbonate linkage in the aliphatic polymer chain may be expected to be enzymatically hydrolyzable and more hydrolytically stable than an ester linkage. The copolymerization of



Scheme 61 Polymerization of TMC initiated with samarium borohydride complexes.

cyclic lactones and carbonates needs pure monomers and anhydrous conditions as well as organometallic catalysts, which must be completely removed before use in medical applications.

In contrast to chemical methods, enzyme-catalyzed polymerization of six-membered cyclic esters and carbonates seems to be the practicable method avoiding the above-mentioned difficulties. Kobayashi *et al.*[287] for the first time have shown that lipase not only catalyzes the hydrolysis of esters and carbonates[288] but can initiate ROP. Enzymatic ROP of a six-membered cyclic carbonate, 1,3-dioxan-2-one, was investigated by using lipase as catalyst in bulk.

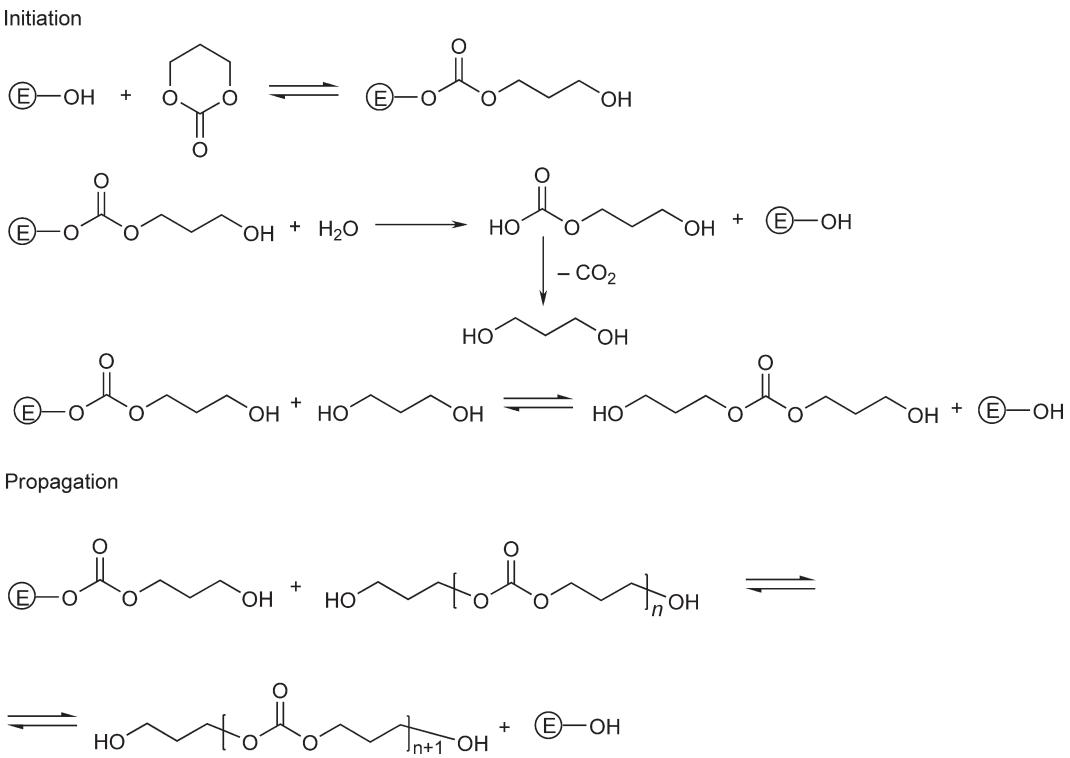
Similarly, supported lipase derived from *Candida antarctica* catalyzes the polymerization to give the corresponding aliphatic PC. Bisht *et al.*[289] have also directed studies on extending the use of lipase-catalyzed ROP to cyclic carbonate monomers. From several lipases screened for bulk TMC polymerization (70 °C, 120 h), Novozym-435 (*C. antarctica*) gave almost quantitative monomer conversion (97%) and PTMC with a $M_n = 15\,000$ ($M_w/M_n = 2.2$) and with no decarboxylation during propagation. The lipases from *Pseudomonas* species (AK and PS-30) and 'porcine pancreas' (PPL) also exhibited high monomer conversions (80%, 120 h) but gave lower molecular weight polymers with broad dispersity. Analyses by ^{1}H NMR spectroscopy suggested that PTMC prepared by Novozym-435-catalyzed polymerization had terminal $-CH_2OH$ functionalities at both chain ends. Novozym-435-catalyzed TMC bulk polymerization at 70 °C has chain-type propagation kinetics. The highest PTMC molecular weight $M_n = 24\,400$ was obtained by conducting the polymerization at 55 °C. The reaction temperature increase led to lower molecular weight (at 85 °C, 6000). Increasing the water content resulted in enhanced polymerization rates and decreased molecular weights. It is proposed that the polymerization rates increase due to an increase in the number of propagating chain ends.[290] Separation of the oligomeric products from the polymerizations of TMC in dried dioxane and toluene catalyzed by PPL led to the isolation of di- and triaducts of TMC.

Bisht *et al.*[289] proposed a mechanism for chain initiation and propagation for lipase-catalyzed TMC polymerization, based on the symmetrical structure of these products and the end-group structure of high-molecular-weight chains (**Scheme 62**).

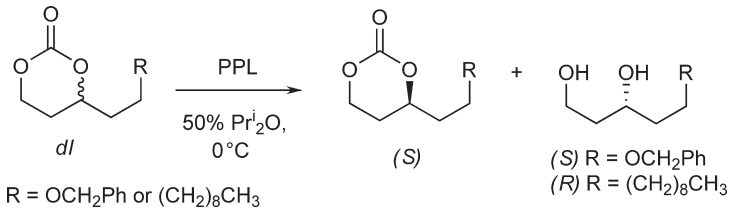
In contrast to the results obtained by Bisht and co-workers, Matsumura *et al.*[291] asserted that no polymerization of TMC took place when lipase Novozym-435 was used at 100 °C, while PPL showed the best results with respect to the monomer conversion and the molecular weight of the PC. TMC readily polymerized in bulk in the presence of PPL yielding a PC with M_w of up to 170 000 at 100 °C after 24 h. The enzymatic polymerization of TMC was significantly enhanced by the immobilization of PPL on diatomaceous earth (Celite).

This apparent contradiction is probably caused by the different reaction temperatures applied and different water content.[287] At 100 °C the lipase Novozym-435 seemed to be inactive and at lower temperatures (55–60 °C) exhibited the highest activity in the ROP of TMC among the tested enzymes.

The higher activity of lipase Novozym-435 over PPL was also confirmed by Deng *et al.*[292] in the study of lipase-catalyzed ring-opening copolymerization of CL and TMC. An increase in the lipase concentration in CL and TMC polymerization led to higher initial rates of conversion. In contrast, the M_n decreased at the same level of conversion with increasing catalyst concentration.



Scheme 62 Mechanism of chain initiation and propagation for lipase-catalyzed TMC polymerization.



Scheme 63 Enantioselective hydrolysis of substituted cyclic carbonate in the presence of PPL and water.

It is suggested that for higher activity some amount of water should be present in lipase.[289,290,293] However, higher concentration of water and suitable pH leads to enantioselective hydrolysis of substituted cyclic carbonate. The reaction of a six-membered cyclic carbonate, 4-(2-benzyloxyethyl)-1,3-dioxan-2-one, with PPL in phosphate buffer containing 50% of iPr$_2$O at 0 °C proceeded enantioselectively to afford optically active (*S*)-4-(2-benzyloxyethyl)-1,3-dioxan-2-one and (*S*)-5-benzyloxypropane-1,3-diol (**Scheme 63**).[288]

As earlier mentioned, catalytic activity of an enzyme can be increased by immobilization. According to Feng *et al.*,[294] synthesis of PTMC using PPL immobilized on silica particles gave polymers of M_n = 87 400 with M_w/M_n = 2.06. PPL and PPL immobilized on narrow distributed micron-sized glass beads were also employed successfully for the ROP of DTC.[295] Immobilized PPL exhibited higher activity than native PPL. Along with the increasing enzyme concentration, the molecular weight of resulting polymer decreased. Immobilized PPL showed outstanding recyclability even after the fifth recycle time for the synthesis of PDTC. The ^{1}H NMR spectra showed no evidence of decarboxylation during the ROP. Similar results were obtained by the ROP of DTC with free and silica-immobilized PPL. Heating of the monomer with the immobilized catalyst (1 wt.%) at 120 °C for 4 days gave a polymer of M_n = 15 700 (M_w/M_n = 1.4) with 85% yield.[296] Even better results including higher molecular weight (M_n = 26 200, M_w/M_n = 1.33) and PC yield (97.6%) could be achieved by second recycling of supported catalyst.

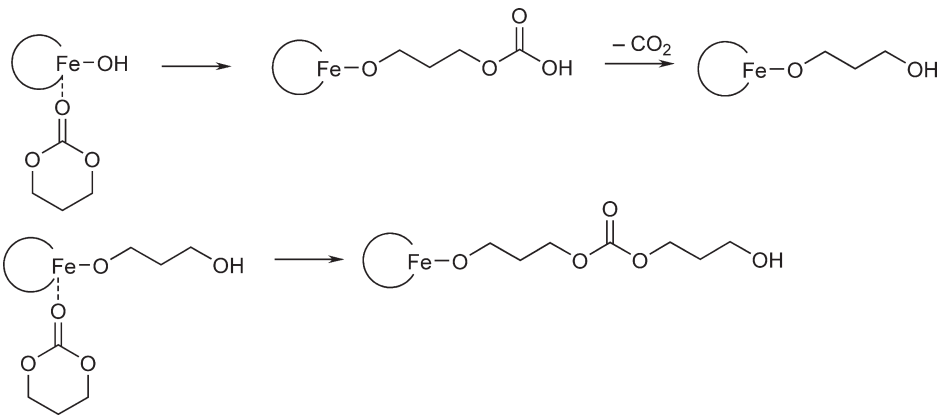
Large ring size cyclic carbonate cyclobis(decamethylene carbonate) was also polymerized using Novozym-435 as a catalyst in toluene.[297] Novozym-435 exhibited higher catalytic activity compared with Sn(Oct)$_2$ and high molecular weight (M_n) up to 54 100 was easily obtained. ^{1}H NMR spectra clearly demonstrated the existence of a terminal hydroxyl group, suggesting that the trace water may act as a substrate in the initiation process during the polymerization. Also solid phase polymerization in the absence of toluene unexpectedly took place at 75 °C below the melting point of macrocyclic monomer. Compared with six-membered TMC, much lower reaction activity was observed.

In addition to homopolymers a number of copolymers of cyclic carbonates were synthesized by enzymatic ROP. Among them are amphiphilic block copolymers of PBTMC and PEG which were synthesized through enzymatic polymerization using immobilized *porcine pancreas* lipase (IPPL).[298] The copolymerization of ω-pentadecalactone (PDL) and TMC was also studied by using lipase catalysts.[299] Of the six lipases evaluated for PDL/TMC copolymerizations in toluene at 70 °C, an immobilized form of lipase-B from *C. antarctica* (Novozym-435) was preferred. Changing the PDL/TMC comonomers feed ratio from 1:10 to 10:1 (mol:mol) provided copolymers that ranged in M_n and PDL mol.% from 7300 to 25 200 and 28–88, respectively. It was also noticed that in contrast to the chemical catalyst systems, Novozym-435 catalysis showed that PDL was consumed more rapidly than TMC. Also copolymers from Novozym-435 catalysis were characterized by random distribution of the repeating units at extended reaction times. Enzymatic ring-opening copolymerization of 5-methyl-5-benzyloxycarbonyl-1,3-dioxan-2-one (MBC) with TMC performed in the presence of *Pseudomonas fluorescens* (AK) gave polymers of random distribution of repeating units.[300] This copolymer was further used for the preparation of aliphatic PCs with pendant carboxylic acid groups.

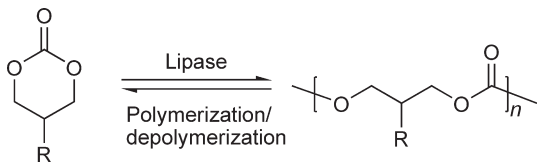
Poly(TMC-*co*-ethylene ethyl phosphate) was prepared by ring-opening copolymerization catalyzed by lipase enzymes (pancreas lipase, PPL and *Candida rugosa* lipase, CL) as catalysts in bulk at 100 °C with molecular weight (M_n) from 3200 to 10 200.[301] Degradation experiments showed that introducing phosphate groups into the TMC chain increases the hydrolysis rate of the copolymer.

Taking into consideration that aliphatic PCs and poly (ester-carbonate)s seem to be potential biodegradable or bioabsorbable materials, special interest has been devoted to the so-called biocompatible initiators, which are part of the human metabolism. Hematin, an insoluble pigment formed from the breakdown of hemoglobin, is an example of an enzyme-type initiator used in the polymerization of heterocyclic monomers. In 1993, Kricheldorf and Boettcher[302] used hematin in the polymerization of cyclic esters: L, L- and L,D-dilactides. Hematin was also utilized in the polymerization of TMC and DTC.[212] The polymerization was conducted in bulk at 100 °C, but high yield and high molecular weights (up to 75 000) were obtained only for unsubstituted 1,3-dioxan-2-one. No polymerization was observed for the reaction carried out in toluene, even at 100 °C. The hematin molecule possesses two types of functional groups: the Fe–OH group and three carboxyl groups, which can react with cyclic carbonate. The postulated insertion mechanism involves initiation by the Fe–OH group and subsequent alkoxide formation with CO_2 evolution (**Scheme 64**).

From the point of view of biodegradability it is important that enzymes can be useful both in the synthesis of polymers and their degradation back to cyclic carbonate monomers. TMC was produced by the enzymatic degradation of PTMC using lipase as the chemical recycling product.[303] The enzymatic degradation of PTMC having an M_n of 3000–48 000 using *C. antarctica* lipase (CAL) in acetonitrile at 70 °C afforded the corresponding cyclic monomer, TMC, in a yield of up to 80%. Thus the obtained TMC was readily polymerized again by lipase (**Scheme 65**). This method may be useful in establishing a novel methodology for sustainable polymer recycling.



Scheme 64 Postulated TMC polymerization mechanism involving initiation with the hematin Fe–OH group and subsequent alkoxide formation with CO_2 evolution.



Scheme 65 Lipase-catalyzed reactions of preparation of polycarbonates and their depolymerization.

The ROP of cyclic carbonates initiated by enzyme or enzyme-like species in which PCs terminated by hydroxyl groups are obtained seems very attractive, especially for the production of polyurethanes for medical application.

4.12.3.2.5 Polymerization of six-membered cyclic carbonates bearing functional groups

Polymerization of six-membered cyclic carbonates bearing functional groups, due to great reactivity and lack of CO_2 elimination, is the preferable way for preparation of functionalized PCs. Table 2 collects recently synthesized cyclic carbonates with respective literature references.

There are several methodologies used in the preparation of functionalized six-membered cyclic carbonates. The first one uses 2,2-bis(hydroxymethyl)propionic acid as a starting material[304–307] or its longer chain analogs (Scheme 66).[317]

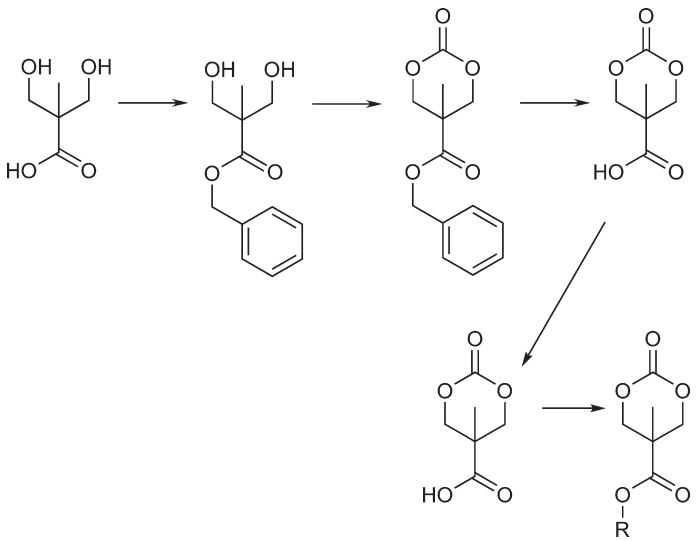
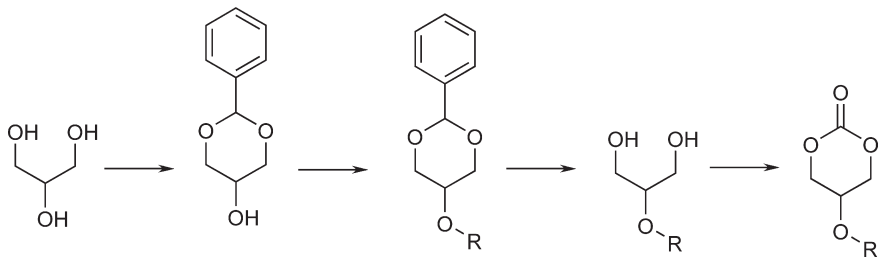
Scheme 66 shows a method of synthesis of a versatile synthon for a family of functionalized carbonated monomers. In the first step the benzyl ester of 2,2-bis(hydroxymethyl) propionic acid is formed, which is then converted into cyclic carbonate with triphosgene. Debenzylation is performed using hydrogen with palladium catalyst. Two procedures for the coupling of cyclic carbonate bearing carboxylic group to alcohols are used: either direct coupling using dicyclohexane carbodiimide (DCC) or conversion to the acyl chloride using oxalyl chloride followed by reaction with the alcohol or amine in the presence of base. The latter method has the advantage that the salt by-products are easily removed. Compared with methods wherein the functional group is attached prior to carbonate formation, the inverse sequence shown here more generally requires only a single unique reaction and purification step. Using these methods, a range of functional groups could be incorporated to generate new ROP carbonate monomers offering opportunities for coupling via substitution, cycloaddition, and amide or disulfide linkages or for introducing strongly hydrophilic or hydrophobic groups (Table 2).



Scheme 66 Synthetic pathway towards 2,2-bis(hydroxymethyl)propionic acid-based functionalized cyclic carbonates.



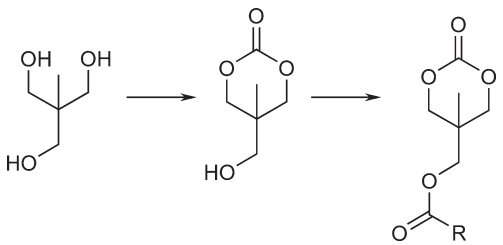
Scheme 67 Synthetic pathway towards glycerol-based functionalized cyclic carbonates.

In the second methodology glycerol is used as a starting material. Differentiation of glycerol hydroxyl groups can be achieved by cyclic acetal formation (Scheme 67).[216,308–313]

In this process benzaldehyde is commonly used in the reaction with glycerol. Acetal (5-hydroxy-2-phenyl-1,3-dioxan) can be isolated from a mixture of products by crystallization from cold ethyl ether. It crystallizes in the *cis* conformation. Then the secondary hydroxyl group can be transformed to the desired functional group. In the end, the protective acetal group is removed under acidic conditions and the cyclic carbonate is formed in the reaction with alkyl chloroformate. Because of the high reactivity of carbonate bonds in the cyclic structure, any further modifications should be carried out under mild reaction conditions.[313] This methodology was also used for other multihydroxyl compounds: 1,1,1-tris(hydroxymethyl)ethane, 1,1,1-tris (hydroxymethyl)propane, and pentaerythritol.[198,314,316,318]

1,1,1-Tris(hydroxymethyl)ethane and 1,1,1-tris(hydroxymethyl)propane were also used for direct carbonate bond formation with use of dialkyl carbonate followed by modification of the remaining hydroxyl group by esterification and carbonate or urethane bond formation (Scheme 68).[103,315]

In another method alkyl malonates are used as starting materials (Scheme 69). This approach uses rather harsh reaction conditions. However, it allows the introduction of allyl-[320,321] or hydroxyl-terminated[308] substituents and further modification.

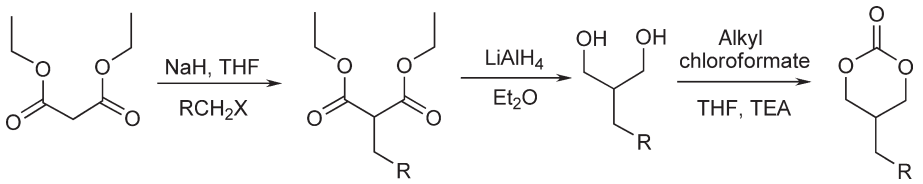


Scheme 68 Synthesis of six-membered cyclic carbonates with ester group.

Other cyclic carbonates were synthesized directly by a one-pot reaction from appropriate dihydroxyl compounds.[322–324]

A number of functionalized PCs and copolycarbonates can be obtained by direct polymerization of cyclic monomers bearing functional groups. Among the functional side-chain groups introduced into PCs are carboxylic group and their derivatives, hydroxyl, allyl, acrylate, methacrylate, styrene, and stilbene derivatives, and even five-membered cyclic carbonates (Table 2).

A series of COOH-functionalized PCs were synthesized via an organocatalytic ROP pathway under mild conditions.[305] The polymers exhibited moderate molecular weight (M_w = 3100–9700) and were very narrowly distributed (dispersity index = 1.07–1.15). Aliphatic amines with different chain lengths (triethylenetetraamine, tetraethylenepentamine, or pentaethylenehexamine)



Scheme 69 Synthetic path towards diethyl malonate-based functionalized cyclic carbonates.

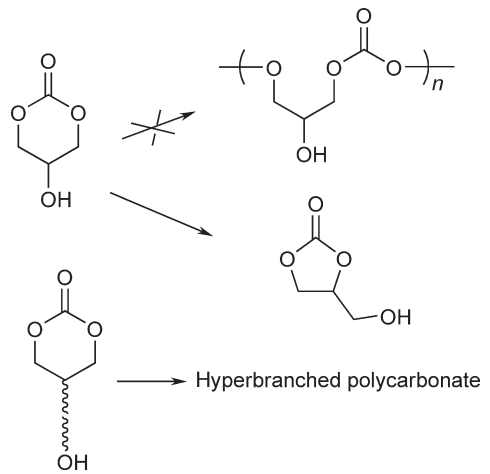
were then conjugated onto the PC backbone using *N*, *N*′-diisopropylcarbodiimide/*N*-hydroxysuccinimide (DIC/NHS) chemistry. These amine-functionalized PCs could form nanoparticles upon simple dissolution in water and were able to condense DNA; therefore, they have the potential to be a useful nonviral vector for gene therapy. Polymers of similar properties capable of drug delivery and gene delivery were presented by Frechet's group.[304] The authors used the cyclic carbonate with pendant COOH group to build dendritic molecules which were then eventually reacted with the appropriate amine. They used DCC chemistry for this purpose.

A simple way of preparation of PCs with side-chains terminated with hydroxyl groups is polymerization of cyclic carbonates bearing benzyl protecting group. The polymers were synthesized by ROP in bulk at 150 °C using aluminum isobutoxide [Al(O*i*Bu)$_3$], aluminum isopropoxide, and stannous octanoate as an initiator or by thermal polymerization of 5-benzyloxy-1,3-dioxan-2-one in the absence of any catalyst.[216,309,310] In all cases polymerization resulted in high-molecular-weight PCs (M_n = 80 000). Subsequent catalytic hydrogenolysis resulted in functional poly(5-benzyloxy-1,3-dioxan-2-one). After deprotection the pendant hydroxyl group resulted in an enhancement of the hydrophilicity of the PC. Furthermore, an evaluation of the degradation and cytotoxicity of synthesized polymers demonstrated better degradability compared with PTMC and similar toxicity compared with poly(lactide-*co*-GL).

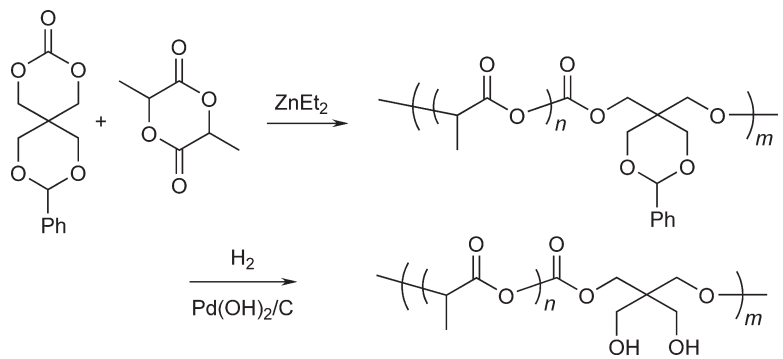
A similar effect was obtained by polymerization and deprotection of 9-phenyl-2,4,8,10-tetraoxaspiro[5,5]undecan-3-one.[318] The poly(ester-carbonate)s were synthesized by the ROP of L-LA and functionalized pentaerythritol-based carbonate monomer with diethyl zinc as a catalyst (Scheme 70). The protecting benzylidene groups in the copolymer poly(L-LA-*co*-9-phenyl-2,4,8,10-tetraoxaspiro[5,5]undecan-3-one) were removed by hydrogenation with palladium hydroxide on activated charcoal as a catalyst to give a functional copolymer, poly(L-LA-*co*-5,5-bis (hydroxymethyl)-1,3-dioxan-2-one), containing pendant primary hydroxyl groups. The cell morphology and viability on a copolymer film evaluated with ECV-304 cells showed that such poly(ester-carbonate)s derived from 9-phenyl-2,4,8,10-tetraoxaspiro[5,5]undecan-3-one are good biocompatible materials suitable for biomedical applications.

Direct anionic ROP of six-membered cyclic carbonate bearing hydroxyl group, 5-hydroxyl-1,3-dioxan-2-one, was not effective in the preparation of PCs due to the preferable isomerization reaction to inert five-membered GC (Scheme 71).[308] However, six-membered cyclic carbonates bearing free hydroxyl group attached to the ring via aliphatic spacer yielded hyperbranched PCs under anionic, coordination-insertion, or enzymatic ROP reaction conditions.[308,313]

In many cases, reactive double bonds were introduced into the cyclic carbonate structure for subsequent cross-linking, epoxidation, or addition reactions.[307,311,312] Polymers of six-membered cyclic carbonate with pendant allyl ether group



Scheme 71 Preferable isomerization reaction of six-membered cyclic carbonate bearing hydroxyl group to inert five-membered cyclic carbonate (a); formation of hyperbranched polycarbonates in case on monomers with hydroxyl group linked via a spacer (b).



Scheme 70 Synthesis of poly(ester-carbonate)s by the ROP of L-LA and functionalized pentaerythritol-based carbonate monomer with diethyl zinc as a catalyst.

were synthesized by ROP in bulk at 120 °C. Two kinds of catalysts $Sn(Oct)_2$ and IPPL on silica particles were applied. Postpolymerization oxidation reactions carried out with *m*-chloroperoxy benzoic acid afforded polymers with epoxide groups placed randomly along the backbone (random copolymer) or in every repeating unit (homopolymer). The epoxide-containing polymers could afford facilities for further modification. A functionalized cyclic carbonate monomer containing a cinnamate moiety, 5-methyl-5-cinnamoyloxymethyl-1,3-dioxan-2-one, was polymerized and copolymerized with L-LA with diethyl zinc ($ZnEt_2$) as initiator/catalyst.[314] The cinnamate-carrying copolymer was further photo-cross-linked.

In other works the authors performed the ring-opening metathesis polymerization (ROMP) of norbornene functional group with a typical ruthenium catalyst [bis(tricyclohexylphosphine)benzylidene ruthenium(IV) dichloride], to smoothly obtain the corresponding polyalkenamers.[323,324] In addition, the $Sc(OTf)_3$-mediated cationic ring-opening reaction of the cyclic carbonate moiety of polyalkenamer proceeded along with volume expansion or nearly zero volume shrinkage to yield the corresponding networked polymer. Introduction of styrene moiety into the cyclic carbonate structure (**19**, **Table 2**) gave opportunity for the anionic polymerization of a six-membered cyclic carbonate and the anionic depolymerization of the obtained polymer, radical cross-linking, and anionic decross-linking of the cross-linked polymer.[317] The monomer 5-ethyl-5-[(*p*-vinylphenyl)methoxymethyl]-1,3-dioxan-2-one (St6CC) underwent anionic polymerization with potassium *tert*-butoxide (*t*-BuOK) as an initiator in THF to afford the corresponding PC [poly(St6CC)]. It was confirmed that this polymerization was an equilibrium process by the relationships between the polymerization temperature and monomer conversion. Poly(St6CC) underwent anionic depolymerization with *t*-BuOK as a catalyst in THF at 20 °C for 24 h to recover St6CC in 60% yield. Treatment of poly(St6CC) with a radical initiator afforded the cross-linked polymer. Employment of styrene as the comonomer satisfactorily afforded the corresponding cross-linked polymer. It underwent anionic decross-linking with *t*-BuOK in THF at 50 °C for 24 h to afford a THF-soluble polymer. The yield of the THF-soluble part increased as the styrene composition in the cross-linked polymer increased. It was suggested that the decross-linking efficiency depended on the cross-linking density.

In case of selective anionic ROP of a bifunctional cyclic carbonate consisting of both five- and six-membered rings a PC remaining a five-membered cyclic carbonate group in the side-chain (**Table 2**) has been afforded.[321] The equilibrium nature of the polymerization allowed the efficient depolymerization of the polymer by a catalytic amount of DBU to recover the monomer in high yield, in which the five-membered cyclic carbonate ring also remained unreacted.

4.12.3.3 Polymerization of Seven-Membered Cyclic and Larger Ring Size Cyclic Carbonates

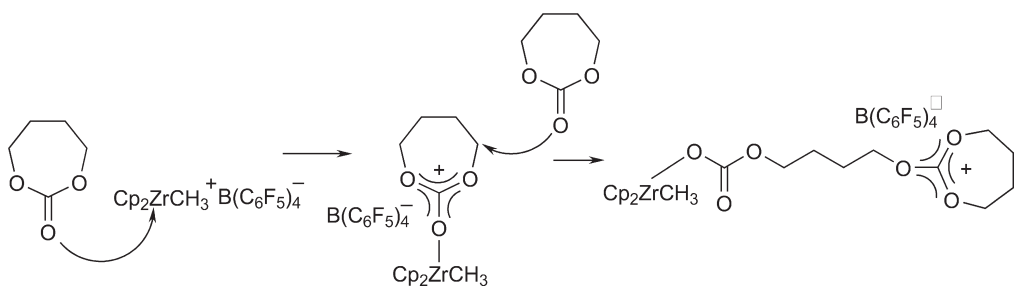
4.12.3.3.1 Polymerization of seven-membered cyclic carbonates

The ROP of seven-membered cyclic carbonate (1,3-dioxepan-2-one, tetramethylene carbonate, TeMC), due to relatively high ring strain, proceeds easier than that of the six-membered one. However, the number of reports concerning the polymerization of seven-membered cyclic carbonate is rather limited, mainly because of difficulty in the synthesis of the monomer. In contrast to TMC, seven-membered TeMC is thermally unstable and difficult to isolate and purify. It is easier to obtain the double size cyclic monomer – cyclobis(TeMC) – than the monomeric form.[325] It is worth to underline that the polymerization of seven-membered cyclic carbonate can be proceeded in a controlled manner.

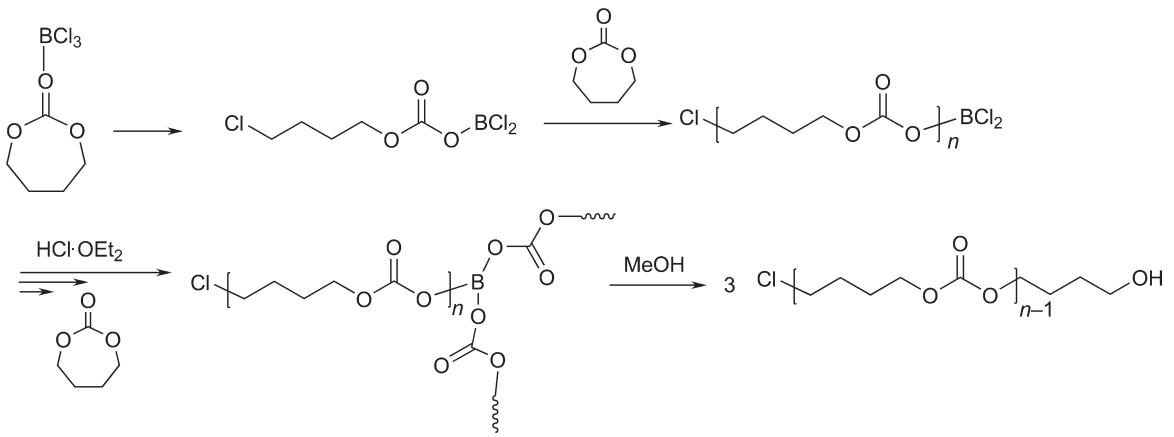
Several attempts have been made to achieve controlled ROP of six-membered cyclic carbonates by the combination of bulky substituents and Lewis acids.[326–328]

Hayakawa *et al.*[329] for the first time reported cationic ROP of seven-membered cyclic carbonates in 1997. Living ROP of the TeMC was achieved when the cationic zirconocene complex $[Cp_2ZrMe]^+[B(C_6F_5)_4]^-$ was used as a catalyst. The authors observed a linear relation between the conversion and molecular weight of the obtained polymer when the reaction was carried out at room temperature. The molecular weight distribution was maintained narrow during the polymerization. The authors claimed that the polymerization proceeds according to an active chain end (ACE) monomer mechanism (**Scheme 72**).

Earlier, Kricheldorf *et al.* examined in detail the polymerization of lactones with several Lewis acids. The authors suggested that some metal bromides with vacant p- or d-orbitals react with lactones to give bromoalkanoic acids via complexation at the *exo*-cyclic oxygen and cleavage of the alkyl–oxygen bond. Especially in the cases of the metal bromide with energetically favorable d-orbitals like $SnBr_4$ and $ZnBr_2$, metal–oxygen bonds are formed leading to polymerization reactions via an insertion mechanism at 60 °C, where M_w/M_n of the obtained polymers is about 1.7.[330] The same group investigated ROP of a TeMC using $BCl_3/HCl \cdot OEt_2$ as an initiator system.[331] It was found that the addition of $HCl \cdot Et_2O$ promoted the polymerization even at low temperature (0 °C) to produce the corresponding PC with controlled molecular weight and narrow dispersity



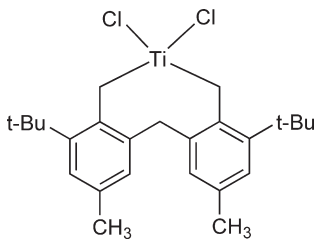
Scheme 72 Cationic polymerization of 1,3-dioxepan-2-one.



Scheme 73 Polymerization of TeMC initiated with BCl_3/HCl·Et_2O.

index ($M_w/M_n < 1.2$), but relatively low molecular weight ($M_n = 6600$). The authors suggested that the presence of $HCl \cdot OEt_2$ may promote the sequential insertion reaction of TeMC between the boron-oxygen bond by the activation of the monomer and/or loosening the boron-carbonate bond by coordination to the carbonate oxygen in the polymer propagating end (Scheme 73).

It was found that a titanium-based catalyst, 2,2′-methylene-bis(6-*tert*-butyl-4-methylphenolate)titanium dichloride, also initiated the living polymerization of TeMC to afford polymers with narrow molecular weight distributions (Scheme 74). The molecular weight of the poly(TeMC) obtained can be controlled by changing the initial cyclic carbonate/catalyst mole ratio. It is characteristic that the PC macromolecules formed in the presence of this catalyst had hydroxytetramethylene terminal units at both ends.[326,332]

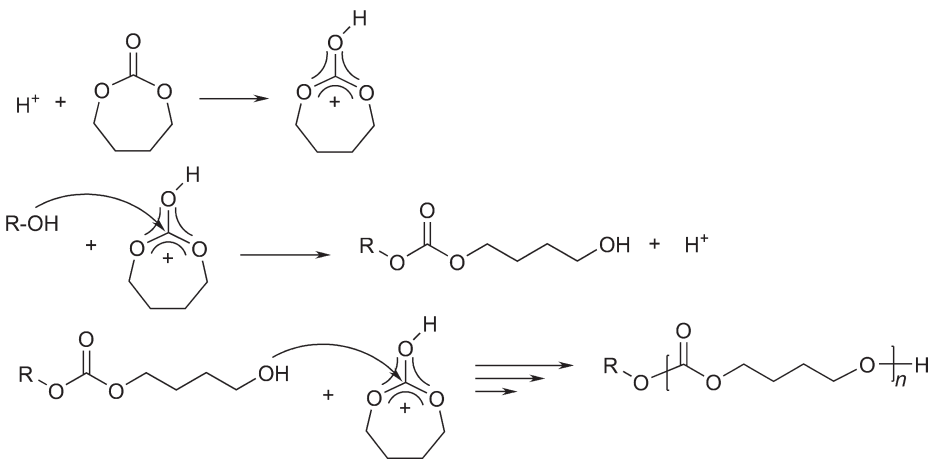


Scheme 74 Structure of titanium catalyst.

Endo *et al.* also found that TeMC underwent polymerization according to an AM mechanism in the presence of alcohol and Brønsted acid as the initiator and activator, respectively (Scheme 75).[333–335]

The first step consists of the protonation of the monomer carbonyl oxygen to produce the AM, which reacts readily with OH groups. The corresponding ring-opening reaction produces a linear carbonate with a terminal hydroxyl group. In the next step another activated molecule of cyclic carbonate reacts with a hydroxyl end-group leading to chain extension. The resulting PC has an R residue which is derived from the initiator alcohol and a hydroxyl group at the chain ends (Scheme 75).

The authors have found that the ROP of TeMC initiated with H_2O or a primary alcohol (e.g., butyl alcohol) in the presence other Brønsted acids such as $HCl \cdot Et_2O$ proceeded without decarboxylation to give linear poly(TeMC) with $M_n = 1000–10\,000$ and a narrow dispersion index (~ 1.15). They postulated that the key feature of this polymerization is the appropriate acidity of the protonic acid, which should be not as high to polymerize the monomer by itself but sufficient to activate the monomer.[333,334]



Scheme 75 Mechanism of AM polymerization of TeMC.

It is worth noticing that in contrast to a six-membered cyclic carbonate, the cationic polymerization of seven-membered cyclic carbonate leads to the corresponding polymer without ether linkages.[101] The polymerization of TeMC carried out in the presence of typical cationic initiators like $CH_3OSO_2CF_3$, $C_2H_5OSO_2CF_3$, $HOSO_2CF_3$, and $SnCl_4$ proceeds at 20 °C about 100 times faster than that of TMC and is not accompanied by elimination of carbon dioxide. The decarboxylation, in the case of the polymerization of seven-membered cyclic carbonate, may be suppressed, since the propagation reaction dominates over backbiting degradation. The activation energies in the polymerizations of TeMC and TMC were estimated to be 6.27 and 8.52 kcal mol^{-1}, respectively.[86,101]

Trifluoromethane sulfonic acid was also used as a catalyst in ring-opening copolymerization of a seven-membered cyclic carbonate and trioxane.[336] However, the carbonate monomer was consumed faster than trioxane and the decarboxylation took place to afford corresponding polyacetal–PC type copolymers containing poly(oxytetramethylene) units.

Similarly, the copolymerization of TeMC with glycidyl phenyl ether initiated by $CH_3OSO_2CF_3$ yielded polymers rich in cyclic carbonate-derived units when compared with the corresponding feed ratio and containing oxytetramethylene units as a result of five-membered cyclic carbonate formation.[337]

Similarly to TMC, TeMC undergoes spontaneous polymerization in bulk at above 100 °C affording the corresponding PC.[212]

As far as anionic polymerization of seven-membered cyclic carbonate is concerned, it was found that a ring strained monomer easily undergoes ring-opening reaction. The polymerization of TeMC initiated with *sec*-BuLi and carried out in THF afforded the corresponding PC in a relatively high yield in a short time.[100] It was shown that the polymerization carried out at higher temperature and with a lower initial monomer concentration led to a lower yield, lower molecular weight of the polymer, and a higher content of cyclic oligomers. These results can be explained by the formation of cyclic oligomers via backbiting reaction proceeding in addition to the propagation reaction, which is characteristic for equilibrium polymerizations. However, the relative polymerization rate of TeMC is about 35 times faster than that of TMC. This significant difference in the polymerization rates is caused by the larger ring strain. The negatively larger ΔH_p for TeMC in comparison with that of TMC was estimated by the MO calculations.[325]

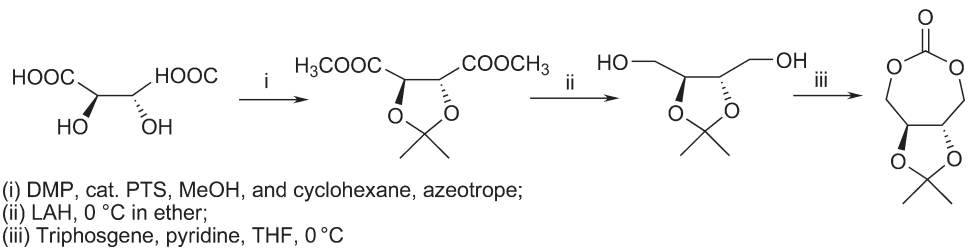
Recently, Wu *et al.*[108] have presented enzymatic polymerization of a novel seven-membered cyclic carbonate monomer, (5*S*,6*S*)-dimethyl-5,6-*O*-isopropylidene-1,3-dioxepin-2-one (ITC), derived from naturally occurring L-tartaric acid. The monomer was obtained in three steps (**Scheme 76**).

The polymerization was carried out with four commercially available lipases (*C. antarctica*, CAL-B) immobilized on acrylic resin, Novozyme-435, *P. fluorescens* (AK), and *Pseudomonas cepacia* (PS-30) at 80 °C, in bulk (**Scheme 77**).

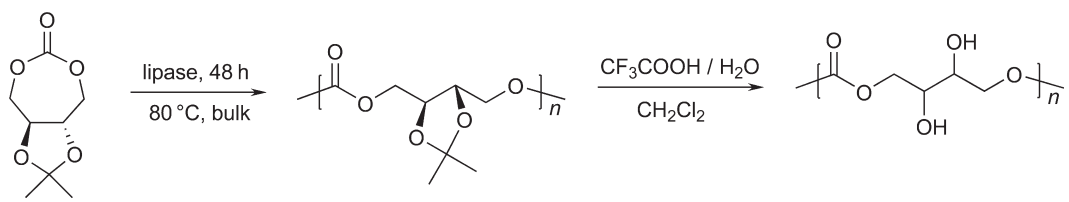
The highest molecular weight (M_n = 15 500 with M_w/M_n = 1.7) of the optically active PC ($[\alpha]_D^{20} = +77.8$) was obtained with immobilized *C. antarctica* lipase-B (Novozyme-435). Deprotection of the ketal groups caused minimal polymer chain degradation (M_n = 10 000, M_w/M_n = 2.0) and resulted in optically pure PC ($[\alpha]_D^{20} = +56$) bearing two hydroxy functional groups in the polymer repeating unit. The presence of the pendant hydroxyl groups enhanced the biodegradability of the polymer.

4.12.3.3.2 Polymerization of cyclobis(alkylene carbonate)s

As was mentioned earlier (Section 4.12.3.3.1), it is more convenient to obtain poly(TeMC) using cyclobis(TeMC) instead of its monomeric form: 1,3-dioxepan-2-one.[325] Cyclobis(TeMC) is easy to isolate and purify by recrystallization. The polymerization with *n*-$BuSnCl_3$ or $Sn(Oct)_2$ as an initiator is usually carried out in bulk, because the polymerization in solution (CH_2Cl_2) at lower temperatures proceeds very slowly. The monomer's high melting point (m.p. 172–174 °C) impels that the polymerization of cyclobis(TeMC) in bulk requires a high temperature (180 °C). However, despite high polymerization temperature no ether group formation was observed. In the case of using $Sn(Oct)_2$ the ^1H NMR studies revealed that these PCs contained octoate and OH terminal groups.



Scheme 76 Synthesis of monomer, ITC derived from naturally occurring L-tartaric acid.



Scheme 77 Enzymatic polymerization of ITC.

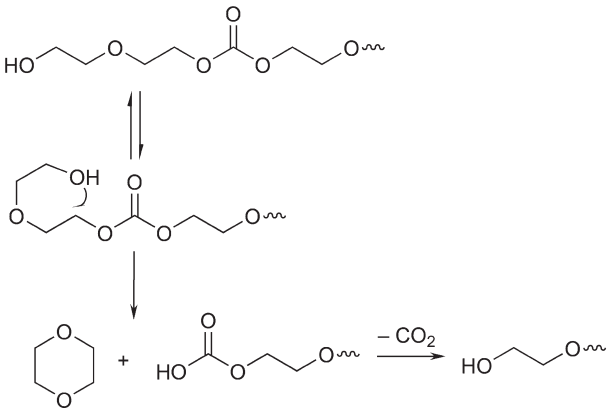
It is particularly interesting that poly(TeMC) crystallizes upon annealing, whereas PTMC does not crystallize despite higher concentration of polar carbonate groups. The susceptibility to degradation at relatively low temperatures is a second interesting feature of this aliphatic PC. The degradation to CO_2 and THF is complete at approximately 340 °C without leaving any residue. The material exhibiting such a complete degradation at below 350 °C may be applied for the production of solid foams, when heated together with a thermostable polymer.[338]

Similarly, cyclobis(hexamethylene carbonate), a dimer of nine-membered cyclic carbonate, was subjected to polymerization in bulk at 140 °C using $BuSnCl_3$ or $Sn(Oct)_2$ as a catalyst.[102] The best results were obtained with $BuSnCl_3$ affording polymer yields up to 89% and weight-average molecular weight of $M_w = 200\,000$. In all cases the M_w/M_n ratio was of the order of 2. DSC measurements showed that the PC rapidly crystallizes even at a cooling rate of 40 °C min^{-1}.

Also Weilandt *et al.*[106] have reported the synthesis, polymerization, and copolymerization of cyclobis(hexamethylene carbonate) and its fluorinated analog using anionic initiators and tin-based catalysts such as *sec*-butyllithium (in toluene), dibutylmagnesium (in THF), and dibutyltin dimethoxide (in melt). The resultant poly(hexamethylene carbonate) with molecular weight of $M_n = 48\,000$ ($M_w/M_n = 1.7$) was a semicrystalline polymer with a melting point of 54 °C and a glass transition temperature of − 51.3 °C, while poly (2,2,3,3,4,4,5,5-octafluorohexamethylene carbonate) was obtained either as a semicrystalline material with molecular weight of $M_n = 12\,800$ ($M_w/M_n = 1.94$) and a melting point of 40.8 °C or as an amorphous material with a glass transition temperature of − 39.8 °C.

It was found that the other cyclic dimer, cyclobis(diethylene glycol carbonate), is more stable and easier to isolate than the corresponding cyclic monomer, similarly as in the case of cyclic carbonates derived from α,ω-dihydroxyalkanes with 6, 7, and 8 methylene groups in a molecule. A comparison of the polymerizations of cyclobis(diethylene glycol carbonate) in bulk conducted at 145 °C catalyzed by $BuSnCl_3$, $Sn(Oct)_2$, or Bu_2SnO under similar conditions suggests that Bu_2SnO appeared to be the most reactive catalyst, but $Sn(Oct)_2$ is more attractive for preparative purposes because of higher molecular weights of the resultant polymers. Both ^1H and ^{13}C NMR spectra proved that all poly(diethylene glycol carbonate)s prepared possess an alternating sequence of ether and carbonate linkages. Despite a regular sequence, the amorphous character of poly(ethylene oxide-*co*-ethylene carbonate) was proven by DSC and WAXS measurements. The highest yields and molecular weights were obtained in the shortest time, whereas prolonged times caused rapid depolymerization. The thermal degradation of poly(ethylene oxide-*co*-ethylene carbonate) begun slowly at above 200 °C reached its maximum rate at 320 °C and yielded CO_2 and 1,4-dioxane as the main degradation products (**Scheme 78**).[104]

Polymerization of the largest (26-membered) cyclobiscarbonate, cyclobis(decamethylene carbonate), was conducted in bulk at 120 °C with $BuSnCl_3$ and $Sn(Oct)_2$ as catalysts.[105] Both catalysts showed almost equal reactivities, but the highest yields (up to 98%) and the highest molecular weights (M_w up to 88 000) were obtained with $BuSnCl_3$. Both catalysts yielded poly(decamethylene carbonate) not containing ether groups.



Scheme 78 Thermal degradation of poly(ethylene ether-carbonate).

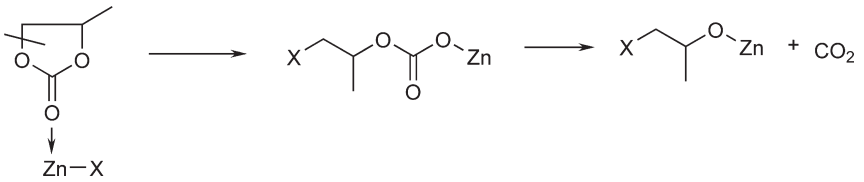
DSC measurements revealed that poly(decamethylene carbonate) is a rapidly crystallizing material with $T_m = 67$ °C. A comparison with PCs having less CH_2 groups in the repeating unit demonstrated that the rate of crystallization increases with an increasing number of CH_2 groups between carbonate linkages.

As was earlier mentioned, 26-membered macrocyclic carbonate, cyclobis(decamethylene carbonate), was attempted to undergo ROP by lipase catalysis in toluene.[297] Novozym-435 exhibited even higher catalytic activity toward cyclic decamethylene carbonate dimer polymerization compared with $Sn(Oct)_2$, while high molecular weight (M_n) of 54 000 and yield of 99% were still achieved at ultra-low enzyme/substrate (E/S) weight ratio of 1/200.

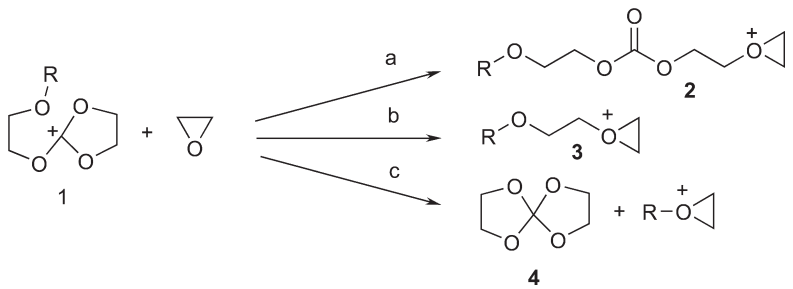
4.12.4 Copolymerization of Cyclic Carbonates with Other Heterocyclic Monomers

4.12.4.1 Copolymerization of Five-Membered Cyclic Carbonates

Five-membered cyclic carbonates such as ethylene and PCs, as earlier mentioned (Section 4.12.3.1), do not homopolymerize to afford poly(alkylene carbonate)s due to unfavorable thermodynamic characteristics. However, they can undergo copolymerization with other more reactive heterocyclic monomers. It has been found that such carbonate monomers could undergo copolymerization with oxiranes in the presence of organometallic catalysts formed in the diethylzinc-phenol and/or polyfunctional phenol system.[129,339] The authors postulated that the initiation step of the copolymerization involves most likely the epoxide reaction. Zinc alkoxide species formed in this reaction can easily propagate the copolymer chain, coordinating and enchaining both the epoxide and cyclic carbonate comonomers. However, in the case of cyclic carbonate, its ring opening may also proceed according to the reaction outlined in **Scheme 79** (via alkyl-oxygen bond cleavage) leading to decarboxylation. For the sake of clarity, participation of the adjacent zinc atom as the nucleophilic attack carrier is omitted. Thus, the poly(ether-carbonate)s obtained are characterized by a lower content of carbonate units with respect to ether units.[129,340]



Scheme 79 Ring opening reaction *via* alkyl-oxygene bond cleavage leading to decarboxylation.



Scheme 80 Possible products of the reaction of five-membered cyclic carbonates with oxiranes in the presence of cationic initiator.

Rokicki and Nguyen[341,342] described that the reaction of oxiranes with five-membered cyclic carbonates in the presence of $BF_3 \cdot OEt_2$ as a cationic initiator led to spiroorthocarbonates, poly(ether-carbonate), or polyether, depending on the oxirane ring substituent. It was found that the copolymerization proceeded through a trialkoxycarbenium cation stabilized by adjacent three oxygen atoms, being thermodynamically favored. A negative charge located on the oxygen atom of the carbonate carbonyl group is twice as large as that located on the oxygen atom of the oxirane, so the reaction with the carbonate monomer is more probable than that with the oxirane one. Trialkoxycarbenium ion (**1**, **Scheme 80**) can react according to three possible reaction pathways.

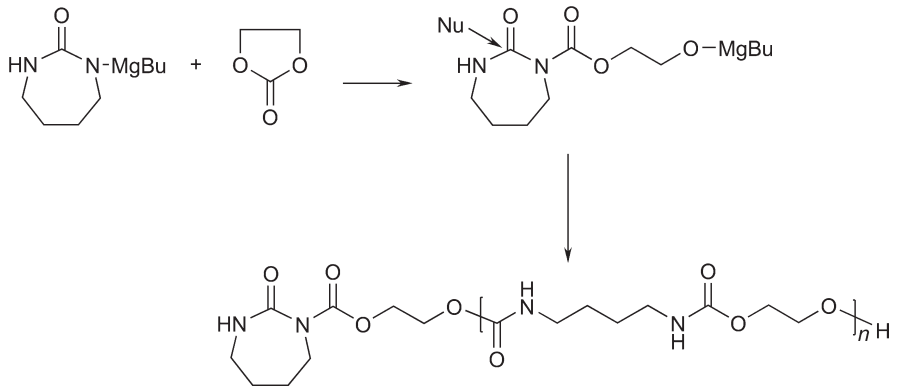
When *exo*-cyclic carbon atom of **1** is attacked by oxirane the product with ether-carbonate group **2** is formed (reaction pathway **a**). On the other hand as a result of oxirane attack on *endo*-cyclic carbon atom of **1** both the ether group **3** and cyclic carbonate are formed (pathway **b**). The intramolecular reaction between the carbocation and an oxygen atom of linear ether leads to spiroorthocarbonate **4** (pathway **c**). It was shown that the reaction proceeded partially according to pathway **a** in the case of using cyclic carbonates bearing phenoxymethyl and chloromethyl substituents, but for other five-membered cyclic carbonates the reaction pathway **b** dominated. Due to higher stability of the trialkoxycarbenium cation the polymerization rate is slower than that of oxirane homopolymerization.

Recently, a similar system was investigated by Cervellera *et al.*[343] They copolymerized mixtures of diglycidyl ether of bisphenol A (DGEBA) or a cycloaliphatic epoxy resin with PC using lanthanide triflates or $BF_3 \cdot MEA$ as a cationic initiator and DMAP as an anionic initiator. However, they observed that the carbonate was not incorporated into the network and acted like a plasticizer, lowering the T_g values of the cured materials. The same authors also used 4-phenoxymethyl-1,3-dioxolane-2-one (PGEC) and aromatic five-membered cyclic carbonate, 1,3-benzodioxolane-2-one (CC), for copolymerization with DGEBA.[344] Lanthanum(III) triflate used as cationic initiator allowed to copolymerize DGEBA with an aromatic five-membered cyclic carbonate, CC. However, PGEC remained entrapped in the cured material. The authors assigned the different reactivities of these two carbonates to the different electrophilicity of the carbonyl group.

Evans and Katsumata[345] showed that the copolymerization of EC and CL is possible when samarium(II) compounds were used as catalysts. In the presence of samarium complexes such as $(C_9H_7)_2Sm(THF)_{1.5}$, $(C_{13}H_9)_2Sm(THF)_2$, $SmI_2(THF)_2$, and $(C_5Me_5)_2Sm(THF)_2$ polymers containing EC units were formed. The copolymerization carried out in the presence of $[(Me_3Si)_2N]_2Sm(THF)_2$ afforded polymers with up to 23.5 mol.% of EC content, but the molecular weights of these polymers were lower than those produced using the $(C_5Me_5)_2Sm(THF)_2$ catalyst.

Copolymers of EC with CL or VL were also synthesized by Shirahama *et al.*[346] using $(C_5Me_5)_2SmMe(THF)$ as catalyst. It is worth noticing that the copolymerization carried out using samarium catalyst yielded a polymer of really high molecular weight ($M_n = 140\,000$). The EC/CL copolymers contained up to 30 mol.% of carbonate units and were obtained in better yield compared with that of EC/VL copolymers. Chen and co-workers used another lanthanide such as neodymium tris (2,6-di-*tert*-butyl-4-methylphenolate) $[Nd(DBMP)_3]$ as a single-component catalyst for EC/CL copolymerization.[347] Copolymers containing up to 22 mol.% of EC with high molecular weights (140 000) and moderate molecular weight distributions ($M_w/M_n = 1.66–2.03$) were obtained at room temperature. Compared with homopoly(CL), the copolymers with EC units exhibited increased glass transition temperatures (−35.6 °C), reduced melting temperatures (44.5 °C), and greatly enhanced elongation percentage at break. It was found that the crystallinity of the copolymers decreased with the increasing EC molar percentage in the products.

Höcker's group reported that unreactive five-membered cyclic carbonates such as EC and PC can be successfully copolymerized with tetramethylene urea (TeU) to afford polyurethanes.[348–350] It is to be underlined that such polyurethanes were synthesized via nonisocyanate methods. The result of all



Scheme 81 Copolymerization of five-membered cyclic carbonates with tetramethylene urea leading to polyurethanes.

copolymerization reactions was the polyurethane with alternating carbonyl-amino-tetramethylene-amino and EC, or PC repeating units. The resulting polyurethane was characterized by relatively high molecular weight (~ 20 000) and dispersity index of 2. According to the mechanism proposed by the authors, the butylmagnesium salt of TeU reacts with EC. The resultant butylmagnesium alkoxide reacts with another TeU molecule leading to an intermediate (Scheme 81). The intermediate adduct of EC and TeU represents an A–B-type monomer suitable for a polyaddition reaction.

The polyurethanes with randomly distributed TeU–EC and TeU-PC units, containing up to 54 mol.% of PC repeating units, were obtained. Studies on the copolymerization of TeU with mixtures of EC and PC showed that the reactivity of EC is approximately 5 times higher than that of PC. The authors proposed a new mechanism for the copolymerization based on ^{1}H NMR spectroscopic investigations of a blocked isocyanate model compound, indicating that the TeU ring is not opened to form an isocyanate under the reaction conditions applied.

The same authors successfully copolymerized EC or PC with mixtures of TeU and γ-butyrolactone (BL) at 100 °C in the presence of Bu_2Mg as a catalyst.[351] From NMR spectroscopic data of the terpolymers obtained ($8100 < M_n < 19\,300$) with up to 62.4 mol.% of BL, it was shown that the reactivity of the five-membered cycles used increases in the following order: EC ≫ PC ≈ BL. ^{13}C NMR spectroscopy revealed that TeU–EC or TeU–PC and TeU–BL units were randomly distributed in the polymer chain.

4.12.4.2 Copolymerization of Six-Membered Cyclic Carbonates

Six-membered cyclic carbonates easily copolymerize with different cyclic carbonates (five-, six-, and seven-membered) as well as with other heterocyclic monomers. The majority of copolymerizations proceed according to the coordination-insertion or anionic mechanisms and most of the copolymers were obtained with the participation of TMC or neopentyl carbonate.

4.12.4.2.1 Copolymerization of TMC and neopentyl carbonate with other cyclic carbonates

As was mentioned in Section 4.12.4.1, six-membered TMC is more reactive, copolymerized with five-membered EC, but still the content of EC units in the resulting copolymer was rather small, not exceeding a few mol.%.

TMC and DTC can be used for the copolymerization with a less reactive six-membered cyclic carbonate such as 5,5-diphenyl-1,3-dioxan-2-one.[92] The copolymerization proceeded according to an anionic mechanism to afford a polymer containing 5,5-diphenyl-1,3-dioxan-2-one units, but in lower ratio than that in the monomer feed. DTC was also copolymerized with other six-membered cyclic carbonates to furnish random as well as block copolymers upon addition of the initiator (*sec*-butyllithium) to a mixture of the monomers or upon consecutive addition of the monomers to the initiator, respectively.[198]

4.12.4.2.2 Copolymerization of six-membered cyclic carbonates with cyclic esters and ethers

Aliphatic polyesters have a leading position among the various biodegradable polymers, due to the hydrolytic chain cleavage catalyzed by enzyme yielding hydroxyacids, which are in many cases metabolized. The modification of the properties of the brittle biodegradable polyesters such as poly(hydroxyalkanoate), polylactide, and polyglycolide has been intensively investigated.[291,352]

Usually biodegradable or biocompatible elastomers were introduced to toughen the brittle polyester. Maxon®, a bioabsorbable suture material, is produced by the copolymerization of GL with approximately 32.5 mol.% of the softer TMC.[353] The addition of TMC decreases the brittleness of pure polyglycolide. The incorporation of carbonate linkages into the polyester constitutes an additional route for improvement of the performance of polyesters. Because the carbonate linkages are more stable to hydrolysis *in vitro* (no autocatalytic effect of acid groups) the material has prolonged shelf life. However, the hydrolysis of the carbonate proceeds faster *in vivo* and the copolymer can be used as a bioabsorbable material.[354,355] In relation to this, the copolymerizations of cyclic carbonates with lactones and lactides have been widely explored. Depending on the comonomer reactivity and reaction procedure, the copolymerization may result in random or block copolymers.

DTC has been copolymerized with CL, pivalolactone (PVL), [(R)-β-BL], and L,L-lactide (LLA).

Höcker and co-workers used CL for the copolymerization with DTC. The reaction was carried out using *sec*-BuLi as an anionic initiator in toluene resulting in the formation of a copolymer containing carbonate and CL block fractions.[91] It

was shown that the reactivity of the cyclic carbonate is higher than that of CL.[356]

The copolymerization of a mixture of DTC and CL at low temperatures resulted in A–X–B-type copolymers, where A was a PDTC block, B a PCL block, and X a random DTC and CL block. As a consequence, DTC–CL and CL–DTC heterodiads were observed in the ^{13}C NMR spectra. The concentration of heterodiads was seen to increase with temperature such that, at 80 °C, a random copolymer was obtained. From a mechanistic point of view, the active species of each monomer would be eligible to react with both DTC and CL. In case of using Mg-, Al-, and Zn-based catalysts, transesterification plays a minor role, and the microstructure of the copolymers prepared is determined by the nucleophilicity of the active species and the electrophilicity of the monomer alone. For alkoxide (Li^+, K^+) initiators and Sn-based catalyst, transesterification takes place and determines the final polymer microstructure, besides the copolymerization parameters, especially at higher temperatures.[357]

The copolymerization of DTC and CL was also initiated by polystyryllithium and lithium polystyrylethoxide, leading to a linear copolymer and a cyclic oligomer mixture.[196]

The copolymerization of DTC with another four-membered cyclic ester, PVL, initiated with potassium dihydronaphthalide at – 10 °C in toluene afforded block copolymers in a yield of about 90% (Scheme 82).[91,357,358]

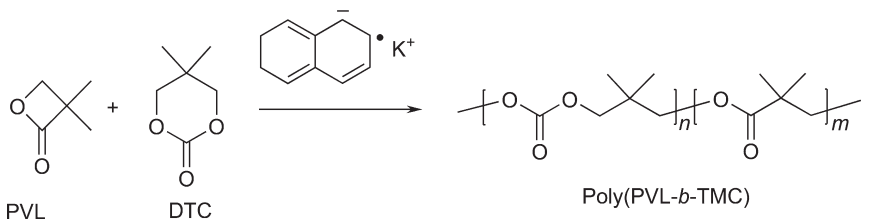
The explanation for this block formation is based on the large difference in the rate of polymerization of DTC and PVL, combined with the incompatibility of the active species of homopolymerizations (potassium carboxylate, active with PVL, does not react with DTC). It is important that no transesterification occurs between the ester and carbonate groups.

The random copolymer of TMC with another four-membered cyclic ester, [(R)-β-BL], exhibits interesting properties (Scheme 83).[359] The presence of ester segments susceptible to enzymatic hydrolysis causes that such poly (ester-carbonate) containing even 80% of TMC easily undergoes biodegradation, while pure PTMC does not degrade under the same conditions.

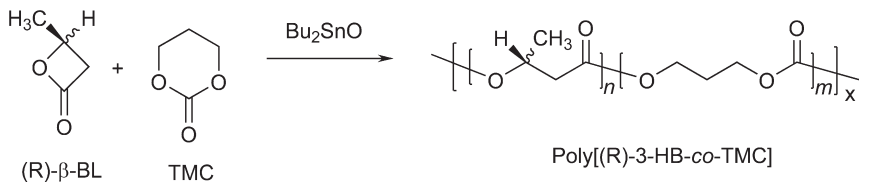
The sequential copolymerization of DTC and LLA revealed different polymer microstructures, depending on the order in which the monomer was polymerized first.[357,360] When LLA was polymerized first, a random copolymer was formed, whereas the addition of LLA to a 'living PDTC resulted in a block copolymer. The copolymerization of a mixture of LLA and DTC also resulted in a random copolymer. Based on these results, the following mechanism was proposed by the authors. The PLLA active centers are well stabilized by the adjacent carbonyl group (enol formation) and by the formation of a five-membered cyclic complex including the metallic species. After reaction of the PLLA active centers with DTC, the newly formed active site has a reduced capability of stabilization (Scheme 84).

The most electrophilic species in the system capable of reacting with the active centers is the ester group of a LLA–LLA diad in the polymer chain. Hence, by this reaction, the active LLA site is regenerated and an LLA–DTC–LLA triad is formed.

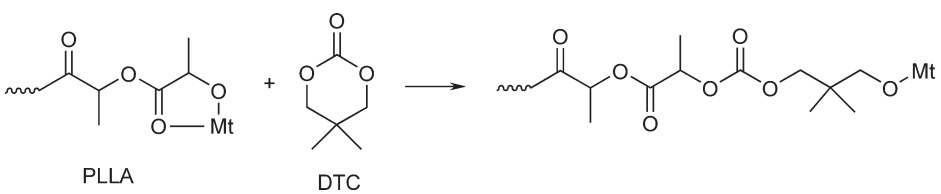
Poly(1,4-dioxan-2-one-*co*-TMC) can also be included to the group of synthetic biodegradable carbonate copolymers.



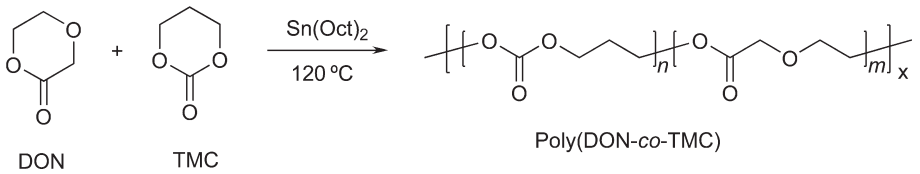
Scheme 82 Copolymerization of DTC with four-membered cyclic ester initiated by potassium dihydronaphthalide.



Scheme 83 Random copolymerization of TMC with four-membered cyclic ester leading to polymer susceptible to enzymatic hydrolysis.



Scheme 84 Sequential copolymerization of LLA and DTC.



Scheme 85 Copolymerization of 1,4-dioxan-2-one and TMC initiated with $Sn(Oct)_2$.

Polymers with different compositions were synthesized by copolymerizations of 1,4-dioxan-2-one (DON) with TMC at 120 °C in the presence of $Sn(Oct)_2$ (Scheme 85).[361]

These copolymers can be used as a matrix for a sustained drug delivery system.

4.12.4.2.3 Copolymerization of six-membered cyclic carbonates with cyclic anhydrides

PTMC degrades slowly in aqueous solution, showing little molecular weight loss, sample weight loss, or change in morphology after several months which may not be desirable for use in medical implants and for drug delivery applications.[355] In contrary, poly(adipic anhydride) (PAA) attracts increasing attention as a new biomaterial due to its rapid degradation rate.[362] Ring-opening copolymerization of TMC with cyclic anhydrides is a feasible method to adjust the degradation rate of PTMC and to enhance polyanhydride mechanical strength. Attempts were made to alter the chemical composition of PTMC by copolymerization of TMC with adipic anhydride (AA). TMC and AA were copolymerized in bulk and solution with aluminum isopropoxide, $Sn(Oct)_2$, *n*-BuLi, $BF_3 \cdot OEt_2$, and Et_3N as catalysts to obtain block copolymers and random copolymers.[363] No formation of a copolymer was detected, although the synthesis conditions were varied over a broad range in terms of temperature (0–100 °C), solvent, reaction time, and type of initiator. No peaks from AA–TMC or TMC–AA heterolinkages were detected in ^{13}H NMR spectra. FTIR analysis sustained that the product consists of a mixture of homopolymers rather than a copolymer.

Polymerizations of TMC with sebacic anhydride or AAs were also studied at 180 °C with quinoline and $BF_3 \cdot OEt_2$ as catalysts. Either most of the TMC did not react or incomplete homopolymerization of TMC was observed.[364]

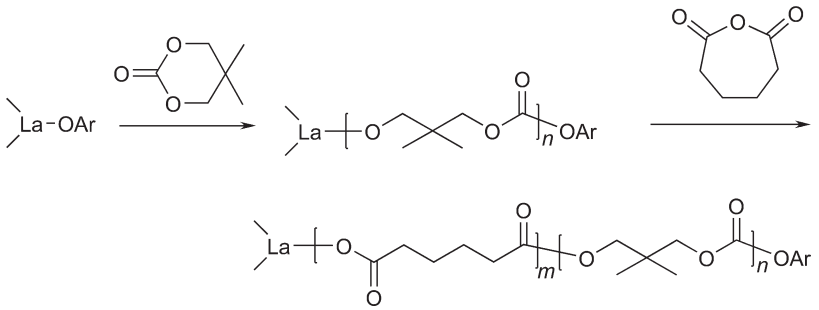
Several polymerizations of TMC with succinic anhydride (SA) or glutaric anhydride (GA) were conducted in bulk.[364] All experiments based on SA failed; however, polymerization of TMC and GA was successful when quinoline, 4-(*N*,*N*-dimethylamino)pyridine, or $BF_3 \cdot OEt_2$ were used as catalysts. It was shown that the reaction proceeded with CO_2 evolution. MALDI-TOF mass spectra revealed the formation of cyclic oligoesters by backbiting degradation. However, the main chain of the copolymer did not contain anhydride bonds. The monomer mixtures containing an excess of TMC yielded poly(ester-*co*-carbonate)s with number-average molecular weights up to 16 000. Analogous poly(ester-*co*-carbonate)s were obtained from TMC and 3,3′-tetramethylene GA.

Recently, Ling *et al.* revealed that a THF-soluble block copolymer of neopentyl carbonate with AA containing 64.7/35.3 DTC/AA in molar ratio with M_n of 123 000 and M_w/M_n of 1.64 could be synthesized at 25 °C in 32 min when the lanthanum tris(2,6-di-*tert*-butyl-4-methylphenolate) catalyst was used[365] (Scheme 86). Copolymers with AA block from 8.5 to 50.8% were prepared by changing the solvent and feeding ratio of DTC/AA.

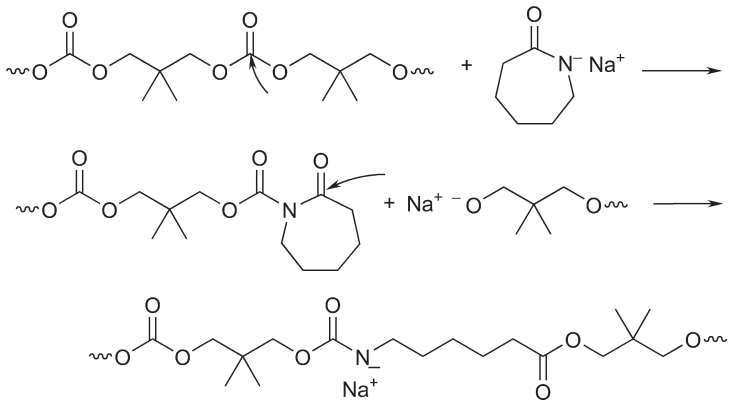
4.12.4.2.4 Copolymerization of six-membered cyclic carbonates with N- and P-containing heterocyclic monomers

In the 1980s, it was reported in the patent literature that lactams can be anionically copolymerized with cyclic carbonates to give a polymer containing urethane and ester groups besides carbonate groups.[366] Similar groups were identified when PCs were treated with ε-caprolactam in the presence of sodium lactamate.[367] In the early 1990s, Wurm *et al.*[368] found that the copolymerization of DTC with ε-caprolactam afforded a copolymer with alternating ester and urethane groups. From mechanistic investigation it was revealed that the polymer is formed in two reaction steps: first the PC is formed, then insertion of the ring-opened lactam moiety into the carbonate group occurs, which leads to ester and urethane groups (Scheme 87).

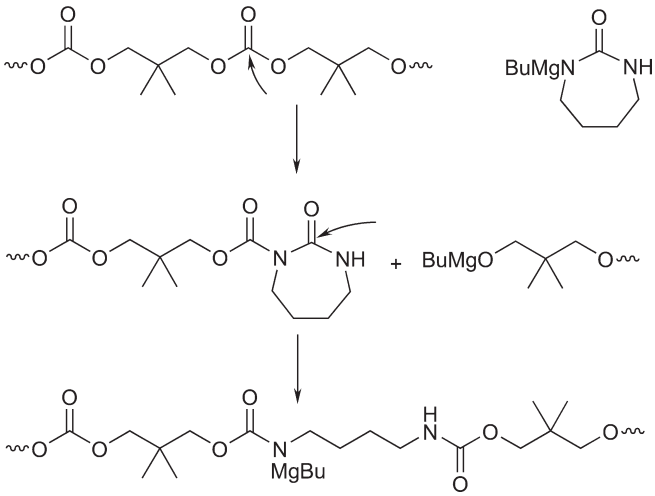
Similarly, the copolymerization of equimolar amounts of DTC with TeU in the presence of *sec*-butyllithium, dibutylmagnesium, or diethylzinc as a catalyst in melt and in solution with *N*,*N*′-dimethylpropylene urea as a solvent at 120 °C resulted in an almost alternating copolymer (Scheme 88).[348]



Scheme 86 Copolymerization of adipic anhydride with DTC.



Scheme 87 Copolymerization of ε-caprolactam and DTC leading to the copolymer with carbonate, ester, and urethane groups.



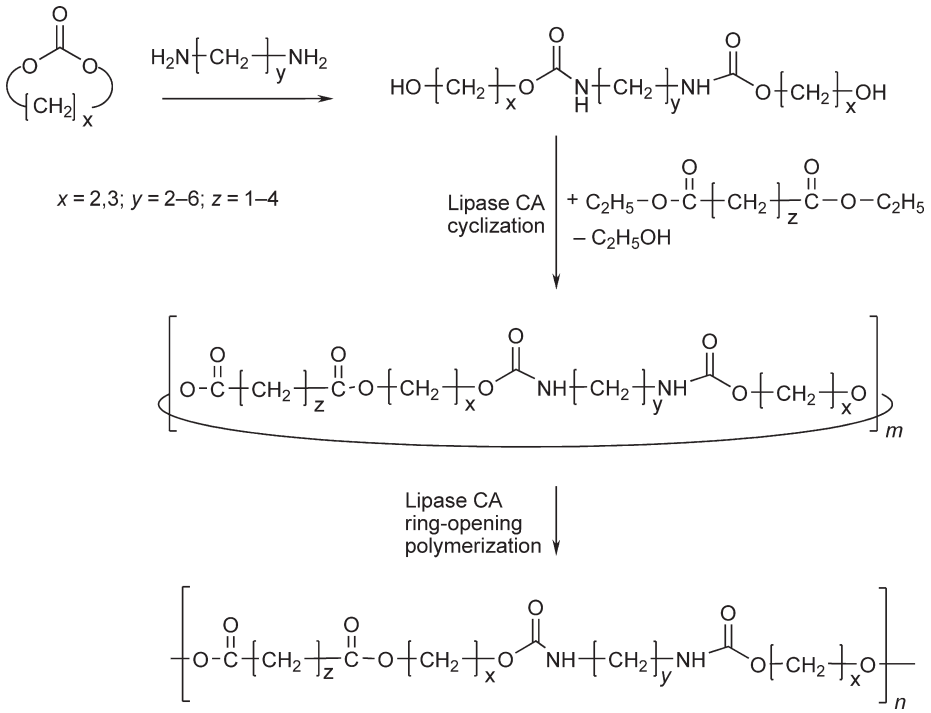
Scheme 88 Copolymerization of tetramethylene urea with DTC leading to the alternating copolymer.

In contrast to the copolymerization with EC (see Section 4.12.3.1), it was revealed that sequences of the PC are formed first. Later, when TeU is consumed, the concentration of carbonate groups in the polymer decreases and that of urethane group concentration increases.[349] After 24 h both monomers were consumed. Bu_2Mg initiates the polymerization of DTC, which is followed by a transfer of the active species to cyclic urea. This nucleophilic TeU species reacts with a carbonate moiety of the PC chain, resulting in chain cleavage and formation of two ACEs. The intermolecular reaction of these two fragments generates a new molecule in which a TeU is inserted formally into a DTC–DTC diad with the formation of two urethane groups. At the same time a new TeU active species is generated by the deprotonation of TeU. In contrast, the copolymerization of DTC with TeU in the presence of dibutyldimethoxytin, tris(*sec*-butoxy)aluminum, or tetrakis (*iso*-propoxy)titanium as a catalyst leads to copolymers with carbonate, urea, and urethane groups.[348] The polyurethane obtained in such a way is an amorphous material with $T_g = 23.3\,^{\circ}C$.

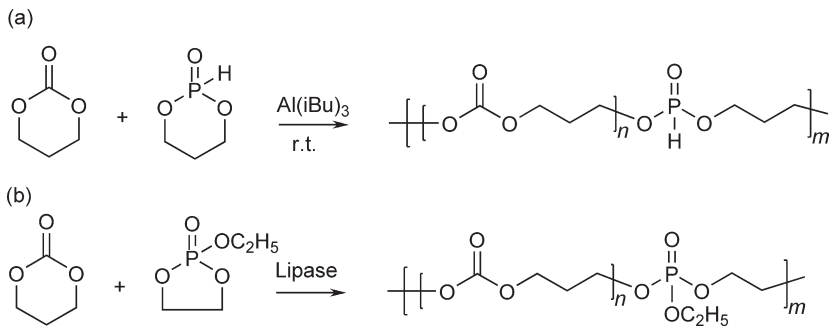
High-molecular-weight poly(ester-urethane)s with an M_w of 103 000 were also produced by the enzymatic ROP of the cyclic ester-urethane monomer.[369] However, this method did not involve polymerization of TMC, but its reaction with aliphatic diamine and then enzymatic cyclization followed by lipase-assisted ROP of cyclic macromonomer (**Scheme 89**).

It is known that poly(phosphoester)s have a great potential as a class of biomedical polymers because of their promising applications in tissue engineering and controlled drug release.[370] The ROP is one of the methods to get high-molecular-weight poly(phosphoester)s. The synthesis of poly (2-hydro-2-oxo-1,3,2-dioxaphosphorinane) and its application as a drug carrier was reported, in the 1970s, by Kaluzynski *et al.*[371] Recently, a new type of synthetic biodegradable copolymer has been synthesized by ring-opening copolymerization of TMC with 2-hydro-2-oxo-1,3,2--dioxaphosphorinane (TMP) in the presence of $Al(iBu)_3$ as a catalyst (**Scheme 90(a)**).[99] The highest molecular weight of the random copolymer was up to 16 000. Conversion studies showed that the composition of the copolymer is in agreement with the feed composition at high conversions, since TMC is more reactive than TMP.

Also, the novel enzymatic ring-opening copolymerization of ethyl ethylene phosphate (EEP) and TMC was performed in bulk at 100 °C using PPL or *C. rugosa* lipase to yield random copolymers having molecular weights ranging from 3200 to



Scheme 89 Enzymatic ROP of a cyclic ester-urethane monomer obtained from cyclic carbonate and diamine.



Scheme 90 Copolymerization of TMC with TMP in the presence of Al(*i*Bu)$_3$ as a catalyst (a); enzymatic ring-opening copolymerization of EEP and TMC in the presence of PPL or *C. rugosa* lipase.

10 200 (**Scheme 90(b)**).[301] The degradability of the copolymers was improved by the introduction of an EEP unit to the copolymer chain.

4.12.4.2.5 Cyclic carbonate block copolymers

Nowadays, block copolymers and terpolymers containing PC segments are of interest of many research groups producing biomaterials of special applications. Changing the composition of polymeric blocks as well as the block length, it is possible to tune the properties of the polymeric material such as biodegradation rate, hydrophilic–hydrophobic balance, and temperature sensitivity.

Copolymers containing aliphatic PC blocks can be synthesized according to two main strategies. The first one consists of sequential monomer polymerization proceeding without transformation of the active center. To obtain the copolymer of narrow molecular weight distribution, the order in which the monomers are introduced into reaction system must be adjusted to their reactivity. Additionally, the nature of the active center must be chosen in such a way to eliminate or reduce transesterification as well as backbiting reactions.

It was found that ROP of TMC (first step) and LLA (second step) allowed for the preparation of A–B–A triblock copolymers without significant transesterification. The optimization of the temperature and reaction time were decisive for the success of this approach.[372]

The PC block copolymer can also be obtained using the macroinitiator which constitutes one of the blocks. For the polymerization of cyclic carbonates, hydroxyl telechelic polymers usually are used. First, hydroxyl terminal groups are transformed into alkoxide ones to initiate the anionic ROP. The monofunctional macroinitiators result in A–B or A–B–C block copolymers and the difunctional macroinitiators in B–A–B block copolymers, where A represents the macroinitiator block, B the PC block(s), and C other polymeric blocks. Copolymerization also can proceed in the presence of

insertion-coordination catalysts. Difunctional macroinitiators based on PEO,[205,373–380] PTHF,[204] and PDMS[206] were applied for the ROP of cyclic carbonate.

Hyun *et al.*[182] have decribed synthesis of PTMC–PEG–PTMC triblock and methyl polyethylene glycol (MEPEG)–PTMC diblock copolymers according to the cationic polymerization mechanism using PEG or monomethoxy-PEG and $HCl \cdot OEt_2$ as an initiation system for TMC polymerization.

The syntheses of triblock PEG–CL–TMC copolymers {methoxypoly[(ethylene oxide)-*b*-(CL)-*b*-(trimethylene carbonate)]} were reported by Ould-Ouali *et al.* and Danhier and co-workers.[381,382] These copolymers spontaneously formed micelles and significantly increased the solubility of poorly water-soluble drugs.

Feijen's group synthesized carbonate block copolymers by the ROP of DL-lactide (DLLA), CL, and TMC in the presence of zinc bis-[bis(trimethylsilyl)amide] (97%) and monomethoxy polyethylene glycol (mPEG, 5800 and 1200) at room temperature.[383] In this case zinc bis[bis(trimethylsilyl)amide] combined with mPEG initiated the ROP of heterocyclic monomers with high conversion, affording block copolymers of controlled molecular weight and low dispersity index. Due to its high activity and low toxicity the zinc-based catalyst could be attractive for the synthesis of copolymers for biomedical applications. A similar catalytic system but based on calcium bis[bis(trimethylsilyl)amide] was presented also by Feijen's group.[384]

Hydroxytelechelic PCs are valuable building blocks to access linear A–B–A triblock copolymers incorporating a soft PC segment, such as for instance in PC/polyester, PC/polypeptide, or PC/polyurethane architectures.[385–388]

The synthesis of temperature-responsive poly[(TMC)-*b*-(L-glutamic acid)] copolymer was investigated by Sanson and coworkers.[389] PTMC–PGA diblock copolymer was synthesized by ROP of γ-benzyl-L-glutamate *N*-carboxyanhydride initiated by a primary amine end-functionalized PTMC macroinitiator.

Krogman *et al.*[390] presented the synthesis of blocked poly(phosphazene-*b*-carbonate)s. First, amino-terminated PTMC was synthesized via ROP. In the synthesis of block copolymers of polyphosphazenes linked to PCs the amino terminus was used to form a covalent link to poly(dichlorophosphazene).

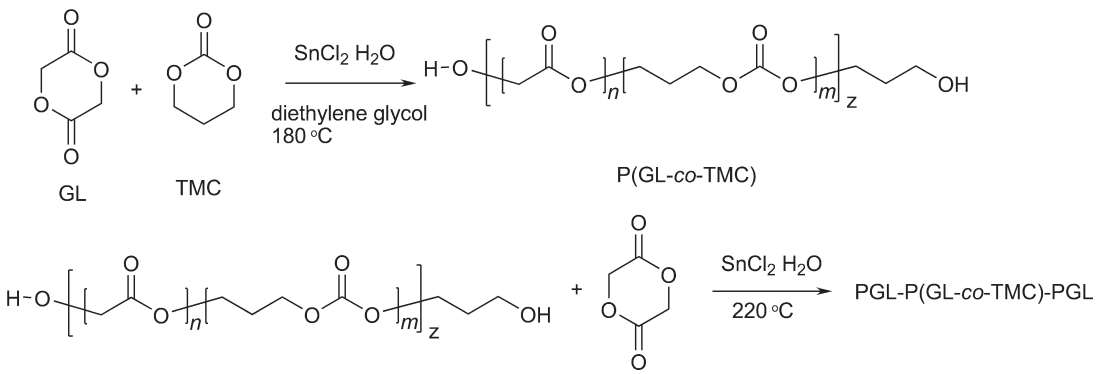
Triblock copolymers containing TMC segments and behaving like a thermoplastic elastomer were presented by Feijen's group.[385,391] Such materials were prepared by sequential ROPs of TMC and L-LA as well as TMC and D-LA under argon at 130 °C using 1,6-hexanediol and $Sn(Oct)_2$ as an initiator/catalyst system. First, a hydroxyl group-terminated PTMC was synthesized. These polymers containing polylactide blocks long enough to crystallize exhibited good tensile strenght and excellent resistance to creep. In equimolar blends of these enantiomeric copolymers, stereocomplexation between the enantiomeric polylactide segments occurred. Due to the enhanced phase separation, the specimens of stereocomplex had better resistance to creep than the enantiomeric block copolymers.

It is worth mentioning that instead of homopolymers also random copolymers may constitute the blocks. Feijen's group used a hydroxyl group-terminated random copolymer – poly(TMC-*co*-caprolactone) – instead of homopolycarbonate.[392]

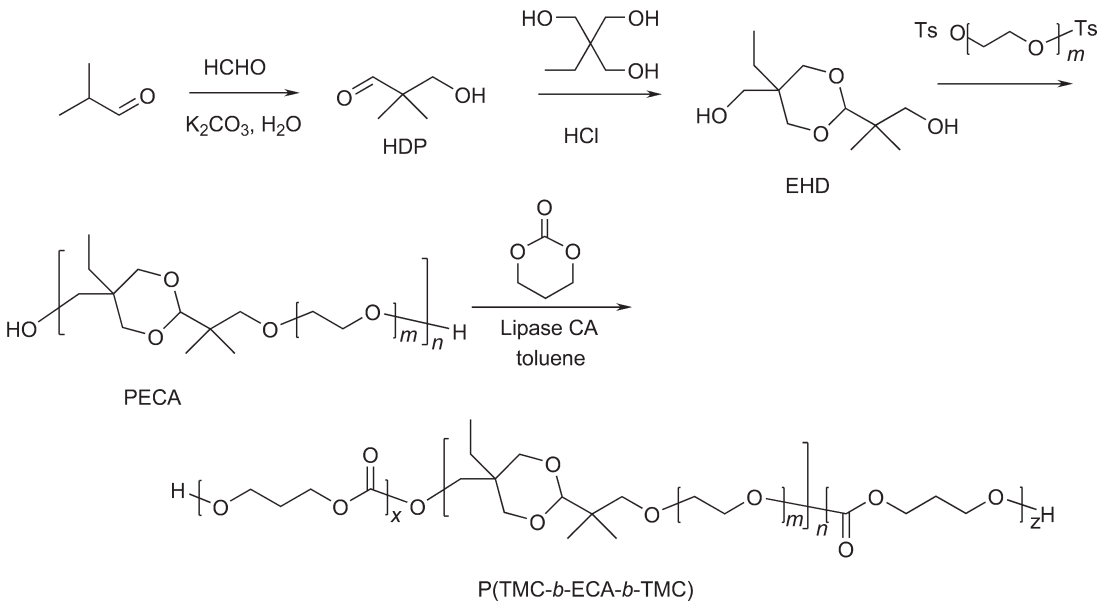
Especially interesting properties exhibited triblock poly{[(CL)-*co*-(TMC)]-*b*-(ethylene oxide)-*b*-[(CL)-*co*-(TMC)]} (PCTC–PEG–PCTC) obtained by Park *et al.*[393] By incorporating up to 25–40 wt.% of the TMC comonomer in the poly(CL) block, the resulting PCTC–PEG–PCTC triblock copolymer achieved sol stability while keeping the thermogelling property in a physiologically important temperature range of 10–50 °C. Thermogelling aqueous solutions of biodegradable polymers can be used as an implantable depot for sustained drug release and tissue engineering. The aqueous polymer solution was a low viscous sol at room temperature (20 °C) and formed a gel at body temperature (~37 °C). The authors assumed that the copolymerization of the TMC and CL would increase the amorphous character of the material and thus avoided the precipitation problem shown in the previously prepared PCL–PEG–PCL triblock copolymer aqueous solution. The PCTC–PEG–PCTC triblock copolymer was prepared according to a classical mode – by random ring-opening copolymerization of CL and TMC in the presence of PEG as a macroinitiator and $Sn(Oct)_2$ as a catalyst.

The first example of biodegradable segmented copolymers introduced in 1980s as a monofilament suture was Maxon™ (Syneture), also containing a random poly(TMC-*co*-GL) middle block. The copolymer was prepared by ring-opening copolymerization of GL and TMC, the final composition being defined by a 67.5 wt.% of GL (**Scheme 91**).[394]

The synthesis of amphiphilic diblock copolymers with various block compositions on the basis of poly(2-ethyl-2-oxazoline) (PEtOz) as a hydrophilic block and PTMC as a hydrophobic block was reported by Kim *et al.*[395] TMC was polymerized in the presence of hydroxyl-terminated PEtOz and $Sn(Oct)_2$ in chlorobenzene under reflux for 39 h.



Scheme 91 Biodegradable segmented copolymers of TMC and glycolide.



Scheme 92 Chemoenzymatically synthesized degradable triblock copolymers (PTMC-*b*-PECA-*b*-PTMC).

Kaihara *et al.*[396] described chemoenzymatically synthesized degradable triblock poly[(TMC)-*b*-(ethylene oxide-*co*-cyclic acetal)-*b*-(TMC)] (PTMC-*b*-PECA-*b*-PTMC) (**Scheme 92**). Cyclic acetal was introduced into a PEG segment as a degradable segment to impart a pH-dependent degradation nature and to prevent the formation of acidic degradation products. Amphiphilic polymeric micelles were successfully prepared from such a triblock copolymer.

According to the second method of carbonate block copolymer synthesis, sequential monomer polymerization is proceeded with transformation of the active center. The block copolymers are prepared in three steps. First, the polymerization of one monomer is carried out. After complete conversion of the first monomer the transformation of active centers is performed, and the initiation of the polymerization of the second monomer is proceeded. For example, this approach was applied for obtaining poly(styrene-*b*-neopentyl carbonate).[203] After completion of the styrene living polymerization, carbanionic centers were transformed into alkoxide ones via reaction with EO and then the ROP of neopentyl carbonate polymerization was performed. In the case of block copolymers of methyl methacrylate with neopentyl carbonate living PMMA, prepared according to GTP, was used as a macroinitiator for DTC polymerization. A silyl keteneacetal active center was transformed to an alkoxide one.[222] Depending on the functionality of the macroinitiator (A) used for cyclic carbonate polymerization, two types of block copolymers can be obtained: A-B or B-A-B.

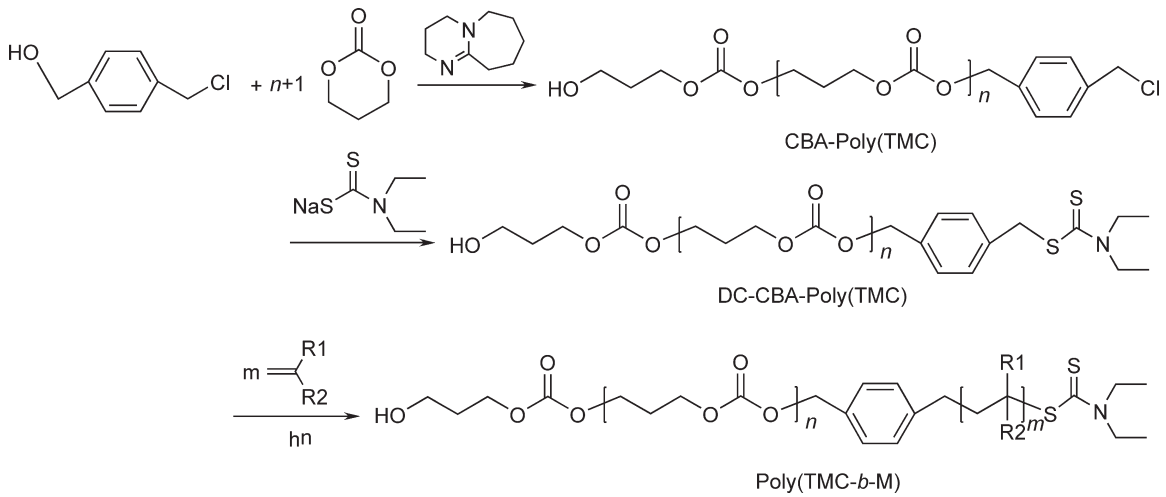
An inverse manner of copolymerization was proposed by Watanabe *et al.*[397] First, they polymerized TMC using 4-(chloromethyl)benzyl alcohol (CBA) as an initiator and DBU as an organocatalyst. The benzyl chloride group was involved in the incorporation of dithiocarbamate for pseudo-living radical polymerization of vinyl monomers. The authors applied *N*-isopropylacrylamide, acrylamide glycolic acid, and 2-hydroxyethyl methacrylate as vinyl monomers for the second step of copolymerization (**Scheme 93**). The resulting block copolymers were water soluble due to incorporation of hydrophilic segment into hydrophobic PTMC.

The synthesis of multiblock cyclic carbonate copolymers was presented by Kricheldorf and Rost.[398] First, telechelic random copolymers were prepared by copolymerization of CL and TMC in bulk using bismuth(III) hexanoate [$Bi(OHex)_3$] as an initiator. A-B-A triblock copolymers were synthesized by chain extension of these random copolymers with L-LA. Finally, the triblock copolymers were transformed into multiblock copolymers by chain extension with 1,6-hexamethylene diisocyanate. It is worth mentioning that all three synthetic steps were performed in a 'one-pot procedure'.

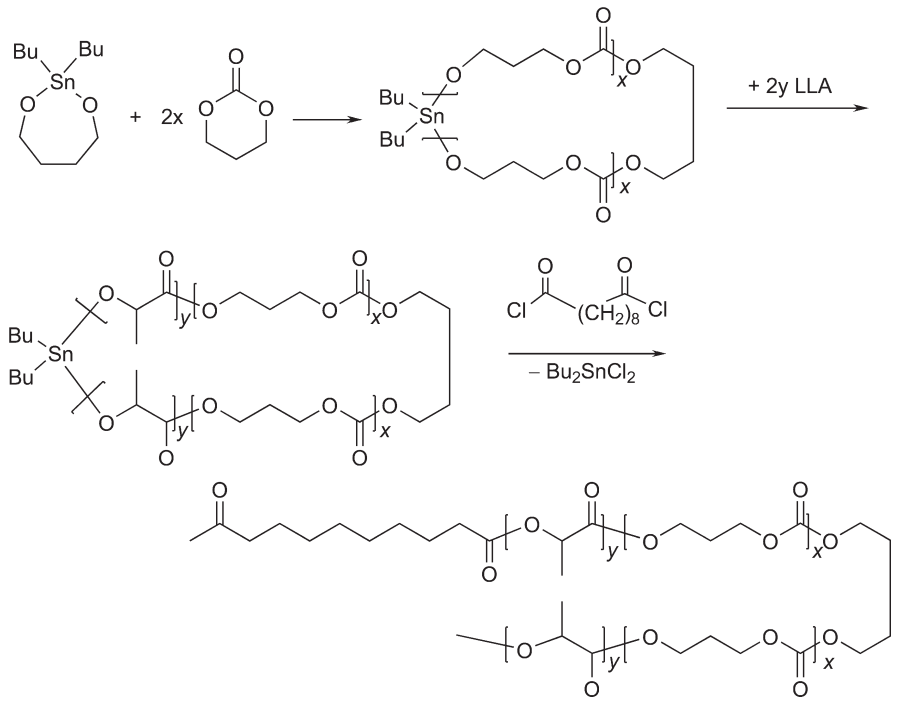
Kricheldorf's group also proposed another approach to multiblock copolymers of TMC and LLA synthesis.[234] Sequential copolymerizations of TMC and LLA were performed with 2,2-dibutyl-2-stanna-1,3-oxepane as a bifunctional cyclic initiator. The cyclic triblock copolymers were transformed *in situ* into multiblock copolymers by ring-opening polycondensation with sebacoyl chloride (**Scheme 94**).

4.12.4.2.5(i) Nonlinear carbonate block copolymers

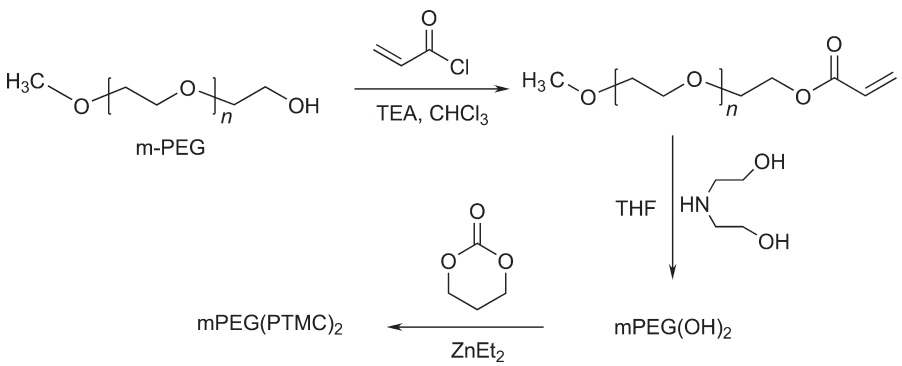
As Hyun has recently revealed, the precise nature of the block copolymer architectures plays an important role in determining their hydrophilic–hydrophobic properties – nonlinear asymmetric (AB_2- or AB_3-type) block copolymers exhibit different micellization behavior compared with the corresponding linear AB diblocks.[399] Taking the above into account Zhang *et al.* prepared the Y-shaped (AB_2-type) amphiphilic copolymers of PEG with TMC, PEG-*b*-$(PTMC)_2$. The block copolymer was synthesized by the ROP of TMC with dihydroxy-modified monomethoxy-PEG [$mPEG(OH)_2$] initiator using $ZnEt_2$ as a catalyst.[400] First, a dihydroxy functional ROP macroinitiator was synthesized by esterification of acryloyl bromide with mPEG, followed by Michael addition using excess of diethanolamine (**Scheme 95**).



Scheme 93 Preparation of polycarbonates with dithiocarbamate groups for pseudo-living radical polymerization of vinyl monomers.



Scheme 94 Sequential copolymerizations of TMC and LLA with 2,2-dibutyl-2-stanna-1,3-oxepane as a bifunctional cyclic initiator.



Scheme 95 Synthesis of Y-shaped amphiphilic PEG(PTMC)$_2$ block copolymers via ROP of TMC using mPEG with bishydroxyl end-groups as macroinitiator and $ZnEt_2$ as a catalyst.

A series of Y-shaped amphiphilic PEG(PTMC)$_2$ block copolymers were obtained via ROP of TMC using this mPEG with bishydroxyl end-groups as macroinitiator and $ZnEt_2$ as a catalyst. It was shown that the Y-shaped copolymer mPEG(PTMC)$_2$ could self-assemble into micelles in aqueous medium and the critical micelle concentration values of the micelles decreased with an increase in the hydrophobic PTMC block length of mPEG(PTMC)$_2$.

4.12.4.2.5(ii) Star-shaped carbonate block copolymers

Morinaga *et al.*[401] reported star-shaped, amphiphilic block copolymers prepared by the polymerizations of TMC initiated with a three-armed, PEG-based surfactant (Tween 20) without any catalysts. The metal- and solvent-free polymerization was proceeded at 150 °C to afford star-shaped poly[(ethylene oxide)-*b*-(TMC)] with a sorbitan monolaurate core of molecular weights of 4500–11 900 in good yields (**Scheme 96**).

Similar star-shaped poly[(TMC)-*co*-(CL)] and its block copolymers with lactide/GL were investigated by Joziasse *et al.*[402] When dipentaerythritol was used as a six-functional initiator, cross-linked rubbers were obtained, swelling in chloroform. Star-shaped lactide/GL block copolymers with a poly[(TMC)-*co*-(CL)] rubber core based on D-sorbitol exhibited good mechanical properties.

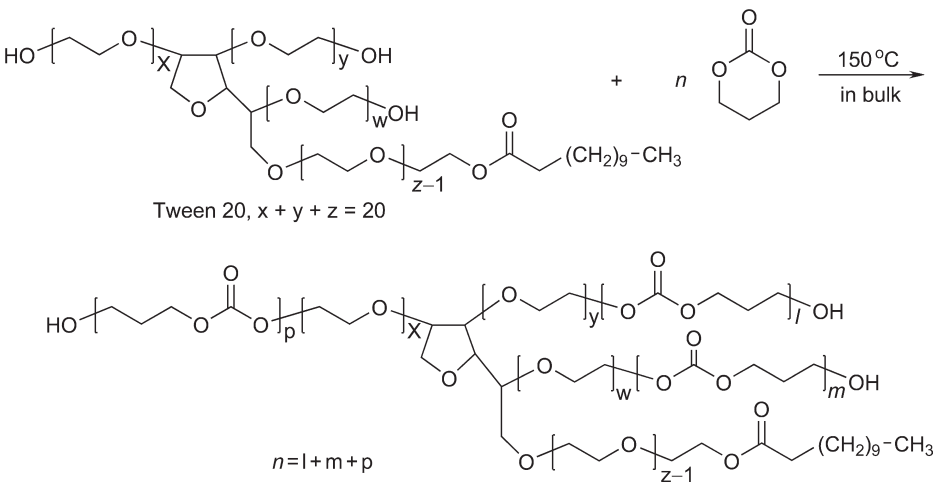
4.12.5 Polymerization of Cyclic Thiocarbonates

The polymerization of ethylene monothiocarbonate (1,3-oxathiolan-2-one) was carried out in the presence of metal alkyls such as $ZnEt_2$ or $CdEt_2$ and metal alkoxides like $Mg(OCH_3)_2$, $Al(OBu)_3$, or $Ti(OBu)_4$. The polymerization with these catalysts was accompanied by carbon dioxide elimination and the polymers obtained appeared to be poly(ethylene sulfide-monothiocarbonate)s. The content of ethylene monothiocarbonate (oxycarbonylthioethylene) units and ethylene sulfide (thioethylene) units in the produced polymers depended on the catalysts used, but all the polymers yielded from the ethylene monothiocarbonate polymerization at 80 °C contained less than 50 mol.% of monothiocarbonate units.[403] As compared with the EC polymerization, the ethylene monothiocarbonate polymerization with coordination catalysts proceeds easier and also may involve decarboxylation to a lesser extent. The decarboxylation during the ethylene monothiocarbonate polymerization seems to involve the metal–monothiocarbonate species that are analogous to those formed in the system with EC. However, the ethylene monothiocarbonate decarboxylation leads to metal thiolate species, which may be outlined schematically as in **Scheme 97**.

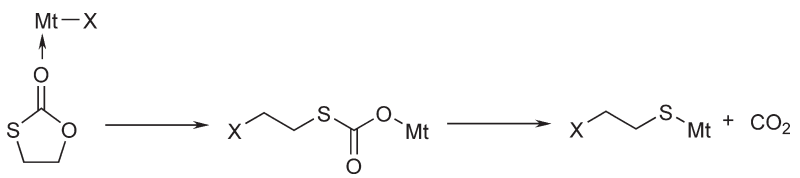
The metal thiolate species are more reactive toward coordinating the monothiocarbonate monomer during the polymerization (**Scheme 98**) than the corresponding metal alkoxide species operating in the EC polymerization.

The relatively highest efficiency of the diethylcadmium catalyst in the ethylene monothiocarbonate polymerization (at 80 °C), as regards the high content of ethylene monothiocarbonate units in the polymer obtained, results probably from the softness of both cadmium and sulfur atoms fitting one to the other, to participate in the covalent bonding. Thus, decarboxylation occurs to the lowest extent. Moreover, the propagation according to **Scheme 99**, involving the formation of the cadmium–sulfur bond leading to the metal thiolate species of relatively high activity, occurs more likely than that which might involve the formation of the less reactive metal alkoxide species.

1,3-Dioxane-2-thione (trimethylene thiocarbonate (**1**), **Scheme 99**) was prepared by the reaction of PPD with



Scheme 96 Star-shaped, amphiphilic block copolymers prepared by the polymerizations of TMC initiated with a three-armed PEG-based surfactant.



Scheme 97 Decarboxylation during the ethylene monothiocarbonate polymerization in the presence of the metal alkyls and metal alkoxides.

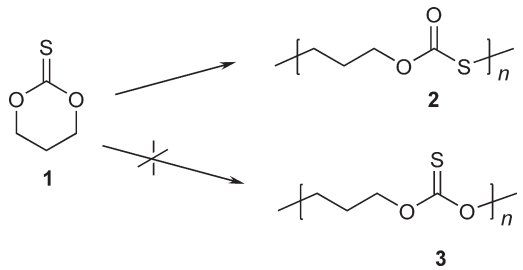


Scheme 99 Cationic polymerization of 1,3-dioxane-2-thione.

thiophosgene and a tertiary amine.[404] This monomer is unstable at >25 °C due to spontaneous oligomerization. Its cationic polymerization in chloroform yielded a relatively high-molecular-weight poly(trimethylene thiocarbonate). IR, ^{1}H, and ^{13}C NMR spectroscopy proved that the oligomers of the spontaneous polymerization and the polymers resulting from the cationic polymerizations possess the structure of a poly (mercaptopropanol carbonate), poly(MPOC) (**2**, **Scheme 99**). All attempts to prepare a polythiocarbonate of isomeric structure (**3**, **Scheme 99**) by anionic polymerizations failed. In contrast to the amorphous PTMC, the poly(MPOC) proved to be a rapidly crystallizing polymer. The cationic polymerization of substituted six-membered cyclic monothiocarbonates such as 5,5-dimethyl-1,3-dioxane-2-thione has also been performed, yielding the corresponding poly(monothiocarbonate)s of the same chain structure.[34]

Similarly, anionic polymerization of six-membered cyclic thiocarbonate derivatives, 5,5-(bicyclo[2.2.1]hept-2-en-5,5-ylidene)-1,3-dioxane-2-thione and 5,5-(bicyclo[2.2.1]heptan-5,5-ylidene)-1,3-dioxane-2-thione, initiated by DBU afforded poly(MPOC) derivatives.[405] It is worth mentioning that those polymers were characterized by a significant 12.3 and 12.6% volume expansion during polymerization, respectively.

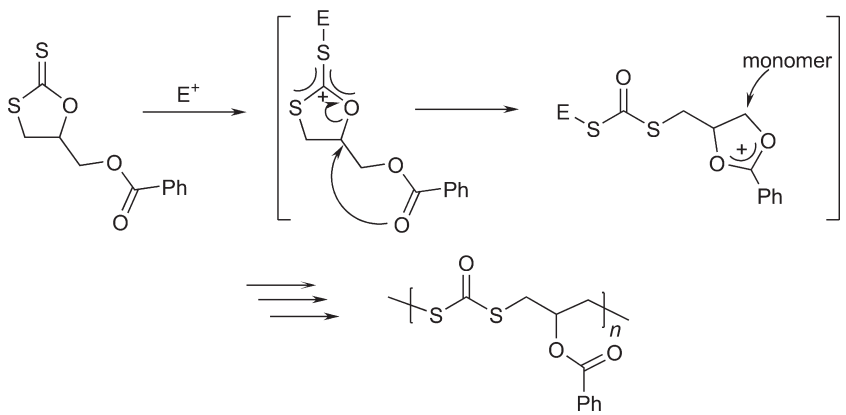
The cationic ROP of a seven-membered cyclic monothiocarbonate, 1,3-dioxepan-2-thione, produced a polymer through the selective isomerization of thiocarbonyl to a carbonyl group as well.[406] The molecular weights of the polymer could be controlled by the feed ratio of the monomer to the initiators or the conversion of the monomer during the polymerization, although some termination reactions occurred after the complete consumption of the monomer.

In contrast to five-membered cyclic carbonates, dithiocarbonates undergo cationic ROP to afford corresponding poly (dithiocarbonate)s without evolution of gaseous compounds.[407,408] A five-membered cyclic dithiocarbonate containing a benzyloxymethyl group exhibits interesting features.[409] The monomer, 5-benzyloxymethyl-1,3-oxathiolane-2-thione, subjected to cationic polymerization initiated by CF_3SO_3H or $CF_3SO_3CH_3$ at 60 °C afforded corresponding poly (dithiocarbonate) with $M_n = 9000–25\,000$ in 60–100% yields (**Scheme 100**). The narrow dispersity of the poly(dithiocarbonate)s (1.09–1.29) and the M_n increase in direct proportion to monomer conversion indicate living cationic polymerization based on neighboring group participation. The formation of a carbenium cation stabilized by neighboring benzyloxymethyl group participation, as observed by NMR spectroscopy, might result in the living polymerization.[409]

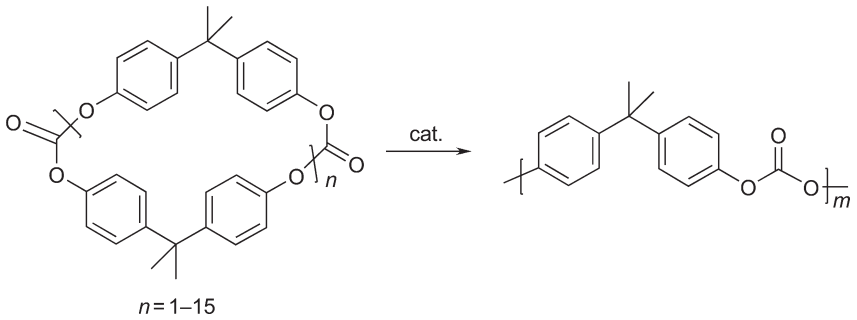
4.12.6 Polymerization of Macrocycles

4.12.6.1 Polymerization of Macrocyclic Aromatic Carbonates

Aromatic PCs are produced technically from bisphenols via transesterification or interfacial phosgenation. In addition,



Scheme 100 Cationic polymerization of 5-benzoxymethyl-1,3-oxathiolane-2-thione.



Scheme 101 Polymerization of macrocyclic aromatic carbonates.

ROP in the melt and solid-state polymerization has been developed.

Reactions of ROP can be divided into three groups: those with large reaction exotherms, such as epoxide of large ring strain polymerization; those with moderate exotherms, such as ε-caprolactam or TMC polymerization; and those that are driven by entropy, rather than enthalpy, such as certain cyclic siloxane polymerizations and the polymerizations of oligomeric aromatic cyclic carbonates described in this chapter.[1] Molecular simulation studies on certain cyclic monomers have been carried out by Stewart.[410] He verified that cyclic dimer (**Scheme 101**, $n = 1$) is a tightly packed molecule with a ring strain of 16 kcal mol^{-1}. However, the cyclic tetramer of 48-membered ring size (**Scheme 101**, $n = 3$) is already stress free and the polymerization of such molecule is driven solely by entropy. It is also characterized by a large (12 Å) cavity inside the ring.

Due to their low molecular weight, the cyclic oligomeric carbonates have melt viscosities significantly lower than that of conventionally prepared PCs. This lowered melt viscosity is one of the most useful properties in several applications. At their melting point the mixture of cyclic oligomers have significant flow and have a greater penetration and wetting of fibers in composite applications. There also exists a great potential for the preparation of inorganic organic hybrid materials starting with these cyclic aromatic carbonates.

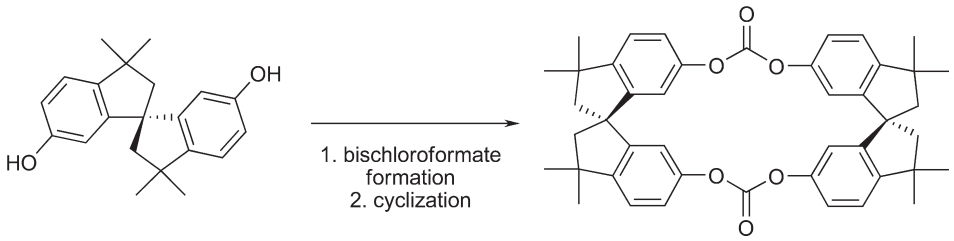
Fundamental studies on the polymerization of BPA cyclic oligomers have been reported by Evans *et al.*[411] As a starting material they used cyclic oligomers of $M_w = 1300$ determined by GPC with the dispersity index of 1.5. Blank experiment of polymerization performed in glass tubes at 300 °C under nitrogen without addition of catalyst showed modest increase in molecular weight up to 17 000. However, the addition of various catalysts (lithium stearate and Tyzor AA) yielded very high-molecular-weight PCs ($M_w = 117\,000$–$300\,000$). HPLC of the fraction soluble in acetone indicated that only 0.25% of cyclic monomers remained after polymerization. The heat measured with DSC was found to be − 1.2 kJ mol. This slight exotherm can be correlated to the release of ring strain in opening the previously mentioned cyclic dimer. Thus, in general, the reaction seems to be driven by entropy toward formation of linear PC.

Moreover, the dispersity index of the polymers approximately equals 2.0, which indicates that ring-chain and chain–chain equilibration are achieved during the polymerization. Total equilibration is a result of nearly equal energies of the attack on a monomer ring and a carbonate bond in a polymer chain. Due to the size and conformation of the monomer, very few rings are present at equilibrium.

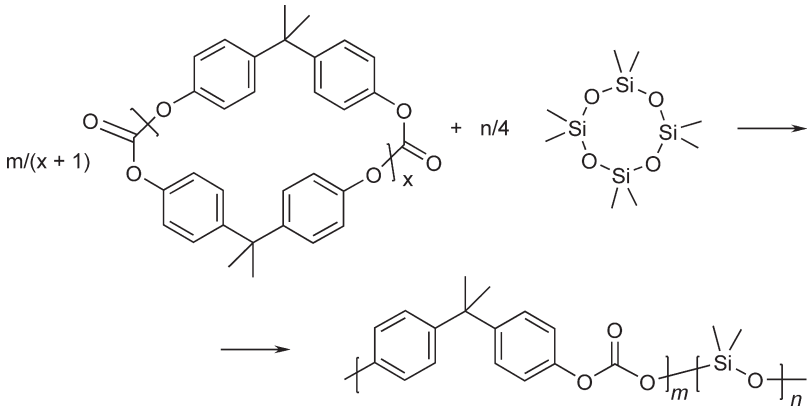
The ROP of BPA-based cyclic carbonates has some of the characteristics of a living polymerization.[1] Upon initiation, the propagation reactions continue until all the cyclic monomers are consumed and the chain ends remain active. Addition of additional portions of a cyclic monomer gives continued reaction and a higher molecular weight as the ratio of monomer to initiator increases. Moreover, the molecular weight of the polymer can be controlled by use of bisphenols or diphenyl carbonate as chain transfer agents.

Stewart has studied the melt polymerization of BPA cyclic oligocarbonates using a rheokinetic method.[412] The reactor was equipped to measure changes in melt viscosity as the reaction proceeded. Despite the fact that melt viscosity is a function of many variables, it was possible to obtain the relative polymerization rates by plotting the viscosity (stirrer torque) as a function of time over the portions of curve where steepest increases were seen. The relative reaction rates for sodium phenoxide-initiated polymerization were measured at five temperatures, in order to construct the Arrhenius plot. The activation energy calculated from the plot (12.5 kcal mol^{-1}) corresponded with the activation energy typical for diaryl carbonate transesterification.[413] Since the activation energy of viscous flow of PC resin is about 23.4 kcal mol^{-1}, it can be concluded that the polymerization of cyclic oligomers is not limited by the diffusion of the reactive end-groups in the polymer melt. In fact, each phenoxide active end-group is surrounded by large excess of carbonate groups coming from cyclic monomers, as well as linear PCs. In such an environment, transesterification reactions are indiscriminate and do not require diffusion over long distances. High-molecular-weight PCs with dispersities lower than those obtained by conventional methods were obtained by Keul *et al.*[208] Polymerizations were performed in THF solution, using potassium dihydronaphthylide as the initiator.

The cyclization and polymerization procedures developed and optimized for the BPA system are fairly general and have been successfully applied to a variety of other bisphenols.[16] Functional groups such as ester, amide, ketone, sulfone, and urethane have been incorporated into the PCs via the cyclic oligomer approach. Brunelle and Shannon[414,415] reported the synthesis of a number of such cyclic monomers and their subsequent polymerization yielding high-molecular-weight PCs. In all cases the reported carbonate functionality played a critical



Scheme 102 Spirobiindane bisphenol-based cyclic carbonate.



Scheme 103 Direct copolymerization of macrocyclic carbonates with cyclic dimethylsiloxane.

role in cyclic oligomer formation and further in ROP. There were also some bizarre structures, such as spirobiindane bisphenol, used for the preparation of cyclic oligomers (Scheme 102).[416] This rigid molecule favored the formation of cyclic structures, which were isolated with 95% yield. Moreover, the polymerization of such a monomer gave PCs of increased glass transition temperature up to 200 °C. The drawback of the rigid structure of the bisphenol was the higher amount of cyclic products at equilibrium; however, it was eliminated by copolymerization of spirobiindane bisphenol cyclic carbonate with a regular, BPA-based one.

There are numerous reports of the uses of cyclic oligomeric carbonates for copolymerization. Evans and Carpenter[417] reported the preparation of PC/PDMS copolymers (Scheme 103). Two approaches were used in the preparation of the copolymers: the first one used direct reaction of macrocyclic carbonates with cyclic siloxanes, the second one reaction of hydroxy-terminated linear PCs with chlorosilane-terminated PDMSs.

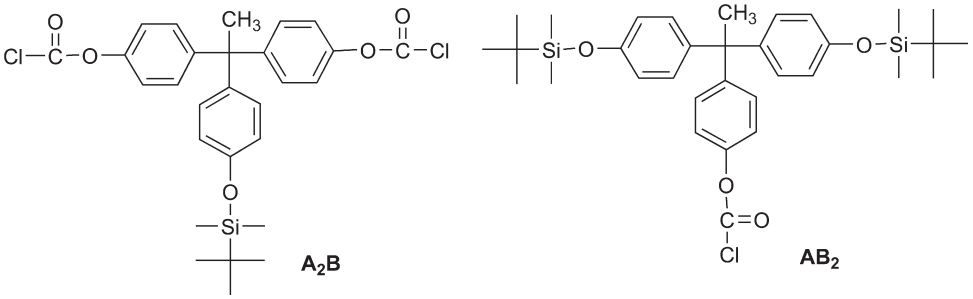
In case of direct copolymerization (Scheme 103) only 52–58% of the siloxane was incorporated into the polymer structure. The PC glass transition temperature (148 °C) was not altered by incorporation of siloxanes. Alternatively, either 'living' PC or 'living' polysiloxane was used to initiate ROP of cyclic siloxane or cyclic carbonate, respectively. Block copolymers were obtained by ROP of cyclic carbonate with BPA, which resulted in hydroxy-terminated PCs, followed by reaction of chlorosilane-terminated polysiloxane. Block copolymers showed good optical clarity and lowered glass transition temperature (110 °C).

Besides siloxane copolymers, poly(phenylene oxide)/PCs,[418] epoxide/PCs,[419] polyimidecarbonates,[420] polyamidecarbonates,[421] polyurethanecarbonates,[422] and copolymers with aliphatic lactones such as pivalactone and CL were also reported.[423]

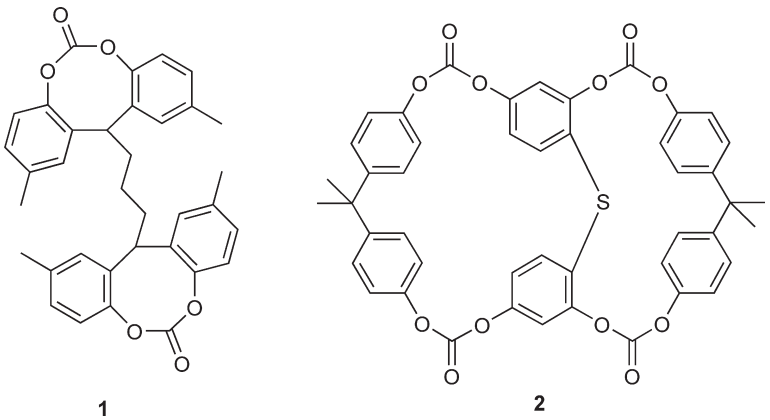
Cyclic carbonate chemistry has also proven to be useful for the preparation of branched or cross-linked polymers. First branched (hyperbranched) PCs were synthesized by Bolton and Wooley.[424] In one of the published methods of synthesis of hyperbranched PCs they used chloroformate-type 1,1,1-tris(4-hydroxyphenyl) ethane (THPE)-based monomers (Scheme 100).[13] The authors synthesized hyperbranched aromatic PCs by the polymerization of A_2B and AB_2 monomers, which involved the condensation of chloroformate (Scheme 104) functionalities with *tert*-butyldimethylsilyl-protected phenols (Scheme 104), facilitated by reactions with silver fluoride.

The same structure of THPE was used as initiator for ROP of cyclic aromatic carbonates by Krabbenhoft *et al.*[425] The polymerization in the system containing 0.3–1.5 mol.% of THPE resulted in branched resins with enhanced shear sensitivities by as much as 660% when compared with linear PC.

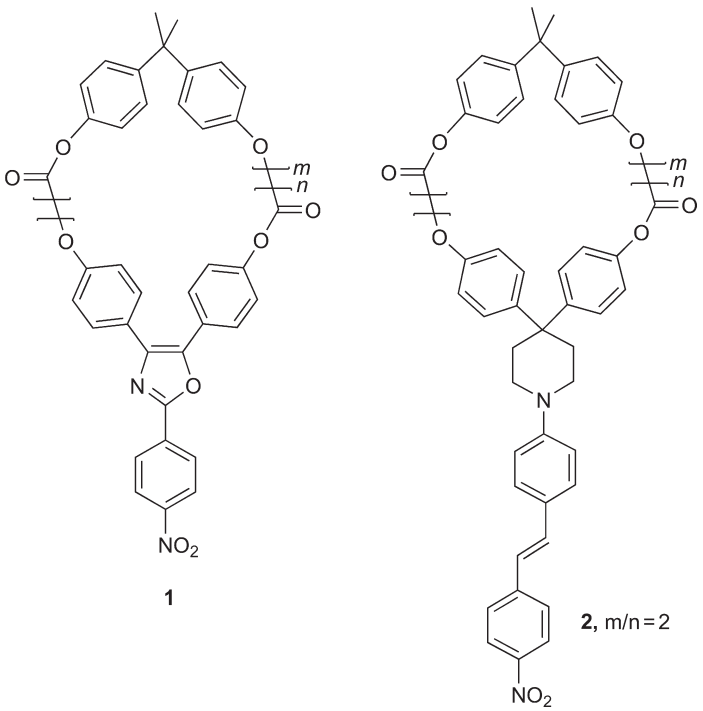
Cross-linked aromatic PCs could be obtained from cyclic oligomers according to three methods. The first one, presented by Rosenquist, is based on the application of biscyclic carbonate (1, Scheme 105) containing two eight-membered rings.[426] Mixtures of small amounts of the biscyclic carbonate with cyclic oligomers were polymerized to give highly cross-linked PC resins characterized by low swelling factor (5.5%) using only 2% of cross-linking agent. The second method utilized multifunctional epoxy compounds. One of the most effective



Scheme 104 Chloroformate monomers used in the synthesis of hyperbranched polycarbonates.



Scheme 105 Biscyclic cross-linking agents for aromatic cyclic carbonates.



Scheme 106 Mixed type macrocyclic oligocarbonates.

were copolymers of glycidyl methacrylate/styrene resins. The third method uses oligomeric oligocarbonates based on tri- or tetraphenols such as resorcinol sulfide (**2**, **Scheme 105**) as cross-linkers.[427] Again ROP of cyclic oligomers with addition of such compounds yielded highly cross-linked PCs.

The preparation of nonlinear optical (NLO) PCs via macrocyclic prepolymers has the advantage that the low viscosity oligomer mixtures make reactive processing possible. The conversion of macrocycles to polymer occurs with nonvolatile by-products or very little change in volume and can be done simultaneously with electric field poling and, if desired, chemical cross-linking. Kulig *et al.*[428] prepared such PCs based on a triphenyloxazole monomer (**1**, **Scheme 106**). This monomer contained a required NLO material-conjugated system with electron donating and accepting groups. Moreover, it showed good thermal stability to withstand ROP conditions (15–30 min at 250 °C) and structural similarity to BPA. The cyclic oligocarbonates were obtained from the corresponding bis(chloroformates), which were prepared by the reaction of a bisphenol molecule with phosgene. Attempts to prepare the homopolymer produced intractable materials. Therefore, a mixture of BPA and triphenyloxazole derivative was used in the reaction feed (**1**, **Scheme 106**). ROP yielded polymers of $M_w = 69\,000$. The T_g of the final polymer could be controlled by the molar ratio of the triphenyloxazole to BPA. The incorporation of triphenyloxazole increased the T_g of copolycarbonate up to 214 °C (30 mol.% of oxazole).

Another NLO chromophore based on 4-*N*, *N*-dimethylamino-4′-nitrostilbene which contained bisphenol functionality for PC preparation was synthesized in the same manner (**2**, **Scheme 106**).[429] It was used to make macrocyclic carbonate oligomers and the oligomers were converted to PC via ROP in solution.

4.12.7 Conclusions

PCs are usually synthesized by a step-growth process, that is, polycondensation, from phosgene or its derivatives and dihydroxy compounds. Instead of phosgene's method dialkyl- or diphenylcarbonate can also be applied for PC production. The ROP of cyclic carbonates is an alternative method for the synthesis of both aliphatic and aromatic PCs. A comparison of these two methods is in favor of chain-growth process. The polycondensation affords rather limited molecular weight polymers, while high-molecular-weight PCs can be prepared in the ROP of cyclic monomers.

Cyclic carbonate monomers with a variety of functional groups have been prepared and polymerized by means of ROP. Not only the polymer microstructure and architecture but also the molecular weight and molecular weight distribution may be well controlled. A variety of carbonate copolymers comprising blocks of different chemical structures were also prepared. By changing the chemical character of the blocks as well as block lengths mechanical as well as chemical and biochemical properties can be tuned in accordance with target applications. The unique property of six- and seven-membered cyclic carbonates concerning volume expansion during polymerization additionally makes this class of compounds valuable prospective monomers. Recent developments in organocatalysts for the ROP of cyclic carbonate allow processes, which proceed without transesterification, to create polymers that are metal-free and, therefore, good candidates for biomedical and microelectronic applications.

Biographical Sketches

Gabriel Rokicki is a chemistry professor at the Faculty of Chemistry, Warsaw University of Technology, Poland, where he received all his academic education (MSc in 1971, PhD in 1989, and tenure professor in 2002). His current scientific activities include synthesis, structure, and properties of polymer materials, such as aliphatic polycarbonates, polyurethanes, epoxy resins, and biodegradable polymers. He has devoted a special interest to the use of functional polymers in obtaining specialty ceramic materials as well as to polymer recycling. Earlier major interests included the utilization of carbon dioxide and cyclic carbonates in the synthesis of condensation polymers. Another topic of interest was polymeric ion-sensors based on modified calixarenes. He is the author and coauthor of 160 scientific papers and holds more than 50 patents in the above-mentioned areas. At the Faculty of Chemistry of Warsaw University of Technology, he conducts lectures on polymer chemistry and technology.

Paweł G. Parzuchowski received his MS degree in chemical technology from the Faculty of Chemistry of Warsaw University of Technology (WUT), Warsaw, Poland, in 1996. He received his PhD degree in chemistry from the same university in 1999. During his PhD studies he worked on a variety of projects related to design and synthesis of improved ion-sensory materials. He developed a method of covalent binding of calixarene ionophores to acrylic polymer matrix as well as methodology of preparation of dendrimers based on calixarene units. Part of this work was carried out at the Department of Chemistry of Johannes Gutenberg University in Mainz, Germany. He then worked as a postdoctoral research scientist at the University of Michigan, Ann Arbor, USA, until March 2002 in the area of nitric oxide-releasing materials and ionophores for optical and electrochemical sensors. He is presently an assistant professor of chemistry at the Warsaw University of Technology, Poland. His current research interests include development of new bio-based and biocompatible materials, hyperbranched polymers and drug delivery systems, as well as recycling of plastics and development of technologies of production of biodegradable polymers.

4.13 ROP of Cyclic Amines and Sulfides

EJ Goethals and B Dervaux, Ghent University, Gent, Belgium

4.13.1 Introduction

Cyclic amines and cyclic sulfides represent two large families of monomers. The variety of structures, and hence variety of physical properties of the corresponding polymers, stems from the variation of ring size and from the possibility of placing one or more substituents on the heterocycle. In the case of sulfides, this is only possible on carbons; in the case of amines, substituents can be added to nitrogen as well.

Three- and four-membered cyclic amines and sulfides possess high ring strains ranging from 80 to 100 kJ mol^{-1}. From these high values it can be deduced on thermodynamic grounds that the polymerizations of these monomers should lead to high conversions. The five- and six-membered rings have ring strains in the order of 0–20 kJ mol^{-1}, which is not sufficient for polymerization.

The possibility of preparing well-defined polymers from these monomers depends on the operating polymerization mechanism, more particularly on control of the initiation reaction and the occurrence or absence of transfer and/or termination reactions. In this chapter, the mechanism of polymerization of different monomer types will be described, with emphasis on control of the polymer structures formed. This control applies not only to molecular weight and molecular weight distribution (MWD) but also to the stereochemistry and the nature of the polymer end groups.

4.13.2 Cyclic Amines

The three- and four-membered rings (aziridines and azetidines) of this group can be polymerized by cationic initiators. Anionic polymerization has not been reported and is probably impossible. The five-membered ring, pyrrolidine, and the six-membered ring, piperidine, have not enough ring strain to be polymerizable.

The polymerization mechanisms display different characteristics depending on the presence or absence of a substituent on the nitrogen atom, that is, whether the monomer is a tertiary or a secondary amine. Furthermore, as in most cationic ring-opening polymerizations (ROPs), the presence of substituents on the carbon atoms of the monomer plays a role in its 'polymerizability'.

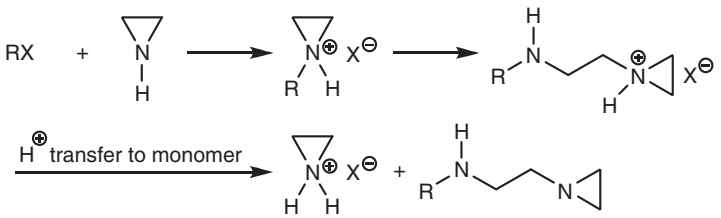
4.13.2.1 Aziridines

4.13.2.1.1 Ethylenimine

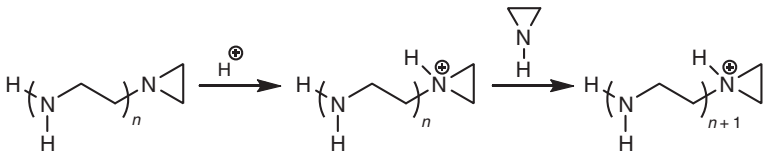
The polymerization of the parent compound of this group, ethylenimine, has been known since the early 1940s,[1] and the polymer, polyethylenimine (PEI), is produced commercially in several countries. The polymerization mechanism is complicated due to the occurrence of transfer of a proton from the active species to other amino functions present in the reaction mixture. As a consequence, the first reaction products are oligomeric compounds. The usual initiation reaction is protonation of the monomer. If an alkylating agent is used as initiator, very soon the initiation reaction becomes protonated due to this proton transfer, as shown in **Scheme 1**.

The oligomers formed in the first stages of the polymerization can react in three ways:

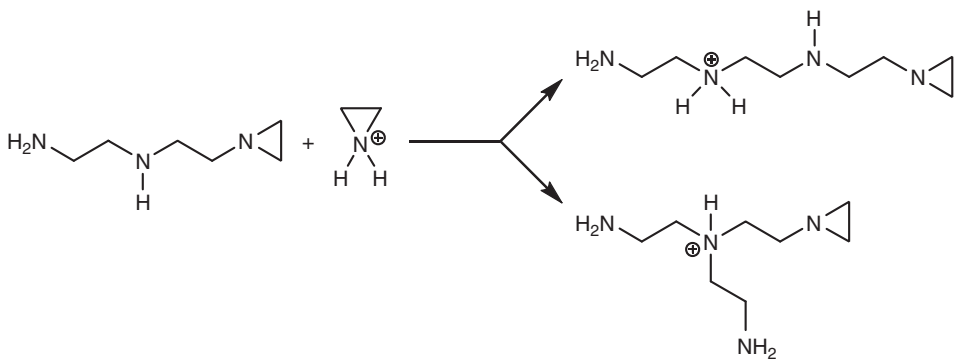
1. After protonation of the aziridine end group, a new monomer molecule can be added to form the linear $n+1$ mer (**Scheme 2**).



Scheme 1 Polymerization of ethylenimine: initiation, propagation and transfer to monomer.



Scheme 2 Polymerization of ethylenimine: re-activation of terminal aziridine polymer end group.



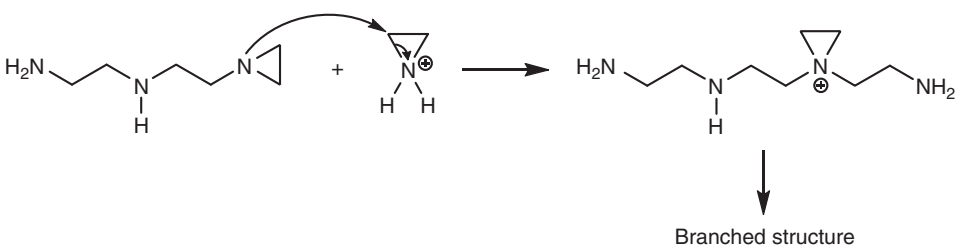
Scheme 3 Polymerization of ethylenimine: formation of linear and branched units.

2. One of the linear amine functions reacts with an aziridinium ion, for example, the protonated monomer, to form a linear or a branched (tertiary amine) structure (Scheme 3).
3. The amino function of the terminal tertiary aziridine reacts as a nucleophile with an aziridinium ion to produce a quaternary aziridinium ion. This will eventually react with an amine also producing a branched (tertiary amine) structure (Scheme 4).

The final polymer has a highly branched structure containing primary, secondary, and tertiary amines (see below) and probably also a small fraction of quaternary ammonium ions formed when a tertiary amine reacts with an aziridinium ion. By this reaction an unreactive cation is formed which means that it is a termination reaction.

The concentrations of the oligomers formed in the first stages of the polymerization have been monitored.[2] The results are shown in Figure 1.

Linear polyethylenimine (LPEI), which contains only secondary amino functions, has been prepared in different ways. The one most used is the hydrolysis of poly(*N*-acyl ethylenimine), which is obtained by cationic polymerization of the corresponding *N*-alkyl or aryl oxazoline[3] (see Chapter 4.24),[4] (Scheme 5). This type of polymerization exhibits living characteristics so that polymers with controlled molecular weight and narrow distribution can be obtained. Consequently, the LPEI obtained from such a polymer will also have a



Scheme 4 Polymerization of ethylenimine: formation of quaternary aziridinium ion.

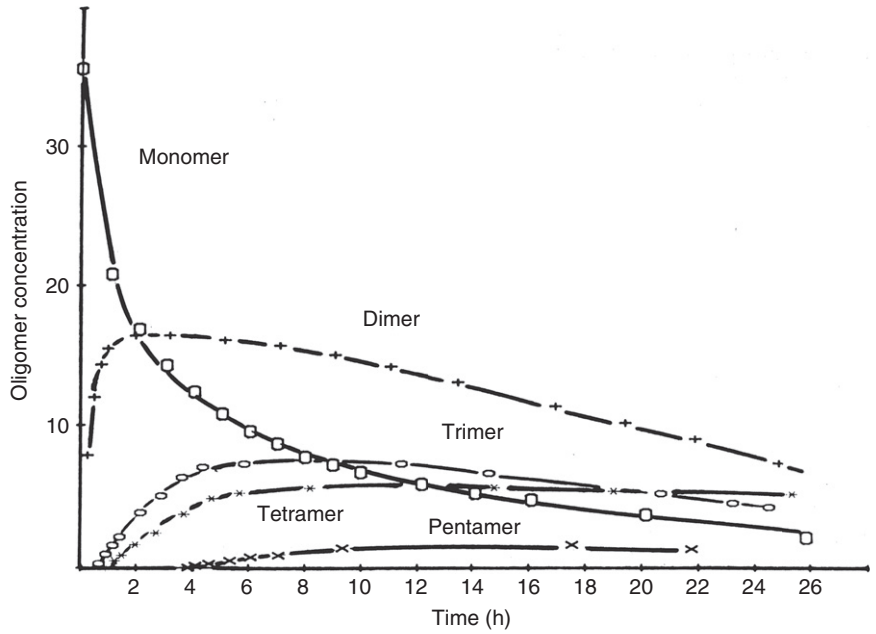


Figure 1 Formation and subsequent reaction of oligomers in the polymerization of ethylenimine.

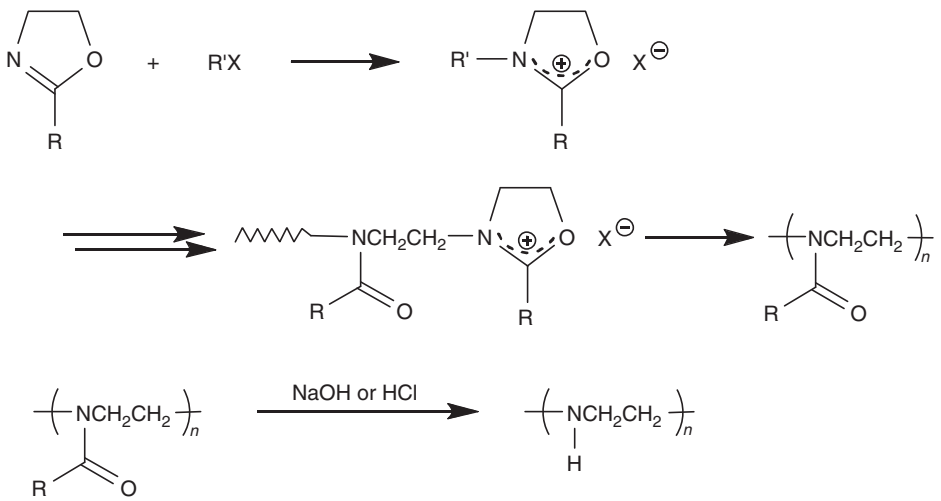
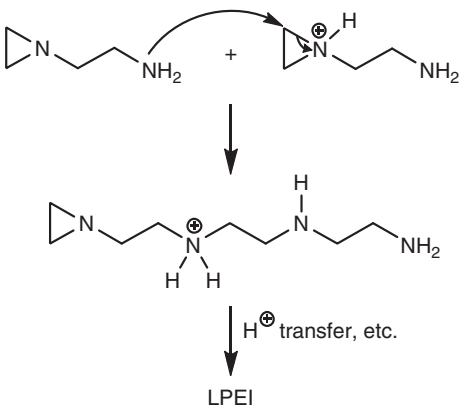


Scheme 5 Polymerization of *N*-alkyl oxazoline and subsequent hydrolysis to LPEI.

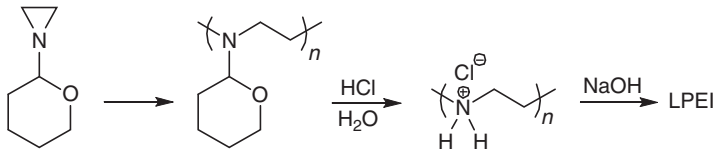
well-defined structure. The hydrolysis of the *N*-acyl-PEI can occur in alkaline or in acidic medium.[5]

Two other methods for the synthesis of LPEI have been described. The first method[6] starts from ethylenimine and proceeds in two steps. The first step is the preparation of a mixture of low-molecular-weight oligomers containing predominantly dimer and trimer as described above. The second step is the proton-initiated head-to-tail coupling of these oligomers in the presence of a well-specified amount of water. The role of water is to form a crystalline hydrate with the polyamine as soon as it is formed, thus preventing the reaction between the aziridinium ions in solution and the secondary amino functions in the polymer chain, which is the main cause of the branching (Scheme 6).

The last method[7] consists of polymerizing an N-substituted aziridine in which the substituent can be removed after the



Scheme 6 Formation of LPEI by head-to-tail coupling of ethylenimine oligomers.



Scheme 7 Polymerization of *N*-(*a*-tetrahydropyranyl) aziridine and subsequent hydrolysis to LPEI.

polymerization. Such a monomer is *N*-(α-tetrahydropyranyl) aziridine. The tetrahydropyranyl group is removed by acid-catalyzed hydrolysis (Scheme 7).

The last two methods have the inconvenience that they start from EI monomer that is not easily available due to its high toxicity. Therefore, the most used route for the LPEI synthesis is via polyoxazoline.

The physical properties of branched PEI and LPEI are quite different. The linear polymer is crystalline (m.p. 58.5 °C) and forms several crystalline hydrates with water, whereas the branched polymer is amorphous. In contrast with the branched form, LPEI is insoluble in cold water but dissolves above its melting point.

The microstructure of PEI, more particularly the relative amounts of primary, secondary, and tertiary amino functions, can be deduced from ^{13}C-NMR spectroscopy. In the spectrum of a branched PEI polymer, eight lines can be distinguished according to the nature of the neighboring amino functions.[8,9] The spectrum of LPEI shows only one peak. The constitution of the polymers has also been analyzed by ^{15}N-NMR spectroscopy.[10]

The Mark–Houwink molecular weight–viscosity relation for LPEI in methanol at 25 °C has been determined.[11]

$$[\eta] = (1.04) \times 10^{-2} \bar{M}_w^{\,0.95}$$

The high value of the exponent in the equation indicates that in this solvent the polymer has a relatively rigid structure. This is in contrast with the values of < 0.5 determined for the branched polymer,[12,13] indicating a compact structure.

4.13.2.1.2 C-substituted aziridines

The polymerization of 2-methylaziridine (propylenimine) has been reported briefly.[14] The structure of the polymer may be expected to be complicated by the presence of head-to-tail, tail-to-tail, and head-to-head diads, tacticity, and branching. Linear head-to-tail polypropylenimine has been produced by isomerization polymerization of 4-methyloxazoline followed by hydrolysis.[15] Starting from optically active monomer, pure head-to-tail, isotactic, optically active polypropylenimine was obtained.[16] The ^{13}C-NMR spectrum of this polymer exhibited only three signals[17] (Scheme 8).

The polymerization of 2-phenylaziridine with several initiator systems has been described. The corresponding polyamines had relatively low molecular weights. The kinetics of the polymerization were studied with perchloric acid and methyl triflate as initiators.[18]

4.13.2.1.3 N-substituted aziridines

The polymerization of N-substituted aziridines is less complicated than that of the N-unsubstituted monomers. The active species are quaternary aziridinium ions so that proton transfer is not possible. The propagation is a nucleophilic attack of the monomer nitrogen on the α-carbon of the aziridinium ion.

The nitrogens of the formed polymer can perform the same reaction, which leads to an unreactive quaternary ammonium ion so that this reaction is a termination. As a consequence, the polymerizations of *N*-alkylaziridines usually stop at limited conversions. This was first observed for the polymerization of *N*-methylaziridine by Jones *et al.*[19] The maximum conversions are determined by the concentration of initiator and by the ratio of the rate constant of the propagation over the rate constant of the termination reaction. This ratio, k_p/k_t, has been taken as a measure of the living character of the polymerization.[20] From kinetic studies and from molecular weight determinations, it was deduced that this termination is predominantly intramolecular, that is, the terminated polymer chains contain a cyclic, nonstrained ammonium ion as an end group (Scheme 9).

As shown in Table 1, the ratio k_p/k_t dramatically increases with the bulkiness of the N substituent. Also, the introduction

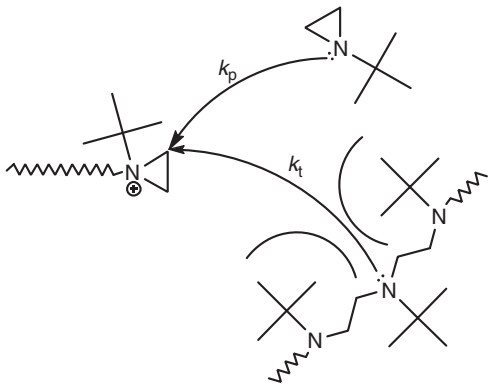
of a substituent on a ring carbon results in a marked increase of the living character. If two substituents are present on one of the ring carbons, the monomer becomes unreactive for (homo) polymerization.[21]

Due to 'steric shielding' of the amino functions in the polymer chains by their own and two adjacent *t*-butyl groups, the polymerization of *N*-*t*-butylaziridine (TBA) has a very high k_p/k_t ratio so that this polymerization may be regarded as being a 'temporary living' one.[22,23] This means that, although there is a termination reaction, its rate is so slow compared with the rate of the propagation that, at almost quantitative conversion, almost every polymer chain in the reaction mixture still contains an active species. The shielding effect is illustrated in Scheme 10.

Thus, end-capping and coupling reactions of living polyTBA can be carried out successfully, provided these reactions are done immediately after the polymerization. These reactions can be performed by addition of a nucleophilic reagent. Table 2 gives an overview of end-capping reactions that have been performed leading to various end group-functionalized polyTBAs or, in case of macromolecular nucleophiles, to graft or block copolymers.



Scheme 10 Schematic representation of 'steric shielding' in TBA polymerization.

Another method for the synthesis of block copolymers is the sequential monomer addition method. In this method, the polymerization of TBA is initiated by the cationic living chain end of another cationic polymerization. This has been carried out with perchlorate-terminated polystyrene[31] and with cationic living polyTHF as the initiating polymer. The polyTHF can be mono-, di-, or trifunctionally living leading to AB, BAB, and three-arm star-shaped block copolymers, respectively.[32]

The copolymerization of polyTBA macromonomers with hydrophilic and hydrophobic comonomers has been reported.[29]

TBA is easily obtained in a two-step reaction from *N*-*t*-butyl-2-aminoethanol.[23] PolyTBA is a crystalline polymer with a melting point of 142 °C. It is soluble in aqueous acid.

Also the bicyclic aziridine monomer, 1-aza-[1,3,0]-bicyclohexane, has been reported to give a living polymerization.[33] Polymerization of one enantiomer of this monomer, synthesized from L-proline, leads to the corresponding chiral polymer[34] (Scheme 11).

When the polymerization of N-substituted aziridines is initiated with a proton acid having a nonnucleophilic anion, a nonnegligible fraction of cyclic oligomers is formed.[35] This is due to the fact that the secondary amino head group formed by the proton initiation is more reactive toward an aziridinium ion than is a tertiary amino function. The probability that this reaction occurs intramolecularly is highest when the secondary amine and the aziridinium end group are separated by three monomer units, leading to cyclic tetramer. The intermolecular reaction results in a coupling between two polymer molecules, leading to higher molecular weights than calculated from monomer consumption and initiator concentration. Moreover, the molecular weight of the polymer continues to increase after all monomer is consumed[36] (Scheme 12).

In the case of TBA, the only cyclic oligomer formed is the pentamer.

If the initiating acid has an anion with a nucleophilicity equal to or higher than the nucleophilicity of the monomer, such as a halide, and if the reaction is carried out in a nonpolar solvent, the main reaction product is the corresponding *N*,*N*′-dialkylpiperazine,[37] formed as in Scheme 13.

In a polar solvent, the intermediate alkyl halide is not formed and the end product is the polymer.

The synthesis and polymerization of 2-(1-aziridinyl)ethyl methacrylate has been reported. This monomer can be polymerized via the methacrylate group or via the aziridine group leading to cross-linkable polymers[38] (Scheme 14).

Poly-*N*-(2-aminoethyl)aziridine has been prepared by polymerization of the corresponding formamide derivative followed by hydrolysis[39] (Scheme 15).

4.13.2.2 Azetidines

4.13.2.2.1 Azetidine

The polymerization of this four-membered secondary amine is similar to the polymerization of ethylenimine.[40] In the first stages of the polymerization, oligomeric products are formed due to the possibility of transferring a proton from the original active species to monomer. In the case of azetidine, this transfer is even more pronounced than in the case of ethylenimine because the basicity of the monomer is higher than that of a substituted azetidine. When all monomer has reacted, 70% of

the reaction mixture consists of dimer. This dimer has two nucleophilic sites that can react with an activated (protonated) azetidine group: the primary amine, leading to a linear structure, and the tertiary, leading to a quaternary azetidinium ion (Scheme 16).

Further reaction of the quaternary azetidinium ion with any amine leads to a tertiary amine. Another route to a tertiary amine group is attack of a secondary amine in a polymer chain on an azetidinium ion. Finally, a polymer containing 20% primary, 20% tertiary, and 60% secondary amino functions is formed.

Linear polytrimethylenimine has been synthesized by isomerization polymerization of 1,3-oxazine to the corresponding *N*-formyl polytrimethylenimine, followed by hydrolysis[41] (Scheme 17).

The linear polymer is a crystalline solid with melting point between 74 and 84 °C, depending on the content of water of

crystallization. The branched polymer is a noncrystallizable viscous material.

4.13.2.2.2 N-substituted azetidines

As with the aziridines, the polymerization of *N*-alkyl-substituted azetidines is not complicated by proton transfer and the mechanism can be described by initiation, propagation, and termination. Three monomers have been studied in detail: conidine (1-azabicyclo[4.2.0]octane), 1,3,3-trimethylazetidine, and *N*-phenylazetidine (NPA) (Figure 2).

Conidine contains a chiral carbon atom and can be separated into its enantiomers. The polymerization of an enantiomer leads to polymers having a strong optical rotation of a sign opposite to that of the monomer.[42] These results show that the attack of monomer occurs exclusively at the methylene carbon atom of the azetidinium ion. The polymers are crystalline with a melting point of 94 °C. The mechanism of polymerization of conidine has been studied for polymerizations initiated with the tertiary or quaternary ammonium salts derived from the monomer by reaction with a proton acid or an alkyl halide. Kinetic studies led to the conclusion that with the quaternary ammonium salt initiators, the concentration of the active species remained constant during the polymerization and the degrees of polymerization were proportional to the conversion. Therefore, it was concluded that this polymerization shows a living behavior.[43] The nature of the active species in the polymerization of conidine has been discussed, more particularly the reactivity of the ion pairs and the free ions.[44] It was found that, in nitrobenzene solution, the rate constant of propagation by free ions was equal to that of propagation by ion pairs for a variety of counterions.

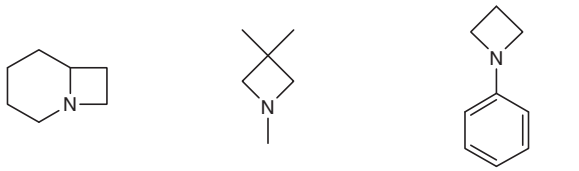

Figure 2 Structure of conidine, 1,3,3-trimethylazetidine, and NPA.

The living character of the polymerization of 1,3,3-trimethylazetidine was demonstrated by kinetic measurements[45] and confirmed by ^{1}H-NMR spectroscopy.[46] With this method it was possible to detect the concentration of the active chain ends during and after the polymerization: the active species concentration remained constant even after all monomer was consumed.

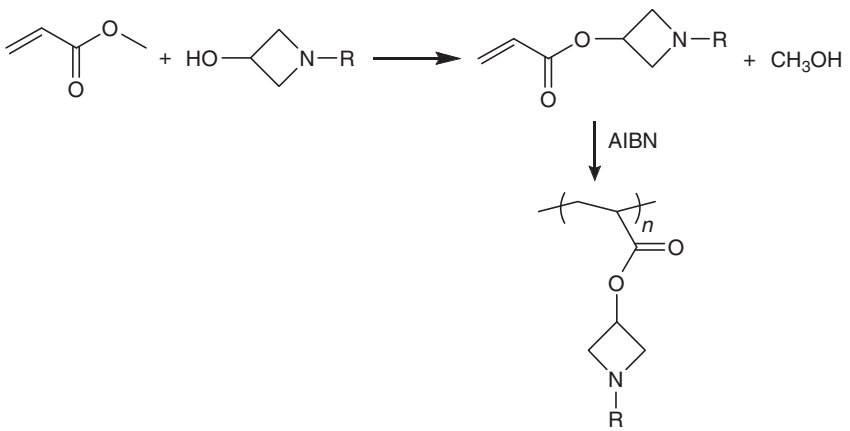
Comparison of the polymerization behavior of 1-methylazetidine with that of 1,3,3-trimethylazetidine shows the importance of the *gem*-dimethyl substituents in the 3-position. With the former monomer, a termination reaction occurring between the active species and an amino function of the polymer, leading to branched or macrocyclic ammonium salts, was observed,[47] whereas with the latter this termination is virtually nonexistent as a consequence of 'steric shielding' of the amino functions in the polymer chain.

The polymerization of NPA with methyl triflate as initiator follows a similar mechanism with a predominantly intermolecular termination reaction by nucleophilic attack of the polymer nitrogens on the active species.[48] At 30 °C, the ratio k_p/k_t is approximately 30.

NPA reacts with living polyTHF to produce an azetidinium-terminated polymer that can be used as macroinitiator for the polymerization of NPA whereby THF–NPA block copolymers are formed.[48] Due to the intermolecular termination, the end products have branched structures.

N-phenylazetidinium ions react with nucleophilic reagents such as carboxylate anions to form the corresponding amino-ester derivatives. This reaction has been used extensively by the group of Tezuka to produce a large variety of cyclic and polycyclic polymer structures by the so-called electrostatic self assembly – covalent fixation method.[49,50]

N-alkyl-3-azetidinols, obtained from epichlorohydrin and a primary amine, have been polymerized to low-molecular-weight hydroxy-substituted polyamines.[51] Transesterification of an azetidinol with methyl acrylate or methacrylate leads to the corresponding azetidinyl esters which can be polymerized or copolymerized with other vinyl monomers to produce reactive, cross-linkable polymers[52] (Scheme 18).



Scheme 18 Synthesis and free radical initiated polymerization of azetidinyl acrylate.

4.13.3 Cyclic Sulfides

4.13.3.1 Thiiranes

The parent compound, thiirane (ethylene sulfide), produces a crystalline polymer with a melting point of 205 °C that is insoluble in most solvents.[53] As a consequence, the polymerizations of this monomer are heterogeneous and mechanistic studies are difficult. The most studied monomer is methylthiirane (MT) often referred to as propylene sulfide. However, other substituted thiiranes have also been described extensively in the literature. The polymerizations can occur by cationic, anionic, coordinative, and 'monomer insertion' mechanisms.

4.13.3.1.1 Cationic polymerization

The cationic polymerization of thiiranes is initiated by proton acids, Lewis acids, and alkylating agents.[54] The counterions of the cationic propagating species must have a nucleophilicity lower than that of the monomer in order to prevent termination reaction with the counterion. Typical nonnucleophilic counterions are tetrafluoroborate, hexafluorophosphate, trifluoromethanesulfonate, and perchlorate.

The propagation reaction is a nucleophilic attack of the monomer on the thiiranium ion (ring substituents omitted) (Scheme 19).

The polymerization is characterized by a rapid (temporary) termination reaction occurring between the active species and a sulfide function in the polymer chain. This termination appears to be reversible so that these terminated groups are 'dormant' rather than 'dead' species.[54,55] The reinitiation reaction can result in the same starting structures; however, as shown in the next scheme, it is equally possible that a neighboring sulfide of another polymer chain produces the thiiranium ion. In that case, polymer P^1 is connected to P^2 and the active species is transferred to polymer P^3 (counterion and substituents omitted) (Scheme 20).

Scheme 19 Propagation reaction in cationic ROP of thiiranes (ring substituents omitted).

This leads to broadening of the MWD of the polymers.

If the termination occurs with a sulfide of the same polymer chain, the subsequent reinitiation results in the formation of a cyclic oligomer. With most monomers, a mixture of cyclic oligomers is formed but the most abundant are the dimers and the 12-membered tetramers, which are formed as in Scheme 21(substituents omitted).

The degradation of polythiiranes leads not only to cyclic oligomers but also to seven-membered trithiepane rings, that is, rings containing a disulfide bond, whereby an olefin is eliminated. The mechanism proposed for this trithiepane formation from poly(*trans*-2,3-dimethylthiirane) is as shown in Scheme 22.[56]

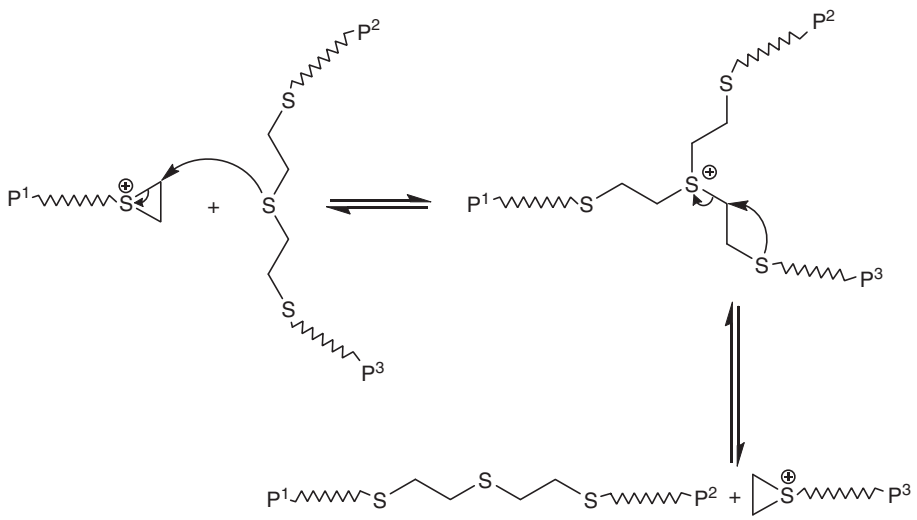
The stereochemistry of this reaction has been studied in detail and has led to the elucidation of the reaction mechanism of the degradation to trithiepanes.

Finally, in cases where the thiiranium ions can form stabilized carbenium ions (e.g., phenylthiirane and 2,2-dimethylthiirane), isomerized five-membered cyclic dimers (1,3-dithiolanes) have been found. These are formed by a mechanism including a hydride transfer in the carbenium ion intermediate.[57]

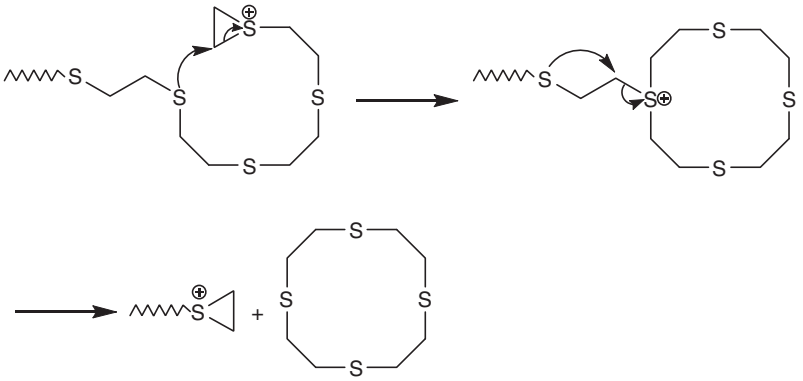
This cyclic oligomer formation continues after all monomer has been consumed. Therefore, the final end product of the cationic 'polymerization' of thiiranes consists of a mixture of low-molecular-weight polymer and cyclic degradation products.

These degradation products are also obtained when polythiiranes, prepared by other polymerization mechanisms, are treated with cationic (photo-)initiators.[56] The degradations occur rapidly at room temperature. The kind of oligomers formed depends on the nature of the monomer and on the concentration of the initiator. At high initiator concentrations, the smaller rings, that is, dimer or trithiepane, are favored and at lower concentrations, the larger rings, mainly tetramer, are favored.[58]

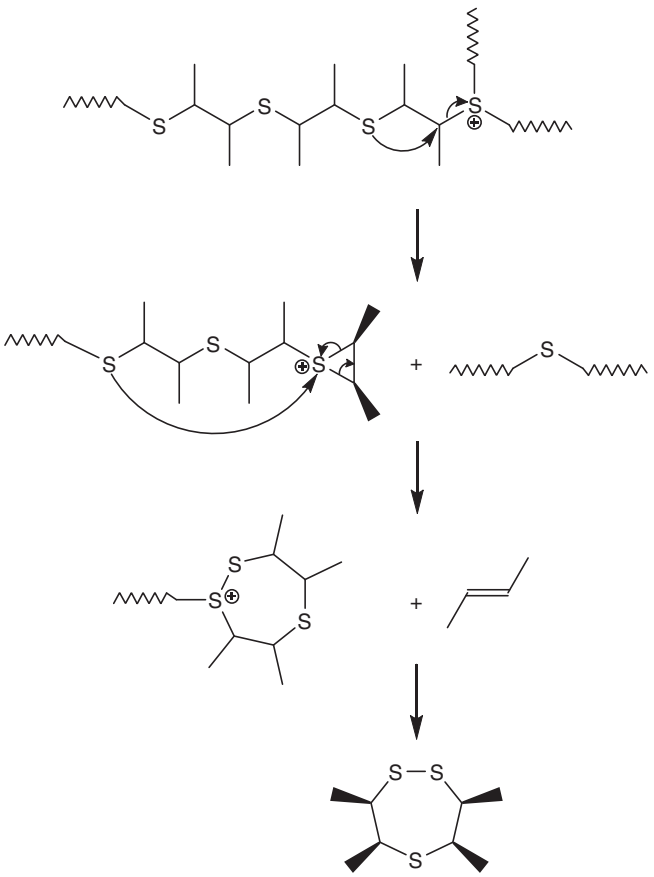
The occurrence of the intermolecular termination followed by reinitiation is the reason why the formation of block



Scheme 20 Termination and re-initiation in cationic ROP of thiiranes (counterion and ring substituents omitted).



Scheme 21 Formation of cyclic tetramer in cationic ROP of thiiranes (counterion and ring substituents omitted).



Scheme 22 Formation of trithiepane in cationic ROP of thiiranes.

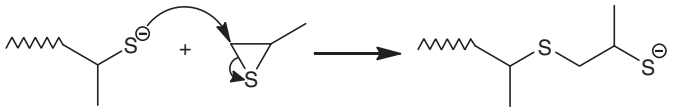
copolymers of different thiiranes by sequential monomer addition is not possible: these reactions are so rapid that a scrambling of the two monomer units along the polymer chains occurs during the polymerization of the second monomer.[59,60]

The cationic polymerization of 9-carbazolylmethyl- and 10-phenothiazinylmethyl thiiranes initiated by several photoinitiators has been reported.[61] Here also, the end products were a mixture of low-molecular-weight polymers and cyclic oligomers.

4.13.3.1.2 Anionic polymerization

The anionic polymerization of thiiranes had been studied in detail during the 1960s and 1970s by Boileau, Sigwalt, and their co-workers.[53,62,63] Thiirane and various substituted thiiranes, especially MT, have been polymerized to high-molecular-weight polymers by various anionic initiators. The active species of the polymerization are of the thiolate type (Scheme 23).

The attack of the thiolate ion on the monomer proceeds exclusively at the methylene carbon so that the polymers are



Scheme 23 Propagation reaction in anionic ROP of MT.

pure head-to-tail structures. There is no stereoselectivity in the propagation step, so that polymers with a random Bernoullian tacticity are obtained.

With a number of initiators, such as naphthylsodium, the polymerizations were found to be of the living type. With this particular initiator, the degree of polymerization was governed by the equation

$$\overline{DP}_n = \frac{2[M]}{[In]}$$

indicating that in this case the polymer chains grow at both chain ends. The initiation reaction was proposed to consist of a desulfurization process producing ion radicals that combine to form dithiolates.[64]

A detailed kinetic study of monofunctionally growing polymerization obtained by initiation with carbazylsodium permitted the calculation of the propagation rate constants and of the thermodynamic parameters for propagation via free ions and ion pairs. It was found that the free ions are about 1000 times more reactive than the ion pairs.[65] However, when the sodium counterion was complexed by cryptants, the ion pair rate constant was found to be a factor of about 3 higher than the rate constant for free ions, resulting in a global rate constant increasing with living end concentration.[66]

The anionic polymerization of thiiranes is also initiated by tertiary amines, of which 1,4-diazabicyclo[2.2.2]octane ('DABCO') is the most effective.[67] The polymerization is believed to occur through zwitterionic structures (**Scheme 24**).

PolyMTs containing thiol groups at both chain ends have been prepared by polymerization of MT in the presence of a dithiol as transfer agent[68] and trifunctional polymers were obtained with a trithiol.[69]

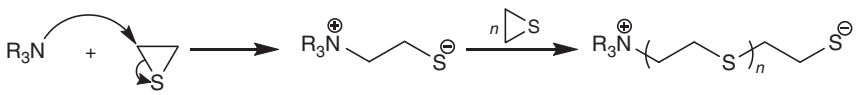
With some anionic initiators, such as lithium alcoholates, zinc thiolates, and triethylaluminum, the polymers contain considerable fractions of disulfide linkages with the formation of the corresponding olefin.[70–72]

Quaternary ammonium salts of thioacids or dithioacids have also been used as initiators but the initiation is slower than the propagation, resulting in broad polydispersities and uncontrollable molecular weights.[73]

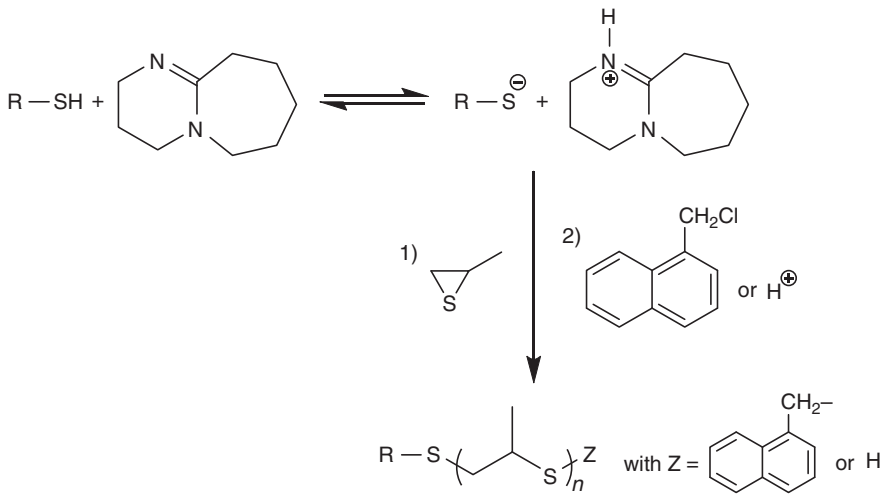
The thiolate function being the active species of the polymerization, it is evident that thiolates should be the ideal initiators. This has been investigated by Nicol *et al.*[74] who described the polymerization of MT initiated by various mono- and dithiolates. The deprotonation of the thiols was accomplished by addition of a strictly stoichiometric amount of a bulky strong organic base: 1,8-diazabicyclo[5,4,0]undec-7-ene (DBU) (**Scheme 25**).

The polymerizations were found to be of the living type producing polymers with molecular weights that were in accordance with the used monomer/initiator ratios.

It was found that the thiolate end group reacts with disulfide functions which results in a transfer reaction.[75] This



Scheme 24 Anionic ROP of thiiranes initiated by a tertiary amine.



Scheme 25 Anionic polymerization of MT initiated by *in situ* formed thiolates.

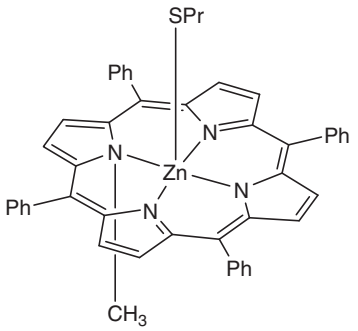


Figure 3 Structure of (NMTPP)ZnSPr.

transfer reaction occurs not only with low-molecular-weight disulfides (leading to a decrease of the molecular weight) but also with disulfide functions present in the polymer chains, leading to a broadening of the MWD. Low-molecular-weight disulfides may be present in the polymerization mixture as a result of oxidation of the initiating thiol. Therefore, several authors describe the use of protected thiols which are deprotected just before polymerization. Examples are the use of thioester, which is transformed into thiolate by the addition of sodium methanolate, and the ring opening of cyclic dithiocarbonates by an amine (see below).

A special kind of living polymerization of MT was developed by Inoue *et al.* Using (*N*-methyl-5,10,15,20-tetraphenylporphinato)zinc propanethiolate ((NMTPP)ZnSPr) as initiator, polymers with predictable molecular weights and with M_w/M_n values of 1.1 were obtained[76] (**Figure 3**).

In the presence of a thiol such as propanethiol or thiophenol, this polymerization exhibits 'immortal' character, that is, the number of polymer molecules exceeds that of the initiator molecules without affecting, however, the narrow MWD. This was attributed to an exchange of the thiol end groups of the polymer chains with the thiolate active species occurring at a rate that is much higher than the propagation rate.

Since the anionic polymerization of thiiranes can be of the living type, it is possible to prepare block copolymers by the sequential monomer addition method. Thus, various AB and ABA block copolymers of thiirane, MT, and 2,2-dimethylthiirane have been obtained by adding the thiirane to a solution of a mono- or bifunctional anionic living polymer. With the (NMTPP)ZnSPr initiator, MT–methyloxirane block copolymers were obtained by first polymerizing the thiirane and then the oxirane, the second-stage polymerization starting on irradiation with visible light.[77] **Table 3** gives a survey of block copolymers that have been obtained via sequential anionic polymerization.

Napoli *et al.*[84] developed a 'one-pot' synthetic method for the preparation of amphiphilic polyethylene glycol (PEG)-*b*-polymethylthiirane (PMT) block copolymers. Their method implies initiation of the MT polymerization by *in situ* generated PEG thiolates, obtained from the corresponding thioacetate PEG end group. Symmetric ABA triblock copolymers were obtained by exposing the thiolate-terminated diblock copolymers to air, to achieve disulfide linking. Asymmetric ABA triblock copolymers were generated by chain coupling by Michael-type addition of the thiolate terminal groups of PMT with PEG monoacrylates.

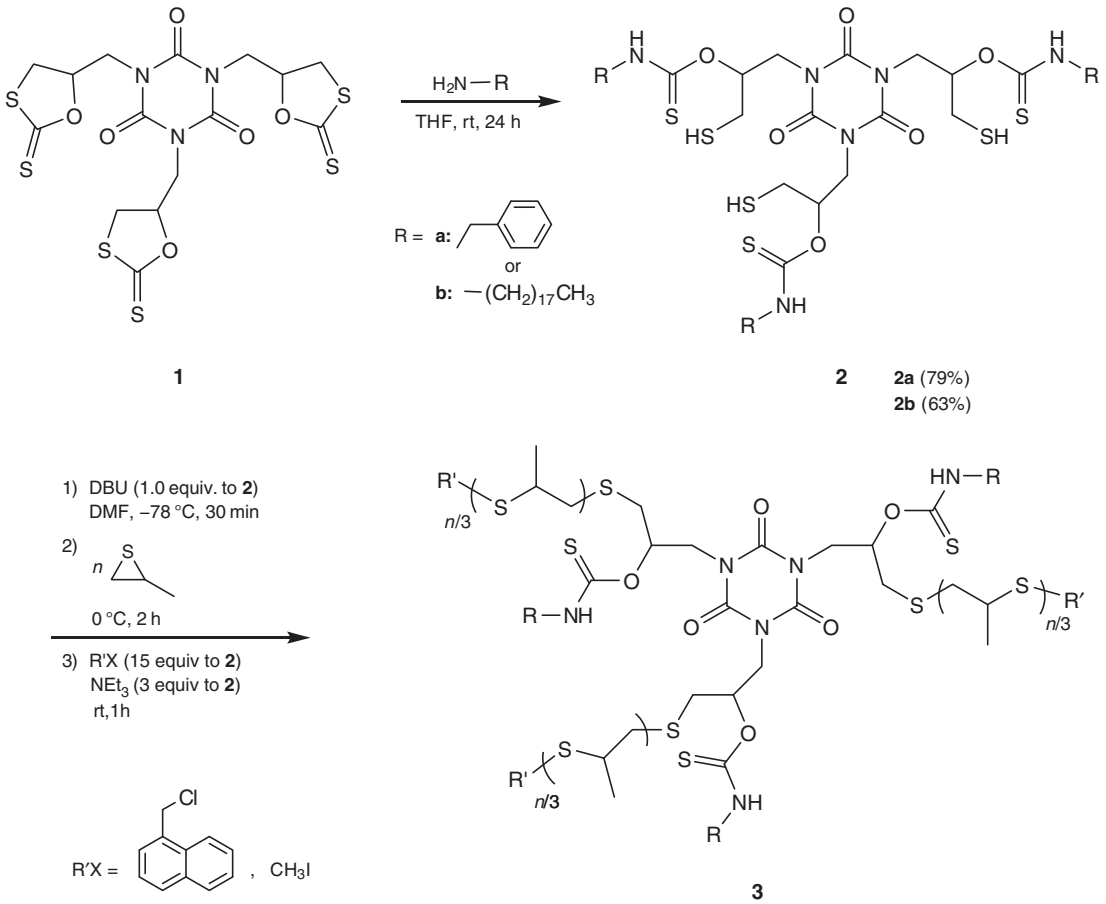
The synthesis of star-shaped polythiiranes, based on the living anionic polymerization mechanism, has been reported by several authors. Nicol *et al.*[85] reported the synthesis of star-shaped PMT by polymerization with tri- and tetrathiol initiators and by end-capping of monofunctionally living polymers with tetrakis(bromomethyl)naphthalene. The latter method produced mixtures of di-, tri-, and tetra-arm polymers. Suzuki *et al.*[86] described the formation of star-shaped PMT by using trifunctional thiol **2** that was formed *in situ* from a tri(cyclic dithiocarbonate) **1** and an amine, as shown in **Scheme 26**.

The initiator system **2a**/DBU was formed by addition of DBU ([**2a**]/[DBU] = 1:1), which leads to the thiolate/thiol equilibrium through proton exchange. The polymerization of MT using this initiator system was carried out in DMF at 0 °C and was quenched by 1-(chloromethyl)naphthalene, which has been reported to be effective for termination of thiirane polymerization. With a feed ratio of $[MT]_0/[\mathbf{2a}/DBU]_0 = 30$, the reaction was complete within 5 min to afford the corresponding star-shaped polymer the number-average molecular weight (M_n) and MWD (M_w/M_n), which were 3500 and 1.05, respectively.

Recently, the same group reported the synthesis of star-shaped poly(phenoxymethyl thiirane) using the same methodology.[87]

Wang *et al.*[88] reported the synthesis of a series of initiators characterized by the presence of one, two, three, or four thioacetates, which, when deprotected with sodium methanolate, produce the corresponding number of thiolates. These initiating systems were used to produce linear monofunctional or difunctional growing polymers and three-arm or four-arm star-shaped thiol-terminated PMTs. In the same paper, the synthesis (and some properties) of star-shaped amphiphilic block copolymers based on PMT and PEG are described. In a subsequent paper by the same group, the role of disulfides in MT polymerization and the methods to minimize their presence and their effect on the final polymer structures are described.[89]

The thiolate chain ends in thiirane polymerizations are unreactive toward hydroxyl groups and even toward water,



Scheme 26 Formation of star-shaped PMT by using a trifunctional thiol.

and it is, therefore, possible to produce living polymerizations in the presence of alcohols and in aqueous medium. It is also possible to polymerize hydroxyl-containing monomers such as hydroxymethyl thiirane (HMT) in a living fashion.[90] Block copolymers of MT and HMT could be prepared by sequential monomer addition on the condition that the PHMT was the first sequence.[83]

'Living' emulsion polymerization of MT in water, initiated by the system propane-1,3-dithiol/DBU, has been reported, but the polymerization stopped at limited conversions producing polymers with molecular weights lower than predicted from the used M_o/In ratios.[91] Although these observations are in contradiction with a living mechanism, it was shown, by end-capping reactions, that all polymer chains conserved thiolate anions as end groups. The limited conversions were attributed to physical causes rather than to chemical.

A similar chemistry was applied by Morinaga *et al.*[92] to use human hair, which contains thiol functions, in combination with DBU to graft-polymerize MT.

Other examples of functionalized monomers are polyoxyethylene (POE) chains linked to the thiirane with monothioacetal or ester functions (macromonomers),[93] POE chains containing a thiirane group at both chain ends (bis-macromonomer),[94] and stilbene mesogen and other side chain liquid crystalline-substituted thiiranes.[95,96]

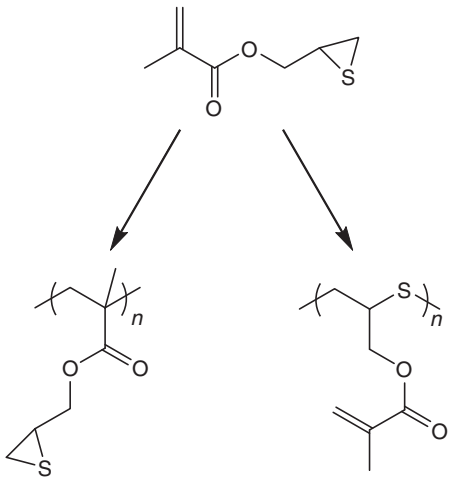
The polymerization of 2,3-epithiopropyl methacrylate either by (controlled) free radical polymerization or by anionic ROP has been described[97] (**Scheme 27**).

End-capping of monofunctionally or bifunctionally living polyMT with 2-(bromoacetoxy)ethyl methacrylate leads to the corresponding polyMT mono- or α,ω-dimethacrylate.[98] The latter has been photo-polymerized to yield materials with controlled cross-linking densities.

4.13.3.1.3 Coordinative polymerization

Mono- or unsymmetrically substituted thiiranes exist as two enantiomers. The polymerization of a racemic mixture can occur in different ways:

1. Both enantiomers are incorporated randomly in the polymer chains leading to atactic polymers.
2. Stereoselective propagation leading to a mixture of two enantiomeric polymer chains, that is, a mixture of poly-*R* and poly-*S* chains. This propagation is called enantiosymmetrical.
3. The propagation rate constant for one enantiomer is larger than that of the other enantiomer. This type of propagation is called stereoelective or enantioasymmetrical. This type leads to optically active polymers and to an enrichment of



Scheme 27 Two modes of polymerization of 2,3-epithiopropyl methacrylate.

one of the enantiomers in the residual monomer mixture. The enantiomeric composition of the polymer is then governed by the equation

$$\frac{d[R]}{d[S]} = r\left(\frac{[R]}{[S]}\right)$$

where r is the ratio of the propagation rate constants for the *R* enantiomer and the *S*-enantiomer.

The anionic polymerizations of racemic mixtures of thiiranes described above generally lead to atactic polymers. When one pure enantiomer is polymerized, the asymmetric center remains unchanged and the resulting polymer is isotactic. This polymer is optically active and has quite different physical properties compared with the atactic analog. Isotactic polyMT, for example, is a crystalline material with a melting point of up to 63 °C,[53] whereas the atactic polymer is an amorphous material.

A number of initiating systems have been found to produce enantiosymmetrical polymerizations, leading to a racemic mixture of poly-*RR* and poly-*SS*. Typical initiators are the reaction products of alkylmetal compounds with water or with an alcohol. Thus, Machon and Sigwalt[99] have shown that the system diethylzinc/water produces crystalline polyMT. From comparison of the crystal structure of the crystalline fraction of the polymer with that of pure isotactic optically active polymer, it was proposed that the crystalline fraction obtained with that system consists of two kinds of optically active crystallites of *RR* and *SS* types.

Also diethylzinc/alcohol systems are efficient initiators giving high-molecular-weight polymers. High degrees of crystallinity are observed when dihydroxyl compounds are used.[100] PolyMT with high stereoregularities are obtained with cadmium tartrate as initiator. The high-molecular-weight compounds have a melting point of 53–54 °C and contain more than 85% isotactic triads.[101]

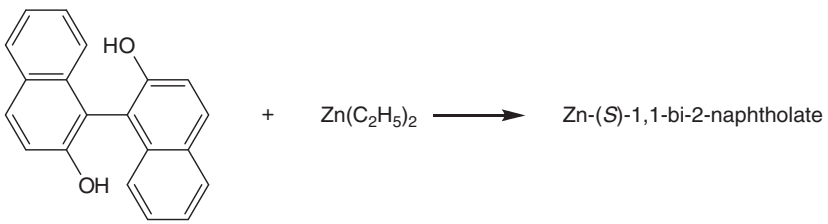
When an optically active alcohol is used for the preparation of the initiator, the polymerizations become of the enantioasymmetrical type. The system diethylzinc/(*R*)-(-)-3,3-dimethyl-1,2-butanediol (1:1) has a high stereoelective nature for the polymerization of MT.[102]

Other thiiranes that have been polymerized with stereoselective and/or stereoelective initiator systems include isopropylthiirane,[103] *t*-butylthiirane,[104] and *cis*- and *trans*-2,3-dimethylthiirane.[105,106] The polymerization of *t*-butylthiirane gives pure isotactic chains with most stereospecific initiators. An exceptionally high stereoelection was observed in the polymerization of methyl- or ethylthiirane with optically active atropisomeric initiator systems. For example, zinc (*S*)-1,1-bi-2-naphtholate gave an *r*-value of 15–20.[107,108] At 67% conversion a residual monomer with an optical activity of [α]D24 = 51.77° (neat, 1 dm) was obtained (**Scheme 28**).

Most of the stereoselective initiators are heterogeneous systems that have a low efficiency, and therefore a precise control of molecular weight and polydispersity is not possible. A number of stereoselective and stereoelective polymerizations of MT have also been studied in a homogeneous phase using chiral cadmium thiolates of cysteine esters and cadmium carboxylates of cysteine and methionine (**Figure 4**).

The most studied of these was the (*S*)-cysteine derivative with *R* = isopropyl. The polymerization of MT with this initiator is of the living type.[109] The molecular weights obey the relationship DP = [M]/[Cd], showing that the main propagation is taking place on one valency of cadmium. The stereospecificity appears only for molecular weights higher than 6000 and also depends on the temperature. The stereospecific propagation is proposed to involve cadmium thiolates associated with 'dimeric species' and coordinated by both the monomer and an oligomer or polymer chain.[110] By means of ^{13}C-NMR studies it was found that during the stereospecific polymerization of MT in homogeneous phase initiated by bis (isopropyl-(*S*)-cysteinato)cadmium, an interconversion between active sites occurred, leading to the formation of stereoblocks with an estimated DP_n of 12–14[111] (**Scheme 29**).

Enantiomer-selective polymerization of *RS*-(phenoxymethyl)thiirane with $ZnEt_2$/L-α-amino acid has been reported.[112] The *S*-enantiomer was consumed preferably and isotactic-rich polymers were obtained. With $ZnEt_2$/L-Leu, a high enantiomer selectivity ($r = 5.36$) was observed.



Scheme 28 Formation of Zn-(*S*)-1,1-bi-2-naphtholate.

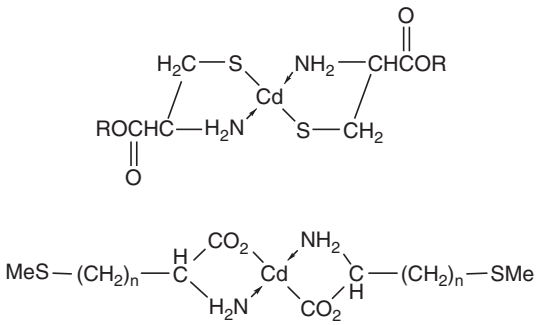


Figure 4 Structure of a cadmium thiolate of cysteine ester and a cadmium carboxylate of methionine.

4.13.3.1.4 Other ROP mechanisms for thiiranes

Acyl-group transfer polymerization of thiiranes using carboxylic acid derivatives and quaternary onium salts is a relatively new method for controlled polymer synthesis from various thiiranes.[113] In this mechanism, an acyl-group is transferred in each propagating step to give the corresponding polythiirane with an *S*-acyl end group (Scheme 30).

When the acyl transfer polymerization method was used with a cyclic dithioester as initiator, cyclic polysulfides are obtained[114] (Scheme 31).

A similar mechanism operates when dithioester such as benzyl dithiobenzoate (BDB) or benzyl 1-pyrrolecarbodithioate (BPC) is used as initiator, resulting in a polysulfide terminated with a RAFT (reversible addition fragmentation chain transfer) agent (Scheme 32).

RAFT polymerization of styrene or dimethylacrylamide with the same compounds in conjunction with AIBN as initiator leads to the corresponding polymers provided with end groups that are capable of initiating the MT polymerization with the formation of well-defined block copolymers[115] (Scheme 33).

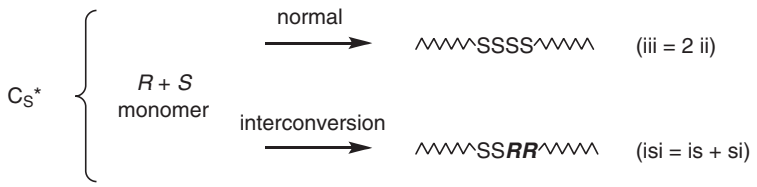
Recently, the same group reported the 'living' insertion polymerization of MT with *p*-tolylcarbamothioate (PTCT) as initiator and tetrabutylammonium chloride as catalyst[116] (Figure 5).

4.13.3.2 Thietanes

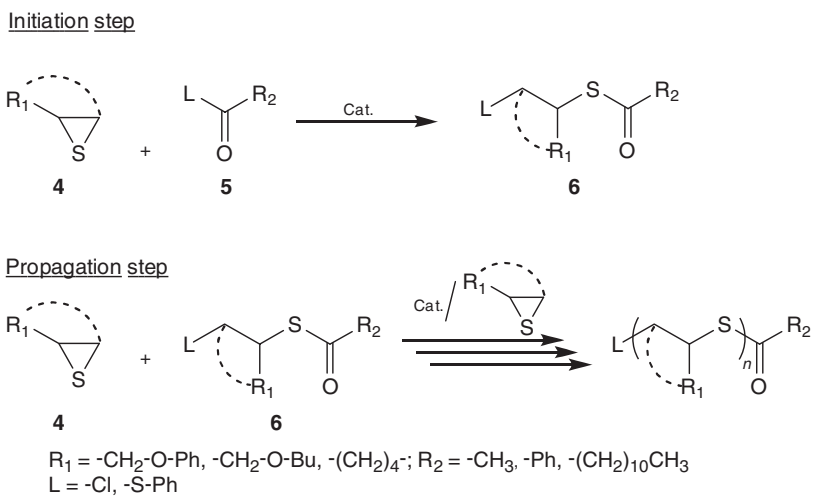
4.13.3.2.1 Cationic polymerization

The mechanism of the cationic polymerization of thietanes differs from the mechanism described for the thiiranes by the fact that the reaction between the active species and a sulfur atom of the polymer chain appears to be irreversible so that it is a real termination reaction. As a consequence, the polymerizations of thietanes stop before all monomer is consumed and there is no formation of cyclic oligomers.[117] The maximum conversions obtained depend on the amount of initiator used and on the ratio of the rate constant of propagation, k_p, to the rate constant of the termination reaction, k_t (Scheme 34).

The ratio k_p/k_t has been taken as a measure of the living character of the polymerization.[118] This ratio is greatly affected by the presence and the nature of substituents on the thietane ring. Substituents decrease the reactivity of the active species toward the sulfide function but, as shown in Table 4, this decrease is more pronounced for the termination reaction than for the propagation reaction. Thus, thietane polymerizes



Scheme 29 Stereoblock formation in the polymerization of MT initiated by cadmium thiolate of isopropyl cysteine.



Scheme 30 Acyl transfer polymerization of thiiranes (the dotted line designates the cycloaliphatic monomer cyclohexene sulfide).

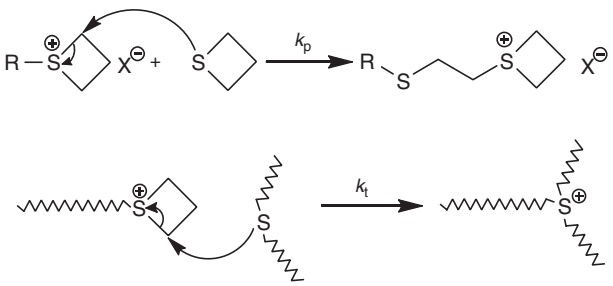
PTCT

Figure 5 Structure of PTCT.

at a high rate but the polymerization stops at low conversions, whereas 3,3-diethylthietane polymerizes very slowly but to almost quantitative conversions. This behavior has been explained by steric shielding of the sulfide functions by two adjacent substituted units in the polymer chain, which reduces the nucleophilic reactivity of the sulfide compared with the sulfide in the monomer.

The occurrence of a termination reaction in the thietane polymerization leads to the formation of branched polymer structures, and therefore it is not possible to control the molecular weight or the MWD, except for the 3,3-diethyl derivative, which shows a relatively high living character.

The occurrence of an intermolecular termination reaction in the polymerization of thietane has been used to prepare star-shaped segmented copolymers.[119] Oxonium ions are excellent initiators for the polymerization of cyclic sulfides and therefore addition of thietane to a living polyTHF solution results in the formation of a block copolymer. Since the thietane polymerization gives the termination reaction described above, the end result of this sequential monomer addition is a



Scheme 34 Propagation and termination in the cationic ROP of thietanes.

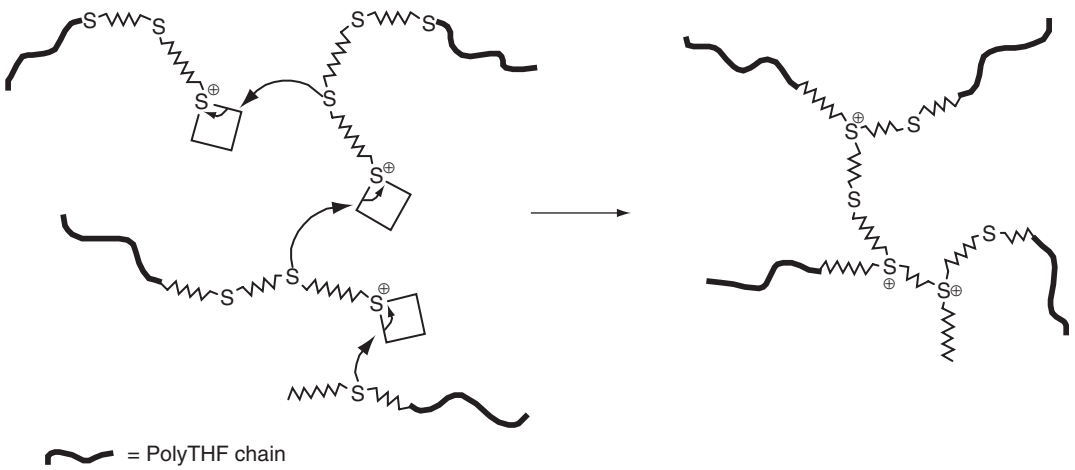
structure consisting of a branched polythietane core with a linear polyTHF shell (**Scheme 35**).

If the polymerization of the THF was initiated by a bifunctional initiator, such as trifluoromethane sulfonic acid anhydride, the addition of thietane leads to a segmented polymer network consisting of linear polyTHF segments connected to each other by branched polythietane segments.[119]

Similar results have been obtained by combining the living cationic polymerization of vinyl ethers and the ROP of thietane.[120] In this case, the thietane acts as growing species stabilizer for the vinyl ether polymerization by reversible formation of an α-alkoxy-thietanium ion. This ion can, however, also be attacked at an endocyclic methylene by another thietane molecule leading to an alkyl-thietanium ion. This ion is incapable of reacting with a vinyl ether but is the active species for the thietane polymerization. Also in this case the end product is a star-shaped segmented polymer.



Scheme 35 Formation of star-shaped segmented copolymers by sequential polymerization of THF and thietane.

4.13.3.2.2 Anionic polymerization

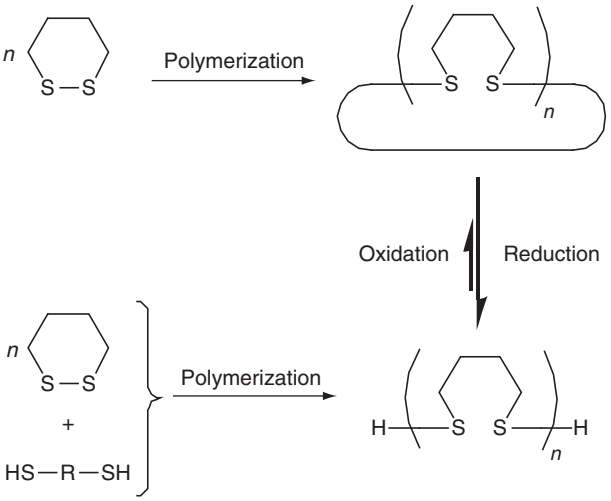
Thietane[121,122] and 3,3-dimethylthietane[123,124] have been polymerized to high-molecular-weight polymers by initiation with naphthylsodium or butyllithium. The polymerizations were shown to occur with carbanions as active species (instead of thiolate as in the case of thiiranes).

4.13.3.3 Cyclic Disulfides

The polymerization of cyclic disulfides to polydisulfides has been reported in the 1940s and 1950s. In some cases the polymerizations occur spontaneously.[125] Tobolsky *et al.*[126] reported that 1-oxa-4,5-dithiacycloheptane and 1,3-dioxa-6,7-dithiacyclononane are polymerized by cationic initiators such as sulfuric acid or boron trifluoride. Davis and Fettes[127] reported the anionic polymerization of various cyclic disulfides. In the same period it was also described that cyclic disulfides can copolymerize with vinyl monomers such as styrene and butyl acrylate with AIBN as initiator.[128] That the incorporation of the disulfide was due to copolymerization and not by chain transfer was established by comparing the thermal polymerization of styrene in the presence of dibutyl disulfide and in the presence of 1-oxa-4,5-dithiacycloheptane. In the first case, the polymer contained 2 sulfur atoms per macromolecule as a result of transfer reactions and in the second case 4–20 sulfur atoms depending on the ratio of monomers.

More recently, the polymerization of several cyclic disulfides has been investigated by Endo *et al.* The thermal polymerization of 1,2-dithiane (DT) did not proceed at monomer concentrations below 4.0 mol l^{-1}. The polymerization was inhibited by addition of radical inhibitors, indicating that the propagation proceeds by a radical intermediate. The molecular weight of the polymers increased with reaction time. It was proposed that the cyclic polymer is formed mainly by back-biting reaction mechanism during the polymerization (**Scheme 36**).[129]

The bulk polymerization of DT proceeds readily without initiators above its melting point, giving a polymer in high yield. The molecular weight of polymers obtained could be controlled by the addition of benzyl mercaptan (BM). The ^{13}C- and ^{1}H-NMR spectra suggest that the poly(DT) has a macrocyclic structure in contrast to the linear polymers that were obtained from polymerization in the presence of thiols. Redox reactions could be used to transform the linear in cyclic structures and *vice versa* (**Scheme 37**).

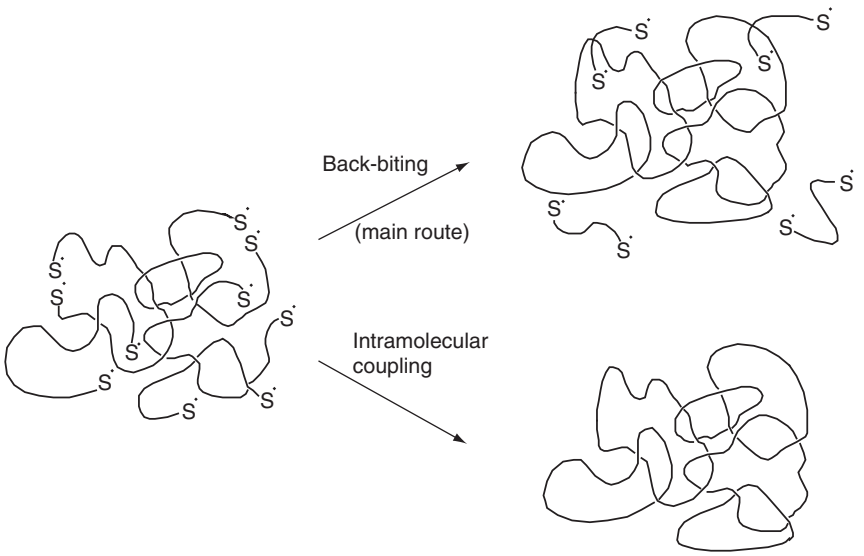


Scheme 37 Two mechanisms for the formation of thiol terminated poly (DT).

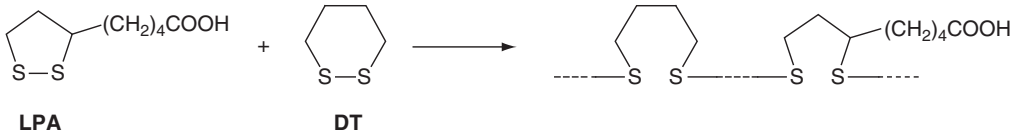
When the polymerization of DT was performed in the presence of cyclic poly(oxyethylene) (CPO), the product included a catenane structure of cyclic poly(DT) and CPO entangled with each other. It was concluded that the poly(DT) obtained from polymerization of DT includes a polycatenane structure.[130]

Copolymerization of lipoic acid (LPA) and DT to high-molecular-weight polymers has been reported by the same group.[131] Also in this case, the formation of polycatenane structures was postulated (**Scheme 38**).

The polymerization of *o*-xylylenedisulfide (XDS) proceeds at temperatures above the melting point of XDS to give high-molecular-weight polymers[132] (**Figure 6**).



Scheme 36 Free radical polymerization DT leading to cyclic polymers.



Scheme 38 Copolymerization of LPA and DT.

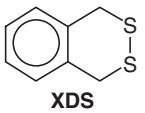


Figure 6 Structure of XDS.

The polymers were characterized to have cyclic structures containing polycatenane structures in contrast to the linear structures obtained in the presence of thiol-containing chain transfer compounds.

4.13.4 Conclusions and Outlook

Polymeric amines in general continue to attract attention in many application fields and several of these products are commercially available. In recent years polyamines have found new applications as gene transfer agents due to the fact that they form interpolymer complexes with nucleic acids. PEI (branched as well as linear) is one of the most studied polymers in this field. It seems, however, that the pure polyamines have several drawbacks and in the latest developments the polyamine is modified with other polymers, such as PEG. Moreover, it is of importance to be able to introduce targeting groups on these macromolecules.[133] Therefore, any method that produces well-defined polyamine structures containing appropriate functional groups for coupling with other polymer chains or with targeting groups is of potential interest in these applications.

Poly(alkylene sulfides) such as those obtained by ROP do not, at the authors knowledge, have widespread applications. However, recently there seems to be some interest in such polymers for biological applications.[134] Here also, the interest stems from the fact that different types of well-defined polymers with well-defined functional end groups as well as polymers with functional groups substituted on the polymer chain can be prepared by relatively simple synthetic techniques. ROP is such a technique. ROP of cyclic disulfides by free radical mechanism has recently gained interest for the production of cyclic polymers containing polycatenane structures.

Biographical Sketches

Eric Goethals graduated from Ghent University (Belgium) in 1958 and obtained his PhD degree in organic chemistry at the same university in 1963. After a postdoctoral year at the Gütenberg University in Mainz (Germany), where he worked with Prof. Rolf Schulz, he returned to Ghent where he started a research group on polymer chemistry. He was appointed associate professor in 1970 and full professor in 1980. He was head of the department of organic chemistry from 1996 till 2002, the year of his retirement from the university. He has lectured organic chemistry to medical students and polymer science to chemists. His research was in polymer synthesis, cationic polymerization, ring-opening polymerization, telechelic polymers, polymer networks, and reactive polymers. He is the editor of 4 books and coauthor of over 400 publications in international scientific journals.

Bart Dervaux was born in 1983 and studied from 2001 to 2005 at Ghent University where he received a master's degree in chemistry. From 2006 till 2010, he did a PhD under the supervision of Prof. F. Du Prez with a fellowship of the Research Foundation – Flanders (FWO), focusing on the synthesis and characterization of block and block-like copolymers and the preparation of block-like copolymers by continuous processes using column reactors. In the framework of his PhD research, he did scientific short-time visits in the research groups of Prof. I. Galaev (Lund, Sweden), Prof. V. Zubov (Moscow, Russia), and Prof. C. Barner-Kowollik (Karlsruhe, Germany). Since 2010, he has been working in the group of Prof. Du Prez as a postdoctoral FWO fellow on the stabilization of polymer nanocomposites. This research is in close collaboration with the research group of Prof. P. Dubois (Mons, Belgium). He is the coauthor of 14 scientific publications and 1 book chapter.

4.14 Ring-Opening Polymerization of Cyclic Amides (Lactams)

S Russo and E Casazza, Università di Genova, Genova, Italy; INSTM, Consorzio Interuniversitario Nazionale di Scienza e Tecnologia dei Materiali, Firenze, Italy

4.14.1 Introduction

Among the heterocyclic compounds able to polymerize, lactams represent one of the most versatile families of monomers. At present, their ring-opening polymerization (ROP) constitutes a very relevant method for the obtainment of polyamides and copolyamides entailing a wide range of properties, covering a large number of applications, and having a crucial industrial interest.

Indeed, even without taking into account the additional contribution of ring substituents, the ring size as such strongly affects not only the lactam reactivity but also the final characteristics of the resultant polyamide; in this respect, the broad range of their behaviors goes from a close similarity with polypeptides for polyamides derived from four-membered lactams to the analogy to polyolefins for polyamides obtained from higher members of the lactam series (e.g., 13-membered lactams).

Before the late 1930s of the last century, the entire class of lactams did not play a role whatsoever in the chemical industry; neither seemed to offer any interesting problem in the domain of scientific research. Carothers,[1] in his famous 1931 work on ring formation and polymerization, for the first time made an extensive and critical investigation on the transformation of cyclic monomers, especially lactones, into linear polymers. He pointed out that, differently from lactones, the five- and six-membered lactams, that is, 2-pyrrolidone and 2-piperidone, were entirely stable substances. On these grounds, the latter lactam resulted quite in counterposition to the easily polymerizable oxygen isologue. Starting from the above misleading findings, Carothers accepted without much hesitation the odd result found together with Berchet[2] that also the seven-membered ε-caprolactam (CL) was not polymerizable, even in the presence of catalysts.

The recognition of the first lactam polymerization should undoubtedly be attributed to Schlack,[3] who polymerized CL using the hydrochloride of ε-aminocaproic acid, replaced by small amounts of water later on, as initiator for the industrial production of polyamide 6 (PA6) for fibers, which started in 1940s in Germany. Since then, the large-scale manufacture of the most important lactam-based polyamide, that is, poly(CL) (PCL), commercially named PA6, has been mostly carried out by what has been identified as the hydrolytic process.[4] It is worth to emphasize here that the hydrolytic mechanism, apart from the initiation step involving the water-catalyzed opening of the lactam ring and the subsequent polyreactions, is also based on polycondensation steps. As a consequence, it cannot be regarded as strictly pertinent to a neat ROP process and will not be deepened in the present chapter. Actually, the water-initiated polymerization is only one of the possible routes to convert some lactams to polyamides inasmuch that the presence of an initiator is essential, with the spontaneous polymerization being presumably attainable only at very high temperatures and for a limited number of lactams. Indeed, due to the amphiprotic character of the amide group, the lactam ROP may be initiated by a base (anionic process), or an acid (cationic process), or simply water (hydrolytic process). Besides the ionic routes, the enzymatic polymerization of four-membered lactams has also been recently accomplished for the preparation of poly (β-peptides), that is, unsubstituted and substituted polyamide 3.

At the end of the 1930s, the cationic polymerization as well has been attempted by Schlack,[5] who discovered that anhydrous hydrogen chloride was capable of initiating the polymerization of CL. However, for reasons unknown at that time, the acid-initiated reaction did not yield high-quality PA6 and was therefore considered to be of no interest for commercial purposes. As a matter of fact, the cationic mechanism of lactam polymerization has always found very limited applications, if any, not only because of the low conversions and the low molar masses of the resultant polyamides but also for the extensive occurring of side reactions.

The anionic polymerization of lactams has been discovered shortly after the cationic polymerization by Joyce and Ritter,[6] who in 1941 patented the conversion of CL to PA6 in the presence of alkali or alkaline earth metals. The reaction was named 'rapid polymerization' by Joyce and Ritter in view of the fact that equilibrium conversion could be attained in a few minutes.

Unlike the abandoned cationic process, the anionic ring-opening polymerization has soon been able to develop several industrial strategies in many fields where hydrolytic polyamides, namely hydrolytic PA6, could not enter because of their inferior mechanical properties and unsuitable synthetic conditions. Indeed, anionic ROP of lactams has shown to be the most versatile process for obtaining, with almost no by-products, polyamides and copolyamides characterized by distinctive properties. Moreover, the possibility of performing polymerization by the activated anionic mechanism by using activators in combination with initiators, soon after Joyce and Ritter's discovery, allowed to pursue very fast reaction kinetics at lower temperatures and reach very high monomer conversions, as well as higher molar masses and higher crystallinity of the resultant PA6.

In more recent years, anionic ROP of CL has also enabled to perform polymerizations directly in the mold and has been found uniquely suited to form thermoplastic composites, such as fiber-reinforced products, by *in situ* reaction injection molding (RIM) and pultrusion processes. The low viscosity and the low melting temperature of the monomer (~70 °C) let to run the reaction at low polymerization temperatures (below T_m of PA6), allowing for a superior fiber wetting and impregnation of reinforced PA6. Additionally, recent studies support the idea that anionic polymerization of some lactams can be efficiently carried out not only in the bulk but also in dispersion, emulsion, and suspension, allowing for a convenient production of polyamides as fine powders and opening new fields of application (e.g., powder coating and cosmetics). In general, for its

versatility, the anionic mechanism of lactam polymerization looks very appealing and still continues to attract the interest of many research groups from both academia and industry.

In the last decades, excellent general reviews have been published on the ROP of lactams,[7–10] with specific attention to their anionic polymerization. Besides, it is worth mentioning here some surveys on PCL by Reimschuessel,[11,12] including outlines of industrial processes and description of all kinds of polymerization mechanisms (i.e., hydrolytic, cationic, and anionic).

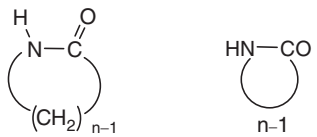
4.14.2 Lactams and Their Polymerizability

4.14.2.1 Lactam Family

4.14.2.1.1 Overview

Lactams (contraction of lactone + amide) are the cyclic amides of aliphatic amino acids and form an extensive homologous series of monomers, showing a large variety of unsubstituted examples whose size so far ranges from 4 to 21 ring atoms. They consist of a polar amide group and a nonpolar hydrocarbon moiety formed by a sequence of $-(CH_2)-$ groups.

The various members may be characterized by either the number of ring carbon atoms, n, or the ring size, $n+1$, and are usually symbolized as Ln:



Ln

In this respect, nonuniform notation rules still exist and some authors identify n with the total number of ring atoms. Therefore, it must always be clarified which type of notation is used. Greek prefixes are often used in trivial names and define how many carbon atoms apart from the carbonyl moiety are present in the ring. Thus, excluding the carbonyl, in β-lactam, there are two other carbon atoms (four ring atoms in total); in γ-lactam, three carbon atoms; in δ-lactam, four carbon atoms; in ε-lactam, five carbon atoms, and so on up to L9 (θ-pelargonolactam). Then after, a generic denomination of ω-lactam is adopted. Hence, ω-laurolactam may be referred to, instead of L12, C_{12}-lactam or 13-membered lactam. The synthesis, structure, and properties of lactams have been extensively studied and reviewed.[8,13,14]

The lactam family may be very widely extended if members carrying substituents on C and/or N atom are considered. Moreover, a large variety of other types of lactam analogues exist: heteroatom-containing lactams (e.g., oxalactams), dilactams (containing two amide groups per ring), bicyclic lactams (bislactams, containing two lactam rings bound together by simple linkage or bivalent groups, and bridgehead bicyclic lactams), thiolactams, bicyclic oxalactams, etc. Apart from their industrial utilization for the production of a few aliphatic polyamides (PA6 from L6, PA12 from L12, PA4 from L4, in decreasing order of relevance), some lactams find very significant applications in medicine, in particular for antibiotics preparation (β-lactam antibiotic chemistry).[15] Indeed, the β-lactam ring is a part of the structure of several antibiotic families, mainly the penicillins, cephalosporins, carbapenems, and monobactams. Substituted β-lactams have recently arisen a lot of interest centered on the synthesis of β-polypeptides (PA3 family),[16] which exhibit an important biological activity.

4.14.2.1.2 Nomenclature

Several systems of chemical nomenclature are adopted to designate lactams. The most common systems are reported in **Table 1**, referred to the family of unsubstituted lactams from 3 to 15 ring atoms. Accordingly, the five-membered lactam may be identified by its trivial names as γ-butyrolactam or

Table 1 Nomenclature of the principal unsubstituted lactams

			IUPAC organic nomenclature	
Symbol	*Ring size*	*Trivial name*	*Official*	*Heterocyclics*[a]
L2	3	α-Acetolactam	Ethane-2-lactam	Aziridin-2-one
L3	4	β-Propiolactam	Propane-3-lactam	Azetidin-2-one
L4	5	γ-Butyrolactam α-Pyrrolidone	Butane-4-lactam	2-Pyrrolidinone 2-Pyrrolidone
L5	6	δ-Valerolactam α-Piperidone	Pentane-5-lactam	2-Piperidinone 2-Piperidone
L6	7	CL	Hexane-6-lactam	azepan-2-one
L7	8	ζ-Enantholactam	Heptane-7-lactam	azocan-2-one
L8	9	η-Capryl lactam η-Caprylolactam	Octane-8-lactam	azonan-2-one
L9	10	θ-Pelargonolactam	Nonane-9-lactam	
L10	11	ω-Caprinolactam	Decane-10-lactam	
L11	12	ω-Aminoundecanoic acid lactam	Undecane-11-lactam	
L12	13	ω-Lauryl lactam ω-Laurolactam	Dodecane-12-lactam	
L13	14	ω-Aminotridecanoic acid lactam	Tridecane-13-lactam	
L14	15	ω-Aminotetradecanoic acid lactam	Tetradecane-14-lactam	

[a] Nomenclature adopted by *Chemical Abstracts*.

α-pyrrolidone, by the IUPAC nomenclature as butano-4-lactam, or by the IUPAC heterocyclic nomenclature as 2-pyrrolidone or pyrrolidon-2-one. The seven-membered lactam may be named as CL, hexano-6-lactam or hexahydro-2*H*-azepin-2-one, etc.

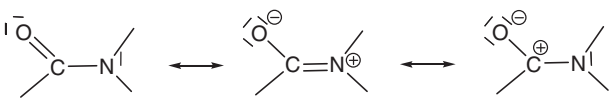
In the present chapter, the trivial nomenclature will be generally preferred, with the exemption of the smaller rings up to L5, which will be identified by the IUPAC heterocyclic system. It is convenient to divide lactams into three groups entailing similar properties. Thus, aziridin-2-one, azetidin-2-one, 2-pyrrolidone, and 2-piperidone are grouped as 'lower lactams', CL, ζ-enantholactam, and η-caprylolactam are classified as 'medium-sized lactams', and all the other higher sized lactams are considered as 'higher lactams'.

All 'lower lactams' have strained rings but with some differences among them: aziridin-2-one and azetidin-2-one are highly strained, while 2-pyrrolidone and 2-piperidone have weakly strained rings. The stability of the highly strained lactams may be increased by substitution; in fact, aziridin-2-one is known only in the substituted form.

4.14.2.1.3 Structure and properties

A distinctive aspect characterizing lactams is the high mobility of the electronic structure of their amide group, resulting from several factors: π-electron delocalization, rearrangement of electron lone pairs on both heteroatoms, inductive effects, changes in atomic hybridization, dipole–dipole interactions, and hydrogen bond formation.

The amide group is traditionally described in terms of resonance between Lewis structures:



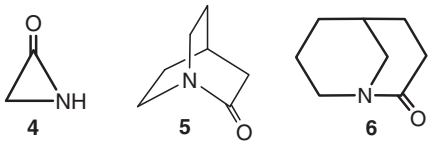
1 2 3

[1]

In general, only the first two structures (**1** and **2**) have been taken into consideration.[17] However, by calculations of C, N, O electron densities of planar and twisted amides, it has been shown[18,19] that while distortion of the amide linkage introduces large variations in the C–N bond length, the bond length of the carbonyl group is hardly changed. Thus, the third resonance structure (**3**) has been introduced in order to rationalize these results, with the two ionic structures becoming the predominant ones in representing the amide group. Furthermore, the methylene groups (as well as methyl groups) linked to nitrogen and carbonyl can enhance the resonance stabilization by hyperconjugation with C=O and C=N bonds. The hyperconjugation effects have also been invoked to justify the higher stability of *N*-alkyl-substituted lactams, for example, *N*-methyl-CL,[20] as compared to their unsubstituted counterparts.

The polarity of the amide bond and also the interaction of the $2p_z$ electrons of N with the π-electrons of the carbonyl group are functions of the ring size and are manifested by different ionization potentials obtained by photoelectron (PE) spectroscopy.[21,22] The map of the spatial electron distribution of *N*-methylacetamide, obtained by CNDO/2 (COMPLETE NEGLECT OF DIFFERENTIAL OVERLAP – SECOND VERSION) and *ab initio* molecular orbital calculations,[23] has already evidenced that the lone pair on the oxygen atom in the amide group is predominant, with the lone pair on nitrogen being involved in the delocalized π system, thus a nonbonding orbital. This result has also given a quite a good explanation for the higher basicity of oxygen, as compared with nitrogen.

However, contrary to unstrained lactams and amides, it has been demonstrated by *ab initio* molecular orbital calculations optimized at the 6-31G* level that the protonation site is a function of the distortion of the amide linkage.[24] Indeed, in aziridin-2-one (**4**) and in bridgehead bicyclic lactams, for example, 1-azabicyclo[2.2.2]octan-2-one (2-quinuclidone) (**5**) and 1-azabicyclo[3.3.1]nonan-2-one (**6**), N-protonation is favored over O-protonation. In particular, in **5**, N-protonation is favored by 100 kJ mol^{-1}:



4 5 6

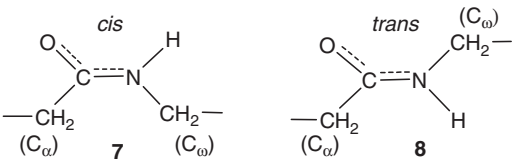
Of interest is the prediction that N-protonated aziridin-2-one spontaneously undergoes ring opening giving a linear aminoacylium ion. Conversely, for azetidin-2-one, the O-protonated form is more stable than the N-protonated one even if the energy gap is reduced.

In the conventional less strained lactams, protonation of the oxygen atom or its coordination to Lewis acids raises the electrophilicity of both the carbonyl and the carbon atom linked to nitrogen ($C_ω$), and increases the nucleophilicity of the carbon linked to the carbonyl ($C_α$); accordingly, the nucleophilicity of nitrogen is decreased. The O-protonated amide group is characterized by a lower energy compared to the N-protonated one; consequently, O-protonation is preferred as the initiation step in the cationic polymerization (see Section 4.14.5).

The sp^2 hybridization of nitrogen and carbonyl carbon and the partial double bond character of the C–N bond, derived from the delocalization of the nitrogen lone pair electrons (p_z-electrons) into the π system of C=O, require a coplanar displacement for all atoms connected to C and N of the amide group (six atoms, in total). Twisting or other distortion of the amide group inhibits this delocalization and thus modifies the electronic structure and the chemical properties of the group, such as, for example, the spectroscopic properties.[25]

Out-of-plane deformations of the amide group from the stable planar form involve the pyramidalization of the amine group and/or twisting around the CO–N bond, which may be accompanied by pyramidalization of the carbonyl carbon atom. The structure and properties of nonplanar amides and lactams have been recently reviewed.[26]

The overlap of the p-π electrons in the O–C–N system brings about the high rotational barrier around the C–N bond, resulting in the two possible configurational isomers: *cis* (**7**) and *trans* (**8**):



7 8

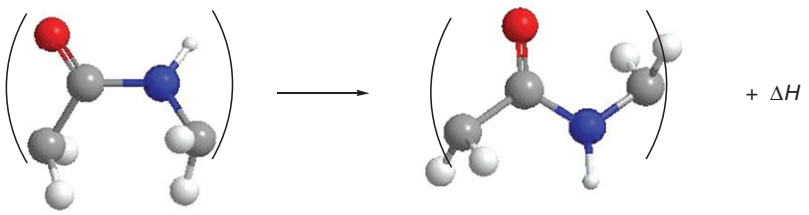


Figure 1 Conversion from the less stable *cis*-amide to *trans*-amide, with liberation of enthalpic energy (approx. 6 kJ mol^{-1}).

Cis-amide group is ~6 kJ mol^{-1} less stable than *trans*-amide group,[7] that is, the *trans* configuration results to be thermodynamically preferred. As a matter of fact, the configuration adopted by the amide group in lactams strictly depends on their size,[27–29] since the physical capability of ring closure and the imposed ring strain must also be taken into account and balanced with previous considerations. In linear polyamides, the amide group can adopt the more stable *trans* form; thus, the ROP of the lactams having *cis*-amide group implies the conversion from a *cis* to a *trans* displacement (**Figure 1**).

In small lactam rings, the amide group is constrained to adopt exclusively the *cis* form. Indeed, in lower lactams and up to the eight-membered ζ-enantholactam, only the *cis* isomer is present. The amide group can adopt the more stable *trans* form only when the ring is large enough to accommodate a torsion angle of approximately 180° around one of its bonds. The crossover point occurs at the nine-membered ring, ζ-caprylolactam, which exhibits a *transoid*-amide form in the crystalline state and an equilibrium mixture of *cis* and *transoid* form in solution, in approx. 4:1 ratio, with the *cis* isomer form having the lowest energy (~4 kJ mol^{-1}).[27,30] The *transoid* form is a distorted structure midway between *cis* and *trans*, derived from the impossibility for this ring size to adopt a strainless planar *trans* configuration.

Discrepancies between the configurations found in the crystalline state and in solution are attributed to the possibility of the molecule to be, in the crystal, more energetically stabilized by hydrogen bonding. Indeed, while the *cis* form of η-caprylolactam is favored in dilute solution, the *trans* form originates a more stable crystal structure where hydrogen bonds link molecules to each other building infinite chains.

In the 'higher lactams', the constraint of the hydrocarbon moiety becomes less and less significant. Thus, the thermodynamically more stable (by ~10 kJ mol^{-1}) *trans* configuration is preferred. The lactam population having the *cis* form decreases with the increasing ring size, not considering the effect of N-substitution, which may alter the configuration.

For example, the 10-membered θ-pelargonolactam in solution at 25 °C consists mainly of the *trans* isomer with only 5–10% of the *cis* isomer,[31] while in crystals, it exists as a mixture of *cis* and *trans* isomers.[27] Conversely, in solutions of the 11-membered lactam, only the *trans* isomer is present.[32] Interestingly, in protonated lactams, the amide configuration is sometimes different from that of the neutral lactams, as shown by the analysis of the hydrochlorides.[27] Drastic is the effect of protonation on η-caprylolactam, which changes its configuration from the nonplanar *transoid* form to a nearly planar *cisoid* form.

The amount of energy relative to the difference between *cis*- and *trans*-amide, released in the conversion from the *cis*-lactams to the *trans*-amide of the polymer chain, significantly contributes to the Gibbs energy of polymerization. In fact, the main driving force in the polymerization of the unstrained 2-piperidone is given by the enthalpic factor related to the above transformation and its polymerization enthalpy has been estimated[33] to be –7.1 kJ mol^{-1}, not very far from the value of approx. –6 kJ mol^{-1}, attributed to *cis–trans* isomerization. The maximum strain energy should be released in the polymerization of bicyclic and tricyclic lactams with the nitrogen at the bridgehead (tertiary amides), in which the amide group is inevitably distorted and less stabilized.

It is noteworthy that in *N*-alkyl-substituted lactams, the resonance stabilization of the amide group is the same as in the open polymer chain, irrespective of the ring size. As a consequence, the polymerization enthalpies of the N-substituted lactams up to ζ-enantholactam are ~6 kJ mol^{-1} lower than those of unsubstituted ones.[7] For instance, the ΔH_p values of CL and *N*-methyl-CL are –15.9 and –9.6 kJ mol^{-1}, respectively (a difference of 6.3 kJ mol^{-1}), and those of ζ-enantholactam and *N*-methyl-ζ-enantholactam are –22.6 and –16.3 kJ mol^{-1} (again a difference of 6.3 kJ mol^{-1}).[8] On the contrary, for higher lactams displaying *trans*-amide groups, similar polymerization enthalpies for unsubstituted and N-substituted lactams are observed.

The overall lactam ring conformation varies greatly as a function of the length of the hydrocarbon sequence, as well.[21,28,29] In the strained lactams, that is, aziridin-2-one and azetidin-2-one, the ring is planar[34] with distortion of the amide group. The aziridin-2-one ring is highly strained (the calculated ring strain being 171 kJ mol^{-1}) and has been predicted, by 6-31G* *ab initio* molecular orbital calculations, to have a pyramidal nitrogen and only 53.2 kJ mol^{-1} of 'operational' resonance.[24] The azetidin-2-one ring (**Figure 2**) is less strained (~109–121 kJ mol^{-1})[35] and has been estimated to have an

'operational' and 'pure' resonance energies of 80.4 and 104.3 kJ mol^{-1}, respectively. For comparison, the 'operational' and the 'pure' resonance energies of acetamide have been reported[24] to be 85.8 and 111 kJ mol^{-1}, respectively.

Since the highest resonance stabilization may be achieved only when the amide group is planar, any departure from planarity results in a higher polymerizability. On the other hand, the preference for coplanarity may render the lactams less stable, introducing some strain into their rings. Contrary to three-and four-membered lactams, the five-membered 2-pyrrolidone is only slightly strained and shows a nearly planar conformation (Figure 3).[36] The impossibility to adopt a fully planar conformation, as it would impose more strain, results in a lower resonance stabilization.

The *cis*-amide group of the six-membered 2-piperidone can easily attain a planar conformation. This lactam displays a nearly strainless ring and for the most part assumes a distorted chair conformation, due to the tendency of the amide group to planarity, and for a minor part an extended chair (envelope) conformation (Figure 4).[14,21]

The most commonly used lactam, CL, exists in only a single conformation (an extended chair type), in both solution[37] and crystals[38] (Figure 5), while the eight-membered ζ-enantholactam (Figure 6), as already mentioned the highest lactam constrained in the *cis* form only, may adopt two different conformations[39] (boat type and puckered ring in crystals).[14]

Going on in the homologous series, the number of existing conformations increases. For example, by X-ray analysis, the crystals of the nine-membered ζ-caprylolactam show two conformers with the *cis*-amide (puckered and boat type) and two conformers with a *transoid*-amide group[30] (Figure 7). In solution, a mixture of *cis* and *trans* isomers with two *trans* conformations has been observed by dynamic nuclear magnetic resonance (NMR) spectroscopy.[40] The 10-membered θ-pelargonolactam has been reported to exist, in the crystalline state, in six *trans* conformers,[41] and 11-membered and 14-membered lactams have been reported to exist, in solutions, in several *trans* conformers.[42] Potentially, the amide group displays three nucleophilic sites, O, N, and C in α position to carbonyl (C_α), and two electrophilic ones, C of carbonyl and C linked to nitrogen (C_ω), which all together give rise to a number of possible reaction routes. As a consequence, lactams are weak acids in terms of –NH and very weak acids relative to $-C_\alpha H$, with the acidity of $C_\alpha H$ being extremely low.[14]

The values of the amide –NH acidity (in terms of pK_a) for the most relevant lactams are given in Table 2, where a few

physical properties have also been collected. It can be observed that the highly strained rings show a higher acidity than do medium-sized and higher lactams (displaying similar pK_a data) and that the *cis* or *trans* configuration has no influence on this property.

Due to their –NH acidity, lactams can react with strong bases, giving the corresponding lactam salts that may be more or less dissociated, for example, in alkali metal cations and lactam anions, the latter being the active species initiating the anionic lactam polymerization (see Section 4.14.7). Lactams are weak bases, protonated by strong protic acids, and their basicity can be estimated from the values of the conjugate acid using different methodologies, which can originate contradictory data, as often obtained.[43,44] With the exemption of aziridin-2-ones and some other highly strained lactams, as previously mentioned, protonation occurs essentially at the oxygen atom since N-protonation would destroy the resonance stabilization.[45] Not considering the basicity value calculated for azetidin-2-one, 2-pyrrolidone has been shown to be the least basic and 2-piperidone the most basic of the series (**Table 2**). The values for larger lactams are close to those for linear amides (the pK_a of *N*-ethylacetamide is reported to be –0.49).[43]

Lactams, as weak bases, may act as hydrogen-bonding acceptors with weak protic acids and as Lewis acid acceptors with strong dissociated acids, forming various types of molecular complexes.[8,14] The amide group itself may function as both proton donor and proton acceptor (with the oxygen of the carbonyl); hence, in the absence of stronger electron donors or hydrogen acceptors, lactams form hydrogen-bonded structures by self-association. Lactams with *cis* configuration mainly form cyclic dimeric associates, while *trans*-lactams can form only linear chain structures (**Scheme 1**).

The energy of formation of intermolecular H bonds for the *cis*-lactams is higher than those for *trans*-lactams, the average values being ~30.7 and 16.7 kJ mol^{-1}, respectively (**Table 2**). In addition to self-association, lactams may form molecular complexes with various hydrogen donor molecules (e.g., water, alcohols, amines, phenols, carboxylic acids, inorganic acids, hydrogen halides, and halogenated hydrocarbons). By using the oxygen atom as donor, lactams may form complexes with polar molecules (e.g., I_2, Br_2, ICl, and SO_2) and coordination compounds with inorganic salts where lactams form the ligand field surrounding the metal cation, with the latter behaving as the acceptor. In this respect, the number of lactam complexes that have been synthesized and fully characterized is remarkably large, since the cation of almost any element can be coordinated to the lactam carbonyl giving rise to very ample possibilities.[14] Relevant effects of complexes between CL and LiCl[46] and CL and $CaCl_2$[47] in both the anionic polymerization of the above lactam and the properties of the resultant PA6 have been found by Russo *et al*. and will be summarized later on (Section 4.14.10).

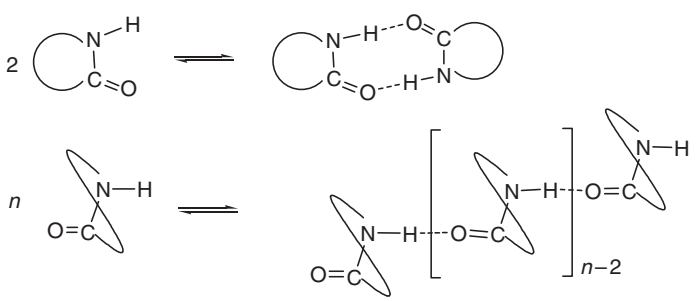
Compared to other homologous series of monomers, lactams possess high values of dielectric permittivity (ε_r), largely varying as a function of ring size (**Table 2**). It is useful to mention here that in lactams containing a *cis*-amide group, a great change of permittivity occurs during polymerization as a consequence of the transformation from *cis* to *trans* configuration; this change may imply differences in polymerization kinetics and can be employed in monitoring the course of the polymerization.[48]

In the lactam series, melting temperatures vary as a function of ring size in a nonuniform manner, as evident from T_m data of **Table 2**. These latter data show the lowest value for 2-piperidone (25.9 °C) reaching a maximum for L10, ω-caprinolactam (162 °C), and then decreasing down to 83 °C for L20. The rather low melting points of the main lactam rings enable to perform bulk polymerization, for example, by the anionic route, at temperatures well below the melting point of the resultant polyamide.

4.14.2.2 Polymerizability

Polymerizability, which should properly be considered a thermodynamic parameter related to Gibbs energy change, is sometimes associated with the polymerization rate, or with the ability to polymerize in milder conditions, or with the capacity to give high polymer yields. Such ambiguity arises from the actual fact that the change in Gibbs energy cannot be the only criterion to describe the aptitude of cyclic monomers, namely lactams, to polymerize.

As a matter of fact, the change of Gibbs energy is only connected to the difference of thermodynamic stability between the monomer ring and the linear chain, regardless of the various ring-opening mechanisms; a negative value of ΔG_p points to whether lactam polymerization is possible and not that it really occurs, since other types of hindrances may take place, such as the absence of a suitable reaction pathway or the existence of more favorable competitive reactions. Therefore, it is obviously affirmed that the thermodynamic polymerizability is a necessary but not sufficient prerequisite and cannot be separated from the kinetic feasibility. On the basis of these two complementary aspects, it must be remarked that the



Scheme 1 Hydrogen-bonded structures of *cis*- and *trans*-lactams by self-association.

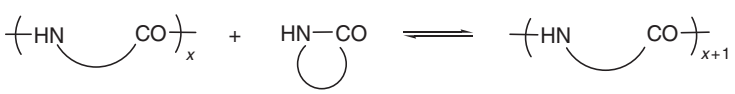
kinetic polymerizability of lactams states the ease or the difficulty to transform a cyclic monomer into a linear chain unit in specific polymerization conditions, defining the chemical reactivity of the monomer in a selected elementary reaction. Unfortunately, the ring-opening mechanisms are more than one; thus, more than one polymerization rates exist for each specific lactam. The actual capability to polymerize is primarily a function of the type of initiation (e.g., hydrolytic, anionic, or cationic) and involves many parameters. The slower cationic and hydrolytic polymerizations give rise to a wider range of reactivities than does the fast anionic polymerization. The initiation type may have some relevance to the conformation of lactam ring, the main factor related to its reactivity; for example, the conformation of the lactam anion in anionic polymerization may differ from that of the protonated lactam in cationic polymerization, resulting in a different reactivity order. Moreover, when considering, for instance, the activated anionic polymerization (Section 4.14.7.4), in addition to ring strain and substitution as well as acidity and permittivity of monomer and its polymer, the nucleophilicity of the lactam anion and the electrophilicity of the *N*-acyl lactam (activator) must also be included. The correlation of all these parameters is extremely difficult and only partial data may be obtained under specific conditions.

Additionally, even when both the thermodynamic and the chemical feasibilities are assured, the conversion to polymer may not occur because of other competitive reactions that are more favored thermodynamically or kinetically (e.g., N-substituted aziridin-2-ones decompose before polymerizing).

The chemical, thermodynamic, and kinetic aspects of lactam polymerizability have been the subjects of many papers mainly published in the 1960s and 1970s.[9,33,49–54] Remarkably elegant has been the study of Korshak *et al.*,[33] who intended to examine the general capability of lactams to polymerize as a function of their structure, by both a thermodynamic and a kinetic approach. However, being fully aware of the many reasons previously mentioned, it can now be concluded that it is impossible to define a generally applicable classification of the chemical reactivity of lactams toward ROP; as a matter of fact, no more attempts on this issue have been made in recent years. For all these reasons, just a few indications on the thermodynamic feasibility connected to the ring structure and only some general kinetic considerations will be hereafter reported.

4.14.2.2.1 Thermodynamic feasibility

The main relationship in lactam polymerization is the equilibrium established between the monomer and the open-chain amide groups [2]:



[2]

The displacement of this equilibrium strongly depends on not only ring size and substituents but also the type of initiation and the reaction conditions. In other words, residual monomer concentration, often interpreted as equilibrium monomer concentration [M_e], is always present in ROP. This concentration may be an extremely small value in nonequilibrated polymers, obtained by very fast, kinetically controlled polymerization processes (e.g., in the activated anionic polymerization of CL, Section 4.14.10).

Assuming that all open-chain *trans*-amide groups are of the same reactivity, thermodynamic parameters have to be considered independent of the reaction mechanism and the polymerizability may be described considering the equilibrium between monomer opening into a linear chain and its reforming.

The molar Gibbs energy change accompanying the incorporation of a mole of lactam monomer in the polymer may be expressed as[55]

$$\Delta G_p = \Delta G_p^0 - RT \ln[M] = \Delta H_p^0 - T\Delta S_p^0 - RT \ln[M] \qquad [3]$$

Thus, ΔG_p and ΔH_p can be calculated starting from the [M] values. At equilibrium ($\Delta G_p = 0$, i.e., when polymerization is completed), the monomer concentration is given by

$$[M]_e = \exp\left(\frac{\Delta H_p^0}{RT} - \frac{\Delta S_p^0}{R}\right) \qquad [4]$$

At standard conditions, lactams for which $\Delta H_p^0 > 0$ and $\Delta S_p^0 < 0$ cannot be converted into linear macromolecules. In the case that both enthalpy and entropy terms are negative, namely for the five- and six-membered lactams, formation of high polymer cannot occur at or above a limiting polymerization temperature (ceiling temperature, T_c) [5]:

$$T_c = \frac{\Delta H_p^0}{\Delta S_p^0 + R \ln[M]_0} \qquad [5]$$

where $[M]_e = [M]_0$, initial monomer concentration.

Significantly low is the so-called ceiling temperature of the six-membered 2-piperidone ($T_c = 60\,^\circ C$). Equilibrium monomer concentration can be obtained by analyzing the equilibrated polymer, but reliable $[M]_e$ data are effectively accessible only in a few cases. For instance, the polymerization of 2-pyrrolidone cannot be regarded as an equilibrium reaction due to the irreversible crystallization during polymerization; thus, only a so-called limiting polymerization temperature has been kinetically extrapolated by experimental data. By this way, the actual temperature limit has been found to depend upon the type of initiation, being ~66 °C for its nonactivated anionic polymerization and ~76 °C for the activated anionic polymerization.[56]

In **Table 3**, some examples of equilibrium monomer concentrations at the polymerization temperatures are reported for unsubstituted and substituted CL and substituted ζ-enantholactam.[57] It is notable that the presence of substituents generally shifts the polymer–monomer equilibrium to higher M_e values.

Table 3 Equilibrium monomer content (bulk polymerization)

Lactam	$[M]_e$[a,b] (mol kg^{-1})
CL	0.72

[b] Data from Korshak, V. V.; Kotel'nikov, V. A.; Kurashev, V. V.; *et al. Russ. Chem. Rev. (Engl. Transl.).* **1976**, *45*, 853; *Usp. Khim.* **1976**, *45*, 1673.[33]

M_e values, calculated from eqn [4] at 25 °C for the most relevant lactams, are listed in Table 4. Considerably higher values are shown for 2-pyrrolidone and 2-piperidone (Table 4).

4.14.2.2.1(i) Enthalpy of polymerization

The ΔH_p of cyclic compounds is always associated with the strain of their rings; additionally, in the case of lactam monomers, other factors must be taken into account. The sources of ring strain in lactams are as follows:

- angular strain (bond angle distortion), accompanied by bond stretching or compression;
- repulsion between eclipsed hydrogen atoms or substituents on neighboring atoms (conformational strain, bond torsion, and bond opposition) and interaction of atoms/substituents in different parts of the cycle (transannular strain);
- amide deformation;
- different resonance stabilization of monomer and polymer due to uneven conjugation or hyperconjugation;
- difference between the energies of hydrogen bonds or dipole–dipole interactions in the monomer and the polymer.

These additional factors may account, at least in part, for the lower (i.e., less negative) enthalpies of polymerization of the lactam rings compared to those of the corresponding cycloalkanes (e.g., −4.6 kJ mol^{-1} for 2-pyrrolidone and −21.2 kJ mol^{-1} for cyclopentane).[33]

Assuming that the enthalpy change is almost equivalent to the internal energy of lactam monomer and due to the fact that in polymerizations at normal pressure, the $P\Delta V$ term in $\Delta H = \Delta U - P\Delta V$ is negligible, it is reasonable to consider the heat of polymerization as a measure of the strain energy of the ring. However, it is worth underlining that in some cases, ΔH_p does not reflect the actual ring strain, since polymerization does not necessarily release all the strain of the cyclic monomer (e.g., in highly substituted lactams).

Lactam polymerizations usually imply a volume contraction and, at very high pressures, the effect of the $P\Delta V$ term on equilibrium cannot be neglected. Lactams that have a low T_c or are prevented from polymerizing at normal pressure for thermodynamic reasons can polymerize at high pressures. T_c increases with pressure in accordance with the Clausius–Clapeyron equation.[58]

Since the ΔH_p may be obtained in different ways (e.g., measured by calorimetric techniques, estimated by comparing the experimental combustion heats of lactams and of the corresponding polymers in the amorphous state, or calculated from the enthalpies of cyclization), discordant data are found in literature. For instance, values reported for the enthalpy of CL polymerization range from −13.8[33,59] to −15.4 kJ mol^{-1}.[7,60]

The polymerization heats of the most representative lactams have been collected in Table 5. The data vary with ring size from practically 0 up to the most negative value attributed to substituted azetidin-2-ones, for example, −81.9 kJ mol^{-1} for 3,3-methyl-butyl-azetidin-2-one.[61] Indeed, aziridin-2-ones cannot polymerize and the ΔH_p data for unsubstituted azetidin-2-one are not available.

With increasing ring size, the heat of polymerization (absolute values) goes through a minimum for the five-membered lactam, reaches a maximum for the nine-membered lactam, and again approaches zero for larger lactams (12- and 13-membered lactams) (Figure 8).

The high ring strain is the cause of the high (i.e., more negative) enthalpies of substituted azetidin-2-ones. Conversely, its absence is the origin of the low values encountered for 2-piperidone and 2-pyrrolidone and large lactams. In the nine-membered η-caprylolactam, the *transoid*-amide reduces the resonance stabilization and a higher enthalpy is found.

4.14.2.2.1(ii) Entropy of polymerization

The entropy of polymerization depends on the difference between the probability of monomer existence in the cyclic form and that in the form of repetition unit of the linear polymer. As in all cyclic monomer polymerizations, the decrease in translational entropy is in part counterbalanced by the increase in rotational and vibrational entropy acquired in the conversion of a strained ring into a more or less flexible monomer unit inside the polymer chain. For this reason, the absolute value of the entropy of polymerization for the seven-membered CL is rather low.[7,53]

Beyond the four- and five-membered lactams, the highest rigidity is expected for medium-sized rings (8–11 ring atoms). In these latter cases, the enhanced flexibility of the open-chain monomer unit inside the polymer results in a large increase in the rotational and vibrational entropy.

Table 5 Thermodynamic data of unsubstituted lactams

Monomer	Ring size	ΔH_p° (kJ mol^{-1})	ΔS_p° (J °K^{-1} mol^{-1})	ΔG_p° (kJ mol^{-1})	References

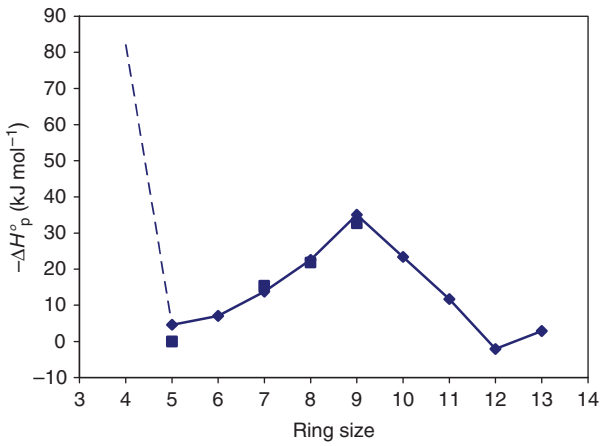

Figure 8 Heat of polymerization of unsubstituted lactams as a function of their size (from data in **Table 5**).

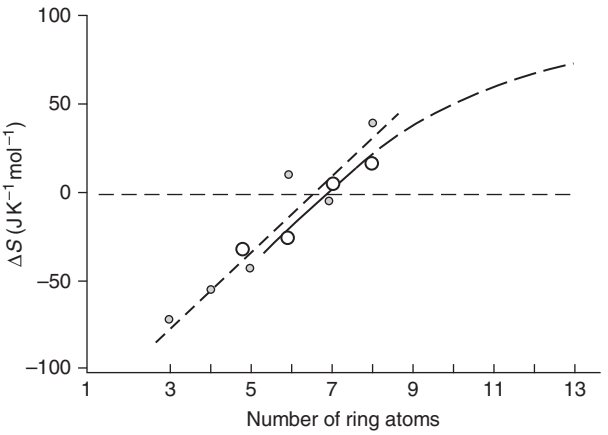

Figure 9 Entropy of polymerization as a function of ring size for unsubstituted lactams (○) and cycloalkanes (●). Reproduced from Sekiguchi, H. In *Ring-Opening Polymerizations*; Ivin, K. J.; Saegusa, T., Eds.; Elsevier: London, UK, 1984; Vol. 2, Chapter 12, p 809.[8]

Indeed, the entropy of polymerization increases roughly linearly from the five-membered to the eight-membered lactam together with the decreased rigidity of the monomer (**Table 5**). It must again be emphasized here that many methods exist for determining the polymerization entropy[33] and they provide discordant values to be found in the literature. Calculated ΔS_p° from the absolute entropy values of monomer and polymer derived from specific heat measurements at low temperature have shown[63] negative entropies only for 2-pyrrolidone and 2-piperidone and a linear increase passing from the five-membered to the eight-membered lactam.[7,53] Notably, these values are of the same order as those of cycloalkanes (**Figure 9**).

However, it is worth noting that incongruent data have been often reported for the entropy of polymerization: for example, the calculated ΔS_p° for CL was found to be 4.6 J K^{-1} mol^{-1}, but a value estimated[64] from the monomer–polymer equilibrium has been found to be equal to –13.3 J K^{-1} mol^{-1} (**Table 5**).

An attempt to obtain the entropy of polymerization for 9–13-membered lactams has been accomplished by operating a linear extrapolation of the values for 5–8-membered lactams,[62] which stay on a straight line, but the results are overestimated and, thus, not very reliable. These data revealed a very sharp increase of ΔS with ring size and are significantly higher compared to those obtained by using equilibrium monomer concentration. For example, for ω-laurolactam, a value of 13.4 J K^{-1} mol^{-1} has been found from the monomer–polymer equilibrium, while a value of 125.5 J K^{-1} mol^{-1} has been derived by extrapolation.[53]

In any case, it can be asserted that the entropy change becomes progressively more important with the increasing

ring size. It is noteworthy to underline that ΔS_p may be more favorable in copolymer formation, that is, in the copolymerization of lactams. Indeed, a lactam may be copolymerized even at a temperature at which homopolymerization cannot proceed. This is the case of the copolymerization of 2-pyrrolidone and CL.[65]

4.14.2.2.1(iii) Gibbs energy

The ΔG_p values calculated from the enthalpy and entropy data in **Table 5** have been plotted to give the approximate trace of **Figure 10**. The Gibbs energy change varies from a small positive value (five-membered ring) and a value close to zero (six-membered ring) to negative values, reaching a minimum for the nine-membered lactam. For five- and six-membered lactams, both the enthalpic and entropic terms are negative; consequently, their polymerization is favorable from the enthalpic standpoint, but not on entropic grounds; the loss of translational degrees of freedom is not well balanced by the gain in rotational and vibrational motions in the polymer. For seven- and eight-membered lactams, the main contribution to ΔG_p comes from the enthalpy factor, while for 9-, 10-, and 11-membered lactams, the contributions of ΔH_p and ΔS_p are approximately the same. For 12- and 13-membered lactams, the enthalpy change is negligible and the entropic factor governs the Gibbs energy.

Taking into account thermodynamic factors only, one may conclude that lactams having ≥ 7 ring atoms are allowed to polymerize. The small positive values of ΔG_p for the polymerization of 2-pyrrolidone and 2-piperidone are surely due to the large errors in the determination of the thermodynamic characteristics, since these two lactams, although long believed to be unable to polymerize, can do it under anionic conditions[66–69] (Section 4.14.11). Taking into account only the Gibbs energies discussed above, it is possible to set up a theoretical series of thermodynamic feasibilities as a function of the ring size:

$$9 > 10 > 13 > 11 > 12 > 8 > 7 >> 6 \sim 5$$

4.14.2.2.2 Kinetic aspects

A few attempts have been made[8,9] to describe the kinetic polymerizability of lactams, but rather poor results have been obtained and contradictory conclusions on reactivities and, in particular, on substituent effects have been published.[49,50,70–73] Sekiguchi and Coutin[51] proposed a criterion for estimating the chemical polymerizability of lactams under anionic conditions, modifying an idea of Carothers,[74] who suggested that polymerizability and rate of hydrolysis for a cyclic monomer should run parallel (in this parallelism, the acid-catalyzed hydrolysis would simulate cationic ring opening and the base-catalyzed hydrolysis would simulate the anionic ring opening).[8] They hypothesized, for the activated anionic mechanism, that the kinetic polymerizability, identified with the propagation rate, might be described by a parameter π, which was assumed proportional to the rate constant of the base-catalyzed endocyclic hydrolysis of the *N*-acyl lactam and inversely proportional to the rate constant of lactam hydrolysis (this latter supposed to be inversely proportional to the basicity of lactam anion). However, scarce and doubtful results have been achieved on these grounds.

As previously mentioned, the complexity of the aspects influencing contemporarily and differently the course of lactam polymerization, in particular under anionic conditions, makes impossible to discriminate between the lactam structural properties (e.g., ring size and substitution) and all other factors. Thus, only limited comparisons under a restricted range of polymerization conditions can be accomplished.

The order of reactivities as a function of ring size, derived from the thermodynamic feasibility, is often modified for the same monomer in a quite different manner, depending on the type of initiation. The slower cationic (Section 4.14.5) and hydrolytic polymerizations (Section 4.14.4) give rise to a wider spread of reactivities than does anionic polymerization.

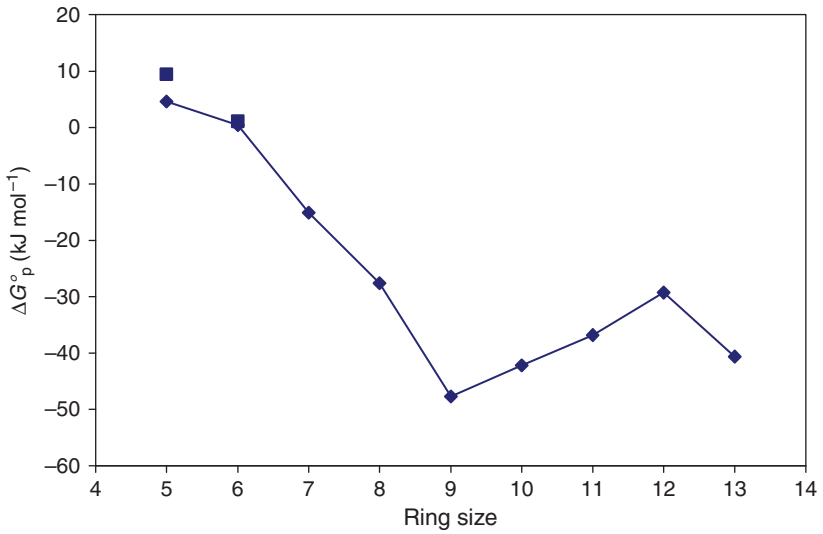

Figure 10 Free-energy change for the polymerization of unsubstituted lactams as a function of the ring size (data from **Table 5**).

Generally speaking, the chemical structure of a lactam monomer influences the kinetic possibilities of polymerization by several aspects, such as the following:

1. configuration of the molecule (e.g., presence of *cis*- or *trans* isomers);
2. resonance stabilization of amide group (presence of mesomeric, inductive, and hyperconjugation effects);
3. basicity and acidity;
4. permittivity and polarity (e.g., presence of hydrogen bonds and dipole–dipole interactions); and
5. substitution (position and nature of substituents).

Surely, five- and six-membered lactams are much more reactive in the anionically initiated mechanism (Section 4.14.7.1), where a nucleophilic attack on the lactam ring is implied, as compared to the polymerization in the presence of water or acids, involving an electrophilic attack and proceeding at a significantly lower rate.

In the anionic polymerization, the monomer structure may have indirect effects as well, influencing, for example, the dielectric properties of the reaction medium and, thus, the course of the polymerization. Since lactam monomers and the resultant polyamides have polar amide bonds, their bulk polymerization rate is strongly affected by the changes in medium permittivity during polymerization. In anionic polymerization, high dielectric permittivities strongly favor the dissociation of the lactam salt (initiator) releasing the free lactam anion (Section 4.14.7.1).

The permittivity of lactams with less than ten ring atoms is lower than that of the corresponding polyamides[48] owing to the different configuration of the amide group: *cis* form in lactams and *trans* form in the polyamide.[75] This effect, for example, is important in the case of CL where polymer permittivity is much higher than that of monomer; this have been invoked to explain the increasing polymerization rate, expressed by an auto acceleration in the propagation step of anionic polymerization in bulk. On the contrary, for the 13-membered laurolactam, the two dielectric permittivities are almost identical (**Figure 11**) and the autoacceleration effect is not shown.

The much higher permittivity of 2-pyrrolidone compared to 2-piperidone (**Table 2**), combined with the lower resonance stabilization of the amide group deriving from the not fully planar conformation, is the main factor contributing to its higher reactivity, although the six-membered lactam is, thermodynamically speaking, slightly more polymerizable.

In higher lactams (carrying a *trans*-amide group), the ring strain is considerably reduced and the reactivity of their amide group is similar to that of the polymer chain (e.g., the acidity of the higher lactams is equal to that of a linear amide group). As a consequence, the rate of the propagation reaction may be reduced. Hence, ω-laurolactam, thermodynamically expected to be more polymerizable than the medium-sized lactams (seven-, eight-, and nine-membered rings), is less reactive than CL.

Strained lactams (in particular, azetidin-2-one rings) are much more acidic than the corresponding linear amide; thus, in all reactions involving the lactam anions, the equilibrium is shifted to the side of these latter species.[9]

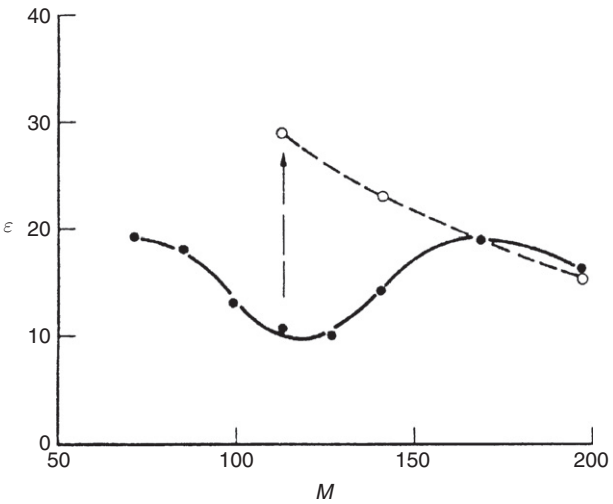

Figure 11 Dielectric permittivity (ε) of lactams (•) and the corresponding polyamides (°) as a function of the molar mass *M*. Reproduced from Šebenda, J. In *Comprehensive Polymer Science*; Eastmond, G.; Ledwith, A.; Russo, S.; Sigwalt, P., Eds.; Pergamon Press: Oxford, UK, 1989; Vol. 3, Chapter 35, p 511.[9]

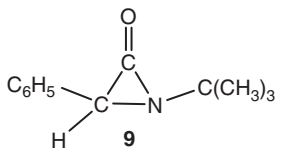
4.14.2.2.2(i) Substitution effects

Lactam polymerizability is significantly affected by the number, size, and location of substituents, acting in general differently on kinetic and thermodynamic factors. Substituted lactams generally show lower reactivity as compared to the corresponding unsubstituted ones, due to the steric hindrance at the reaction site. This fact has allowed the synthesis of highly strained aziridin-2-one rings, in contrast to the unsubstituted aziridin-2-one, which is too reactive to be isolated. Starting from the isolation of the first α-lactam, 1-*tert*-butyl-3-phenylaziridin-2-one (**9**)[76]



9

a number of aziridin-2-ones have been isolated. A structural requirement for the existence of an α-lactam is the presence of a bulky substituent (e.g., *tert*-butyl, trityl, and 1-adamantyl) on nitrogen and the ability to sterically shield the carbonyl group, to slow down the rate of nucleophilic reaction, and thus to stabilize the lactam from a kinetic point of view.

4.14.2.2.2(i)(a) C substitution Kinetically speaking, the presence of substituents on the methylene groups in the lactam ring may drastically decrease their reactivity since they can both modify the electron density of the amide group, that is, its nucleophilicity, and create steric hindrance. Substituents affect polymerizability in a complex manner since not only their position but also their size and polarity play an important role.[7] From a thermodynamic point of view, substituents affect both the enthalpy and the entropy of polymerization, essentially due to conformational effects. Although the enthalpy and the entropy of a lactam are little influenced by C substitution, the presence of substituents creates new interactions in the

linear monomer unit of the polymer, which may result in a higher enthalpy of the latter and a reduced $|\Delta H_p|$ value.[77] Also from an entropic standpoint, substituents significantly reduce the possibility of free rotation in the polymer chain. In this respect, substituents facilitate ring closure, shifting the monomer–polymer equilibrium toward the monomer side; these effects are relevant in the case of small rings, that is, for the five- and six-membered lactams.[8]

2-Pyrrolidone and 2-piperidone entirely lose their capability to polymerize even in the presence of only one alkyl substituent at the ring carbon atom. However, C substitution does not prevent them from copolymerizing.[8] Thus, C-methyl-substituted 2-pyrrolidones may be copolymerized to a certain extent with 2-pyrrolidone, being mainly incorporated as chain terminators.[78,79]

Since C-alkyl substitution enhances ring closure, the polymerizability of a given lactam is expected to decrease with the increase of substituent length. However, steric repulsions between large substituents and ring atoms (transannular interactions) may result in a relatively higher polymerizability. For example, on the basis of the equilibrium polymer content, the following order of polymerizability for ε-alkyl-substituted CL has been reported:[7]

unsubstituted ε-caprolactam > ε-methyl- ≅ ε-hexyl - > ε-ethyl- >> ε-dodecyl-ε-caprolactam

In the case of 3,3-dialkyl-substituted azetidin-2-ones (α,α-disubstituted β-lactams), other factors must be taken into account to explain, in some reaction conditions, the favorable effect of bulky substituents. Indeed, contrary to previously published data,[70] the propagation rate constant in the anionic polymerization of 3-alkyl-3-methyl-azetidin-2-one, conducted in dimethyl sulfoxide (DMSO) at 22 °C using potassium (or tetramethylammonium) 2-oxopyrrolidin-1-ide and *N*-acetyl-2-pyrrolidone, has been found to be approximately twofold enhanced by increasing the length of R from methyl to *n*-butyl[71,72] (following the order shown in Scheme 2 and being in any case much lower than that for the 4,4-dimethyl derivative).

This effect, not encountered in other lactams (e.g., CL and 2-pyrrolidone) or in lactones, has been attributed to the large hydrophobic R group that inhibits the contact, or intimate ion-pair formation, between the counter ion (K^+ or Me_4N^+) and the lactam N anion. Such phenomenon occurs in polar DMSO solvent, where the 3-butyl-3-methyl-substituted lactam may probably exist as an almost free ion having enhanced reactivity. Indeed, subsequent studies[73] conducted in tetrahydrofuran (THF) revealed, as expected, a decrease in the polymerization rate with the size of substituents.

From a kinetic standpoint, the rate-determining step in the ROP mechanisms is more sensitive to steric effects in the

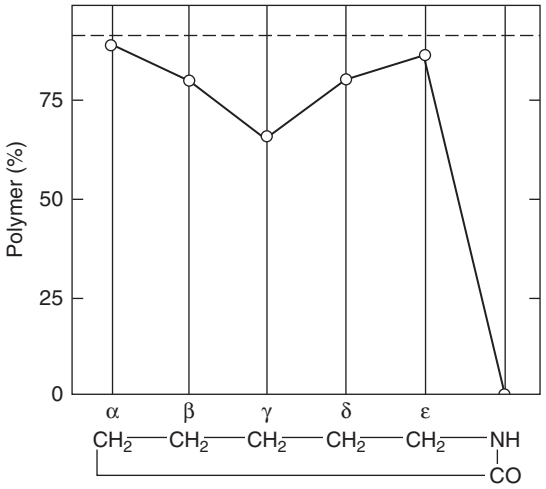


Figure 12 Equilibrium polymer content for methyl-CL isomers at 250 °C as a function of the position of the methyl substituent. The dashed line represents the unsubstituted lactam. Reproduced from Šebenda, J. In *Comprehensive Chemical Kinetics*; Bamford, C. H.; Tipper, C. F. H., Eds.; Elsevier: Amsterdam, The Netherlands, 1976; Vol. 15, Chapter 6, p 379.[7]

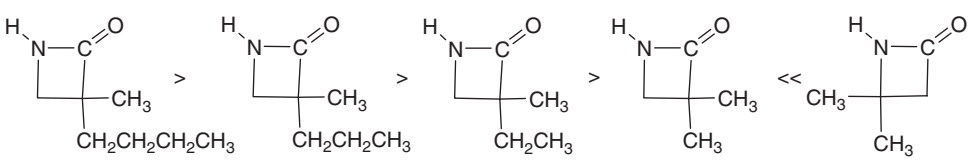
vicinity of the amide group (i.e., substituents at the C_α and C_ω atoms), while, thermodynamically speaking, the Gibbs energy of polymerization is more affected by the substitution on the mid-chain methylene groups, favoring ring closure. An example of this fact is given by the monomer–polymer equilibria of the methyl-substituted CL isomers,[7,53] as illustrated in Figure 12. The α-methyl- and the ε-methyl-ε-CL show a lower polymerization rate but a more negative Gibbs energy (i.e., a higher equilibrium polymer yield) as compared to γ-methyl-CL. Moreover, α,α-dimethyl- and ε,ε-dimethyl derivatives are also polymerizable. Namely, the γ-position (position 4) is very sensitive to the increase of the substituent size; thus, γ-*n*-propyl-, γ-phenyl-, γ-*n*-heptyl-CL show an extremely low reactivity or do not polymerize.[7]

The influence of substituents on the Gibbs energy of polymerization decreases with increasing ring size, becoming negligible for higher lactams. It is noteworthy that substitution of both hydrogen atoms in the vicinity of the carbonyl group prevents, in the anionic polymerization, the rise of secondary reactions that destroy active species. This fact is a prerequisite for maintaining a steady concentration of growth centers and obtaining a quasi-living polymerization (see Section 4.14.11.4).

4.14.2.2.2(i)(b) N-substitution The most important feature related to N-substitution is the impracticality of the anionic polymerization, because of the obvious impossibility of forming the lactam anion. Consequently, polyamides from



Scheme 2 Order of propagation rate constants for disubstituted b-lactams.

N-substituted 2-pyrrolidone and 2-piperidone cannot be obtained. N-substituted lactams are more or less easily polymerized through the cationic or acidolytic mechanism[80] (Sections 4.14.5 and 4.14.6).

N-substitution affects polymerizability of the *cis*-lactams much more than does C-substitution. The largely reduced reactivity given by substituents with +I effect on nitrogen has been attributed to the loss of resonance stabilization[50] and the *cis* character of the amide bond.[81]

As a consequence, the influence of N-substitution also decreases with increasing ring size. The more strained and reactive four-membered rings (N-substituted azetidin-2-ones) are still able to polymerize, while the five-, six-, and seven-membered lactams generally do not polymerize. Actually, the polymerization feasibility of *N*-methyl-CL, at very low temperature, has not been completely excluded, while it has been ruled out for *N*-methyl-2-piperidone.[80]

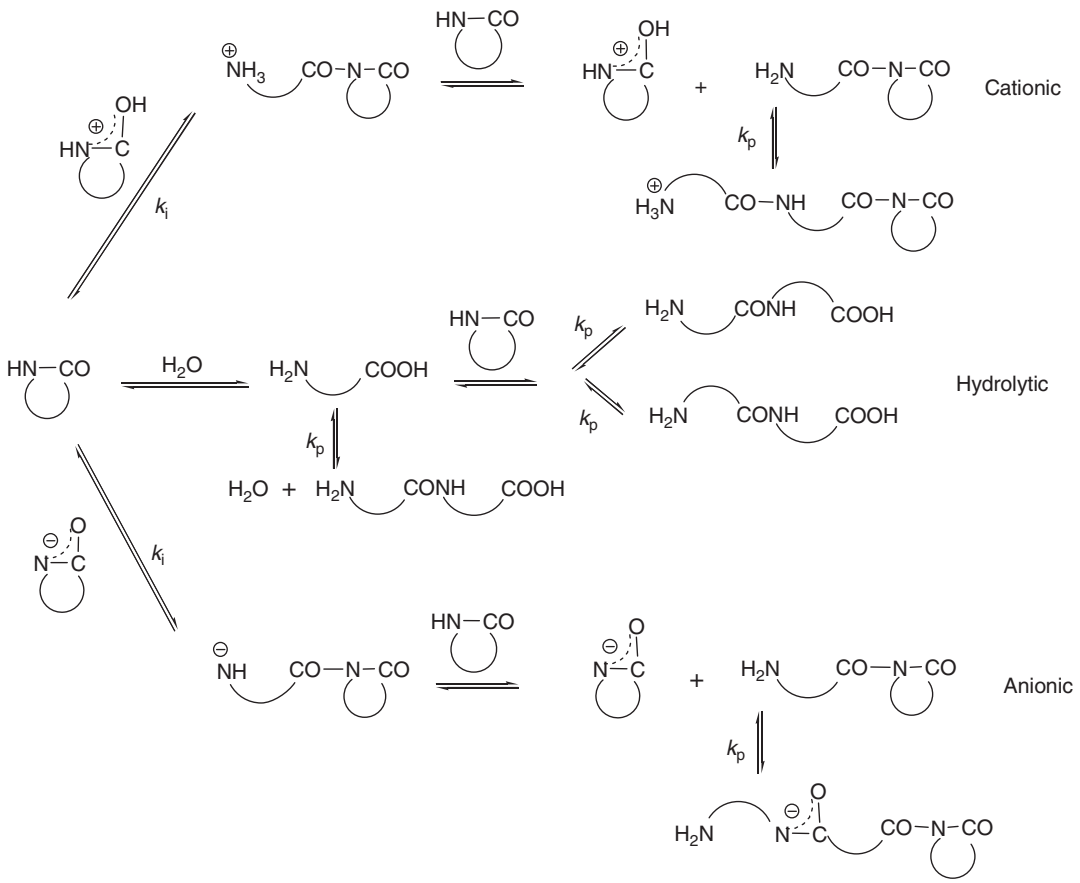
For larger lactams, N-substitution does not prevent polymerization; thus, the 8-membered up to 13-membered lactams are polymerizable by the acidolytic and/or hydrolytic route (e.g., *N*-methyl-η-caprylolactam and the *N*-alkyl-ω-laurolactams are hydrolytically polymerizable).[61]

4.14.3 Outline of Lactam Polymerization Routes

The ROP of lactams is based on reversible transamidation/transacylation reactions in which the ring amide groups are converted into linear ones. Due to the amphoteric character of the amide group, the cleavage of the amide bond may proceed by both nucleophilic and electrophilic attack in a number of different transamidation reactions (e.g., aminolysis, acidolysis, and transacylation). Indeed, lactams are versatile monomers that may be polymerized by various polymerization routes with different initiation and propagation mechanisms, namely solvolytic (hydrolytic, acidolytic, and aminolytic), anionic, and cationic. Moreover, even within the same process, polymerization mechanisms and kinetics are functions of the type of initiating species.

The opening of the lactam ring by cleavage of the resonance-stabilized amide group is achieved by hydrolysis or, more easily, by ionic reactions, using lactam anions or protonated lactams. The basic polymerization reactions for lactams having the hydrogen at the amidic nitrogen (N-unsubstituted lactams), in relation to the cationic, hydrolytic, and anionic initiation, are summarized in **Scheme 3**.

Looking at these reactions, a specularity between the anionic and the cationic mechanism is observable. Different from conventional ionic polymerizations, the growth center in cationic and anionic lactam polymerizations is always neutral, and it is the lactam monomer that carries the ionic charge. Such polymerizations follow what is sometimes referred to as 'activated monomer mechanism',[82] since the reactive species are lactam cations/anions, thus activated monomers. However, in order to avoid misunderstandings, it must be well clear that this definition has nothing to do with the term activated



Scheme 3 Opening of the lactam ring by cationic, hydrolytic and anionic initiation mechanisms.

anionic polymerization, which designates a mechanism implying the use of activators (Section 4.14.7.4).

Propagation proceeds essentially by acylation reactions between a nucleophile (donor) and the cyclic carbonyl group of the lactam or the N-acylated lactam (acceptor). Depending on the type of initiation (e.g., hydrolytic, cationic, and anionic), different donors and acceptors may be involved. Some examples are summarized in **Table 6**, where the main reacting donor–acceptor pairs are related to the various polymerization mechanisms.

The order of reactivity of the most important species, as nucleophilic agents (with respect to oxygen or nitrogen atom), is given below (**Scheme 4**):[8]

and the order of the carbonyl acylating strength is (**Scheme 5**)

Not all these active species can coexist simultaneously. However, more than a single type of propagation reactions is possible with a given initiator. In general, under specific polymerization conditions, one of the many feasible reactions predominates. The most probable acylation reactions occur by consuming the most reactive species in the system (the most nucleophilic ones and those with the highest acylating ability). Actually, the anionic mechanism that involves the strongest nucleophile and the most powerful acylating agent is characterized by the highest propagation rate.

Due to the reversibility of the transamidation/transacylation reactions involved in lactam polymerization, several equilibria of linear chains, cyclic molecules, and initiators are established. Linear polymer chains are thermodynamically in equilibrium with monomer (monomer–polymer equilibrium) and with cyclic structures in general (ring-chain equilibria).

The ring-chain equilibria are governed by the ability of the chain segments and the active species to achieve the favorable conformation for ring closure. Indeed, backbiting reactions involving the active terminal group (–COOH, $-NH_2$, RCO–, RNH–, etc.) as well as intramolecular transamidations give rise to monomer, cyclic dimer, or higher cyclic oligomers (an example of backbiting is illustrated in **Scheme 6**).

The reaction of an initiator with an amide group of the polymer chain, instead of that of the monomer, may result in the breaking of the macromolecule. Intermolecular transamidations can also modify the length of the polyamide chains and may generate cyclic structures. These exchange reactions result in a modification of the molar mass distribution.

4.14.4 Hydrolytic Polymerization

The term hydrolytic polymerization refers to the polymerization initiated by water or other substances able to generate water at the reaction conditions. Namely, the above term is widely adopted for the production, at 240–300 °C, of PCL (PA6) and poly(ω-laurolactam) (PA12).

The hydrolytic route is the most important industrial process for the production of the above polyamides, due to the severe drawbacks that have characterized so far both anionic and cationic polymerizations. They have made almost impossible for the latter routes to be employed in various fields, for example, for textile uses. The mechanism and kinetics of the

water-initiated polymerization have been studied in detail in the past decades and are now well established.[7,11,12,54,83,84] More recently, the investigations have been focused on both the modeling and the optimization of the industrial polymerization process for PA6[85–87] and the modeling of its higher cyclic oligomer formation.[88] In recent years, some studies on novel polymerization processes for synthesizing hydrolytic PA6, for example, by microwave irradiation, have been reported. The ring opening of CL has been performed in a microwave oven[89] in the presence of ω-aminocaproic acid as initiator for periods of 1–3 h at temperatures varying from 250 to 280 °C.

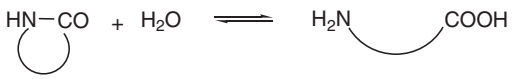
Both unsubstituted and substituted lactams may be polymerized by the hydrolytic process, provided that the monomer ring size is ≥7. Smaller rings, such as those of 2-pyrrolidone and 2-piperidone, are not polymerizable by the hydrolytic mechanism and, because of this, the above lactams have been long believed to be not polymerizable.

4.14.4.1 Reaction Mechanism

Since the hydrolytic polymerization proceeds as both a stepwise addition and a condensation reaction, it cannot be classified as pure ROP and will not be treated in detail in the present chapter. Only the most relevant aspects of the reaction are hereafter briefly reported.

The water-initiated polymerization is governed by three main equilibrium reactions:

1. Hydrolytic ring opening, with formation of the ω-amino acid:

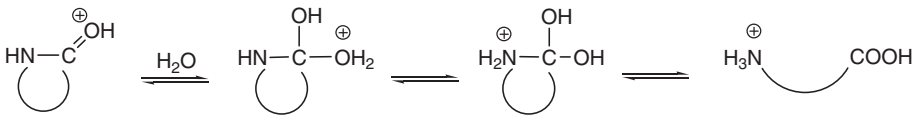


[6]

At high temperatures, the lactam amide is hydrolyzed to give the ω-amino acid [6], which then acts as the initiator. Of course, the introduction of a preformed ω-amino acid at the very beginning of the polymerization achieves the same results. This ring-opening reaction is endothermic and, thus, favored by a temperature increase.[90]

The same reaction, at a later stage, is catalyzed by the carboxyl groups. Indeed, the ring-opening step may be considered an autocatalytic process in which the catalytic function is exerted by the carboxyl groups. The overall rate constant, therefore, is given by the rate constant of the uncatalyzed reaction plus that of the catalyzed reaction. The above polymerization may also be initiated by the addition of phosphoric acid or its alkylammonium salts, as will be mentioned later on.

The acid-catalyzed hydrolysis of the amide group takes place after protonation of the oxygen atom [7]. The rate-determining step is the attack of water and the formation of a tetrahedral intermediate; then, rapid N-protonation and C–N bond cleavage occur:[57]



[7]

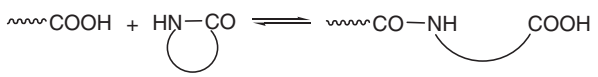
2. Condensation between amine-terminated and acid-terminated chains with formation of amide groups (polycondensation reactions):

[8]

This reaction contributes to the increase of polymer chain length. In this respect, the presence of water negatively affects the obtainment of high molar masses and must be removed in the final steps of polymerization. The condensation reactions occur even in the solid state and allowing their occurrence is an easy method to increase polyamide molecular masses. In that case, the rate-controlling step is the diffusion of reactive end groups.

3. Stepwise addition of lactam molecules to either amine or carboxyl groups (aminolytic and acidolytic polyreactions):

[9]



[10]

It has been proven that the polyreaction occurs mainly at amine end groups and the reaction can be catalyzed by the carboxyl groups.[91] In reaction [9], a tetrahedral intermediate, similar to that occurring in the acid-catalyzed hydrolysis, is involved (see Section 4.14.5.1.1, **Scheme 7**). Intermediate amidine groups may also be generated. As a matter of fact, amidines are reported to be present in the polymerization of CL and η-caprylolactam initiated by the corresponding amino acids.[92]

In the simplified reaction schemes given above, the formation of cyclic oligomers has not been considered, although it plays an important role in the industrial production of PA6. Namely, the cyclic dimer formation and its relevance in both the polymerization process and the properties of the resultant polyamide cannot be neglected.[93]

Since the dimer is the major component among the cyclic by-products, in addition to the aforementioned reactions, other equilibrium reactions have to be considered as well: the ring opening of the dimer to (aminocaproyl)aminocaproic acid (hydrolytic ring opening) and the polyreactions, involving the dimer instead of the lactam.

The contribution of the individual processes to the overall lactam consumption depends on both the type of monomer and the reaction conditions. In CL polymerization, the stepwise addition is prevailing[94] and only a small fraction of the monomer is incorporated in the polymer chain through hydrolysis and subsequent condensation.

The reaction is often carried out in the presence of carboxylic acids and/or primary amines (e.g., acetic acid and hexane-1,6-diamine), which act as chain length regulators. Consequently, the concentration of functional end groups is modified.

4.14.5 Cationic Polymerization

The cationic ROP of unsubstituted lactams has been studied in detail, mostly by Rothe *et al.*[95–97] and Bertalan *et al.*,[98–101] between the late 1960s and the late 1980s of the past century, essentially for mechanistic purposes only, since this type of polymerization found very limited applications in practice. At present, cationic polymerization is considered industrially unimportant among the various lactam polymerization processes and has been nearly abandoned. However, it is interesting to point out that, contrary to the anionic route, which obviously is possible only for N-unsubstituted lactams, both N-unsubstituted and N-substituted lactam may be polymerized by the cationic process. Indeed, this latter has been successfully employed for the polymerization of several N-substituted lactams.[80]

The cationic polymerization is initiated under anhydrous conditions by species capable of being coordinated by the lactam molecule to give a lactam cation, which is the reactive species in the polymerization. A variety of compounds may be used as cationic initiators operating with different action mechanisms: strong protic inorganic acids[100] and their salts with ammonia or primary and secondary amines,[99] Lewis acid and metal halides (e.g., $AlCl_3$, $TiCl_4$, WCl_4, WCl_6, $FeCl_3$, $CaCl_2$, and $CrCl_3$), carbenium ions[80] (e.g., $Ph_3C \cdot AsFe_6$ and $PhCO \cdot SbFe_6$), salts of complexing cations (e.g., $(RCOO_2)Zn$), phosphoric and metaphosphoric acids, arsenic acid, sulfonic acids (e.g., CF_3SO_3H), acyl chlorides, and carboxylic acids[102] (giving rise to what is referred to as acidolytic polymerization, Section 4.14.6).

4.14.5.1 Reaction Mechanism

The reaction mechanisms can be very complex since they are functions of both the initiating system and the lactam substitution. Among the various mechanisms, the polymerization initiated by protic inorganic acids, such as hydrogen chloride or bromide, will be those mainly considered and described in detail in the present section.

Strong protic acids act through an easy protonation of the lactam amide group, while several metal halides, such as chromium, iron, aluminum, tungsten, and calcium chlorides, can form complexes with lactams.[8] It has been assumed that the O-coordination with Lewis acids activates lactam

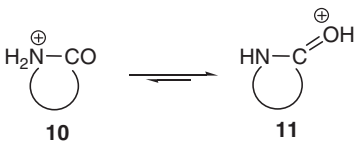
polymerization similarly to the initiation with strong protic acids, yielding to a similar mechanism.[80]

Polymerization initiated by phosphoric or metaphosphoric acid, or their alkylammonium salts, in the absence of water, proceeds probably through a hydrolytic mechanism. Indeed, phosphoric acid at the polymerization temperatures undergoes dehydration and the lactam amide group is then hydrolyzed.[8] The resultant diphosphoric acid catalyzes both hydrolysis and propagation.

4.14.5.1.1 N-unsubstituted lactams

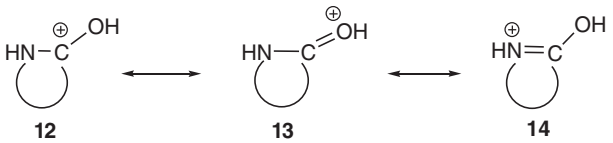
Two potential sites of protonation exist in unsubstituted amides: the nitrogen atom and the oxygen atom. Protonation occurs preferentially at the oxygen (structure **11**), but a small amount of N-protonated lactam (structure **10**) is present.

It is generally assumed that a tautomeric equilibrium [11] between the two protonated forms is established, shifted to the oxygen-protonated one:



10 **11** [11]

In fact, although nitrogen would be inherently more basic than oxygen, there is an important contribution from three resonance structures in O-protonation [12], particularly the form **14** with the double bond between C and N:

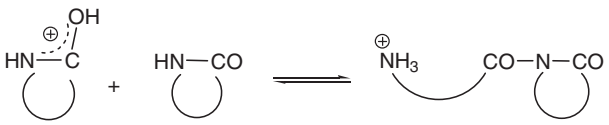


12 **13** **14** [12]

Due to the lack of resonance stabilization, the nitrogen-protonated lactam has a high acylating capability and is the most active species capable of reacting with a lactam molecule at the nitrogen atom.

4.14.5.1.1(i) Initiation

In a reaction mixture where the initiators are strong acids, such as HCl, the strongest nucleophile is the monomer. Indeed, the neutral lactam is more nucleophilic than the chlorine anion; thus, initiation occurs by attack of the monomer on the N-protonated amide. Fast acylation of the monomers with the protonated lactam results in the formation of aminoacyl lactam cations as ammonium salts [13]:



[13]

Indeed, in the above reaction, N-acylated lactams with amine hydrochloride terminal groups are generated. According to the most probable mechanism,[103] the reaction involves several steps: attachment of N atom to the positively charged C, proton transfer from one to the other N, and ring opening with proton transfer from –OH to $-NH_3^+$.

Bertalan[98,100,104] was the first to suggest the formation of a tetrahedral intermediate via stereoelectronic control: the nucleophile approaches the protonated amide group perpendicularly to its plane so that the lone pair orbitals of the amide heteroatoms are oriented antiperiplanar to the direction of the newly formed C–N bond.

Mechanisms based on tetrahedral intermediates apply well for protic acid-initiated polymerization, amine salt-initiated polymerization, and also for hydrolytic polymerization, being in good agreement with experimental data. The existence of a tetrahedral intermediate implies a two-way reaction (**Scheme 7**), which fully accounts for the formation of amidine groups (reported as positively charged amidine hydrochloride). If cleavage of the carbon–nitrogen bond takes place, the lactam monomer is incorporated in the polymer chain (pathway 14); if cleavage of carbon–oxygen bond occurs, amidine groups **16** are formed and water is split off (pathway 15).

This two-way cleavage of the tetrahedral intermediate may be well explained by the theory of stereoelectronic effects:[105]

The protonated *N*-(aminoacyl)lactam **15** is characterized by two reactive sites: the *N*-acyl lactam group and the ammonium ion. As a consequence, it can participate in chain growth reactions that pertain to two different propagation mechanisms.

4.14.5.1.1(ii) Propagation

4.14.5.1.1(ii)(a) Chain growth by acylation The ammonium cation **15** is involved in the equilibrium reaction [16], due to proton transfer to monomer with regeneration of the

protonated lactam plus an electrically neutral molecule carrying the amine end group:

15 [16]

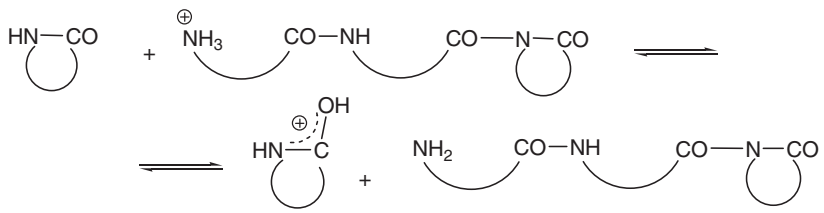
The formation of a certain amount of protonated lactam is allowed by the higher concentration of monomer, despite the higher basicity of the amine group compared to lactam amide. Since the neutral amine group is the strongest nucleophile, it is immediately acylated by the lactam cations, thus incorporating one more monomer unit and giving rise to a chain growth by acylation [17]. As such, the propagation may proceed in a manner similar to the initiation step, by nucleophilic attack of the primary amine group on the protonated monomer:

[17]

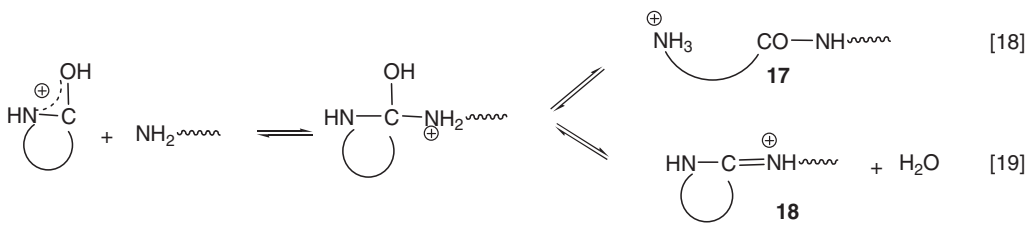
A complete agreement does not yet exist about the pathway of this reaction. In fact, some authors support the addition of the neutral lactam to the ammonium cation, justified by the higher basicity of $-NH_2$, as compared to lactam amide group. However, it seems reasonable to take into account the predominant concentration of the neutral monomer, thus shifting the equilibrium in reaction [16].

Actually, the reaction mechanism to be considered is more complex if, in analogy to the initiation reaction (**Scheme 7**), the participation of a tetrahedral intermediate is taken into account (**Scheme 8**). In fact, in this case also, the two-pathway decomposition of such intermediate results in the formation of either the protonated (aminoacyl)lactam (**17**) or the *N*-acylamidine groups (**18**).

Bertalan *et al.*[100] considered the reactions [18] and [19] to occur between neutral lactams and terminal ammonium groups ($-NH_3^+$), but giving the same products. The ammonium site undergoes proton exchange with the monomer, as in reaction [16], reforming the neutral amine group [20] that can react again with lactam cations, similarly to [17]:



[20]



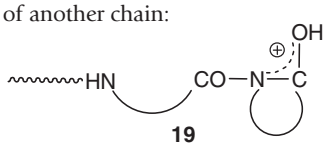
[18]

[19]

Scheme 8 Formation of a tetrahedral intermediate in the propagation reaction.

The above reactions attain equilibrium very rapidly.

4.14.5.1.1(ii)(b) Chain growth by aminolysis The second propagation mechanism is characterized by the interaction of the *N*-acyl lactam moiety with the neutral or the protonated amine group, linking two polymer molecules (aminolysis of aminoacyl lactam). Indeed, protonation of the *N*-acyl lactam moiety in the already formed polyamide molecule provides a strong acylating group (**19**), which can react with the terminal amine groups of another chain:



19

Actually, this acylation reaction may involve the endo- as well as the exocyclic carbonyl of the terminal acyl lactam; consequently, two propagation pathways are possible. Moreover, since the bimolecular aminolysis of *N*-acyl lactam may be schematized via formation of a tetrahedral intermediate, four pathways [21]–[22]–[23]–[24] are possible and amidine structures (**21, 23**) may be obtained as well (**Scheme 9**).

These reactions destroy amine groups, which are regenerated by the initiation equilibrium of disproportionation between lactam and protonated amide [13]. The sequence of the disproportionation reaction [13] and the bimolecular aminolysis [21] contributes to the total lactam consumption with the formation [25] of new aminoacyl lactam molecules (**20**).[57,106] Hence, the incorporation of lactam units into the polymer chain proceeds by the reaction of a protonated lactam with amine groups [18] as well as by the sequence of reactions [13] and [21].

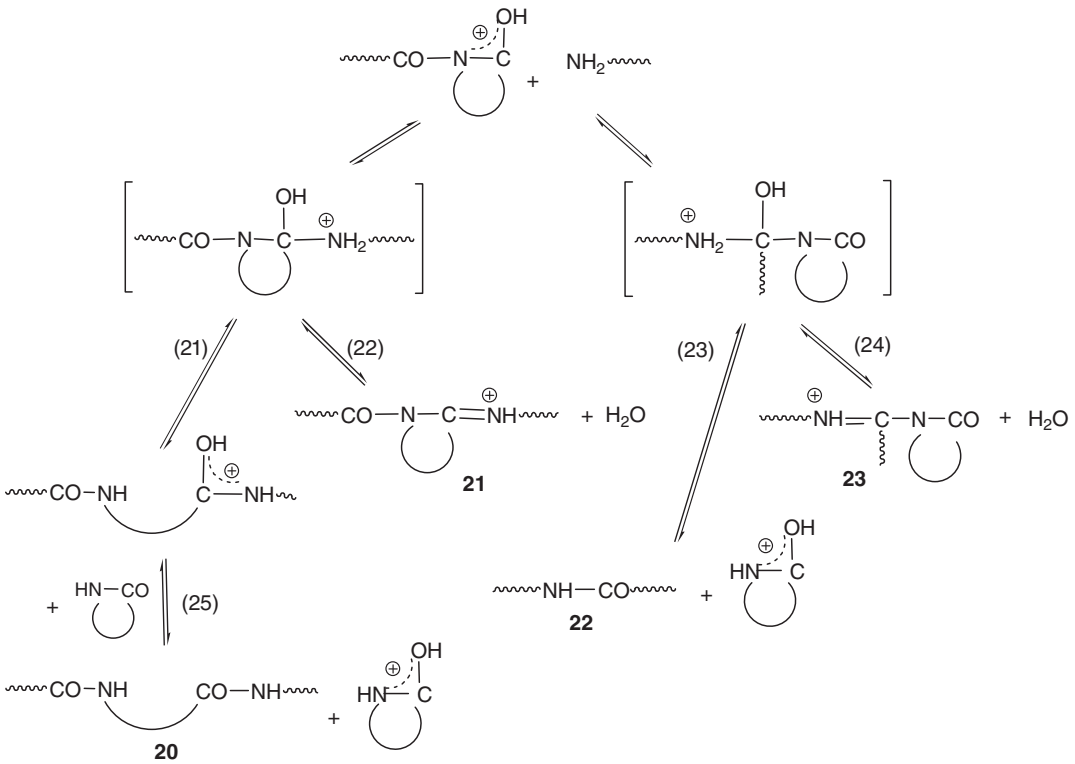
In the literature, in this case also, the detailed description of this type of reaction, in relation to the nature and the role of the species involved, has not been unanimous. Sekiguchi[8] described this reaction as occurring between neutral amine groups and neutral acyl lactams. Rothe and Bertalan[97] assumed, as reported here in **Scheme 9**, the bimolecular condensation of neutral amino groups and protonated *N*-acyl lactams, entailing the two possible tetrahedral intermediates and the corresponding elimination products, even taking into account the imide groups in the polymer chain. Bertalan *et al.*,[100] in their study on the mechanism and kinetics of CL cationic polymerization, regarded reactions [23] and [24] as occurring between neutral *N*-acyl lactams and terminal ammonium groups ($-NH_3^+$). Additionally, the reaction between neutral amine groups and *N*-acyl lactam was taken into account as well, yielding amide groups plus neutral lactams (instead of protonated lactams) together with amidines plus water.

4.14.5.1.1(iii) Deactivation of the active species

In spite of the fact that the cationically activated polymerization reactions proceed at high rates, they generally stop at rather low conversions and low molar masses, indicating the relevant presence of side reactions with deactivation of the active species.

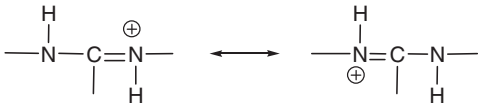
For instance, in the case of CL, the initially fast cationic polymerization slows down well before reaching the monomer–polymer equilibrium. Namely, after a short reaction time, particularly at temperatures above 200 °C, both ammonium and acyl lactam groups disappear, resulting in a large decrease of the polymerization rate.

It has been reported[107–109] that all basic groups are essentially represented by the strongly basic amidine functions, while



Scheme 9 Possible propagation pathways and structures originated therefrom in lactam cationic polymerizations.

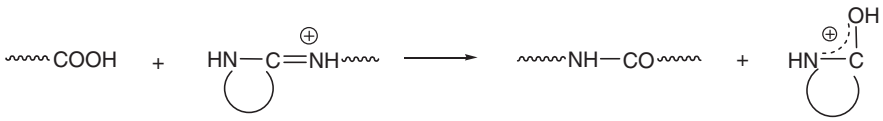
primary amine groups are practically absent. Protonated amidine groups, described by the two resonance forms



[26]

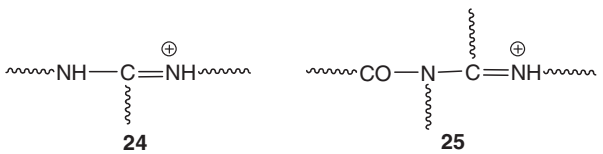
are assumed to be generated, together with water, by the dehydration of the tetrahedral intermediate, as illustrated in the Schemes 7–9.

As a result, polymerization does not stop completely because of the water and the carboxylic acid groups formed, which are capable of initiating a new slow polymerization. Indeed, the time–conversion curve exhibits an inflexion point that more or less corresponds to the highest concentrations of amidine groups, coinciding with the minimum concentration of amine groups. For example, carboxylic groups may react rapidly with amidine structures restoring the catalytically active strong acid and increasing again the rate of the polymerization process:



[30]

Furthermore, polymer amide and imide (diacylamines) groups may undergo reaction with terminal NH_2 as well, according to the same reaction pathways depicted in Schemes 8 and 9, respectively. The result is the formation of amidine and acylamidine structures (24 and 25) inside the polymer chain, representing points of branching:



24 25

Due to their high basicity, amidines are capable of neutralizing the acidic initiator and deprotonating the lactam cations, strongly reducing the formation of new propagation centers. Moreover, the terminal amidine groups (18) are unable to react with the monomer and, therefore, stop the chain growth. Consequently, the rate of polymerization, especially at low initiator concentrations and high temperatures, is reduced long before the monomer–polymer equilibrium is attained.

In addition, irrespective of the fact that polymerization has started under anhydrous conditions, water is always generated during amidine formation. Water may give rise to hydrolytic reactions, in particular with acyl lactams and acylamidine structures, yielding carboxylic end groups (Scheme 10), which take part in the polymerization process as well.

Consequently, different active species and more than a single polymerization mechanism are operating in the second stage of the cationic lactam polymerization.

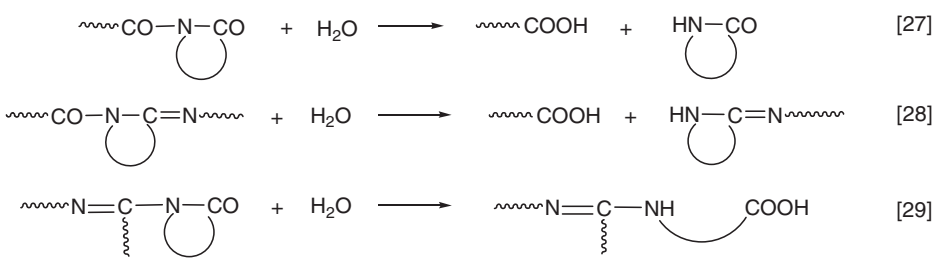
4.14.5.1.2 N-substituted lactams

Polymerization of *N*-alkyl lactams,[80] as already mentioned not polymerizable anionically, can be accomplished cationically by protic and Lewis acids, carbenium and oxocarbenium salts of complex acids, primary and secondary amines, and water.

As compared to the acidolytic, aminolytic, and hydrolytic routes, entailing the same reactions involved for unsubstituted lactams (excluding amidine formation), the polymerization initiated by protic acids, such as HCl, differs for the most part. The most relevant aspects characterizing the cationic polymerization of N-substituted lactams are, as said already, the absence of the detrimental formation of amidines and a much simpler mechanism compared to that pertaining to N-unsubstituted lactams.

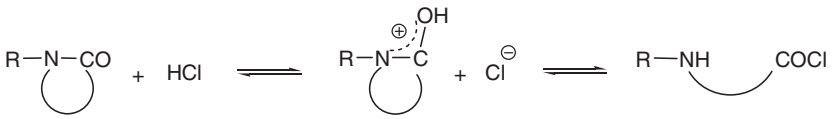
4.14.5.1.2(i) Initiation

The free lactam cannot be acylated to give the (aminoacyl) lactam owing to the N-substituent. On the other hand, the anion of the initiating acid (e.g., Cl^-) can undergo acylation by the O-protonated lactam giving rise, for example, as described in reaction [31], to the acyl chloride of the amino acid:



[27] [28] [29]

Scheme 10 Formation of carboxylic end groups by hydrolytic reactions.

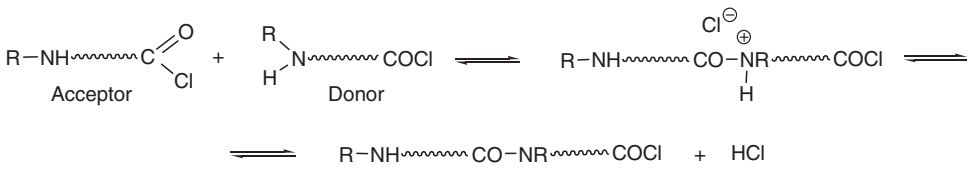


[31]

The formation of the aminoacyl chloride represents the kinetically controlling step of the process.

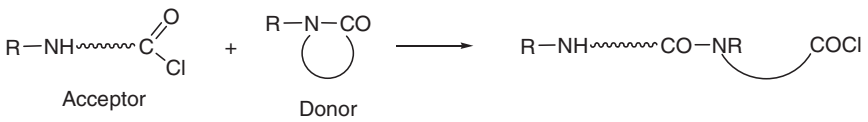
4.14.5.1.2(ii) Propagation

Propagation then proceeds by fast bimolecular condensation, similar to the bimolecular aminolysis previously described, with a molecule acting as the acceptor and the other as the donor [32]:



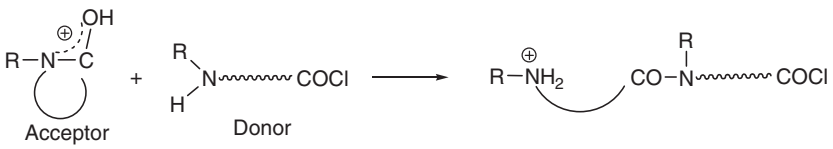
[32]

The regenerated hydrogen chloride enters again into the initiation reaction [31]. Besides this main growth reaction, other competitive propagations are present.[80] In fact, the acyl chloride group may react directly with the lactam monomer; in this case, the aminoacyl chloride acts as the acceptor and the monomer as the donor [33]:



[33]

Additionally, the O-protonated lactam may undergo a nucleophilic attack [34] by the terminal nitrogen of the amino acid (the donor), this reaction nonetheless being an order of magnitude slower than the condensation of the aminoacyl chlorides [34]:



[34]

It is worth underlining that, depending on polymerization time and temperature, the added HCl may result differently distributed in –COCl groups or in acid–base equilibria to give –NHR·HCl [34] and –NRCO·HCl [32]. Hence, not every initiator molecule, in contrast to what happens in the acidolytic polymerization, necessarily yields a polymer chain.

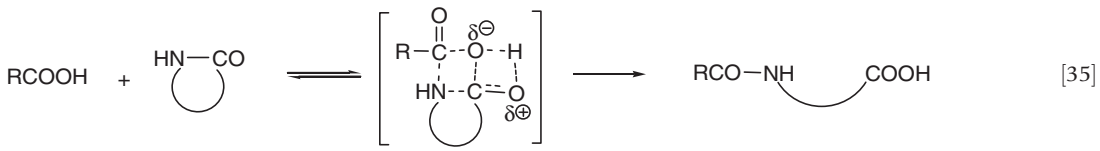
4.14.6 Acidolytic and Aminolytic Polymerizations

Lactam polymerizations initiated under anhydrous conditions by carboxylic acids and primary/secondary amines are referred to as acidolytic or aminolytic polymerizations, respectively. Actually, these terms do not clearly identify different polymerization mechanisms, since their basic reactions simultaneously participate in the cationic and the hydrolytic processes.

The conversion–time curves of amine- and carboxylic acid-initiated polymerization of CL have been reported to show a sigmoidal shape analogous to that given by water initiation.[102] The curves exhibit an initial period during which the rate of conversion increases up to a maximum and, afterward, is constant for some time before decreasing (**Figure 13**).

Acidolytic polymerization is a very slow process, with acids being less efficient than amines in initiating the polymerization. When CL and monocarboxylic acids are considered, the reaction rates have been proven to be inversely proportional to the pK_a of the acid. By extrapolating the experimental data, it has been suggested that acids having pK_a higher than 6–7 are not effective in initiating the polymerization.[102]

The acylation of the monomer by carboxylic acid (acidolysis), or of the protonated monomer by carboxylate anion, is assumed[8,80] to proceed via a transient four-center intermediate. The subsequent acyl exchange and opening of the lactam ring, by splitting of the CO–N bond, gives rise to an amide group and a terminal carboxylic group (reaction [35]):



[35]

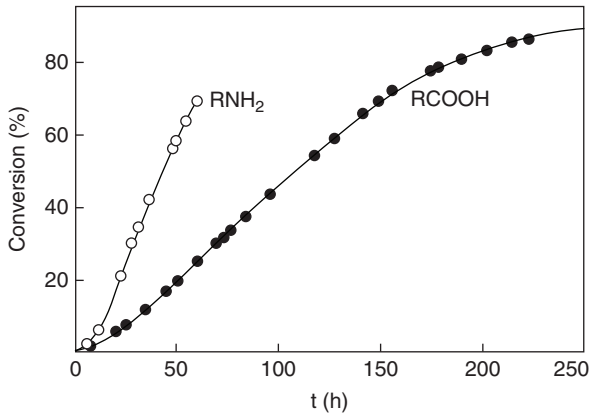


Figure 13 Acidolytic and aminolytic polymerization of CL conducted at 230 °C. Initiator: RNH_2, benzylamine (0.106 mol kg^{-1}) and RCOOH, caproic acid (0.120 mol kg^{-1}). Reproduced from Šebenda, J. In *Lactam-Based Polyamides*; Puffr, R.; Kubánek, V., Eds.; CRC Press: Boca Raton, FL, 1991; Vol. 1, Chapter 2, p 29.[57]

Chain growth then proceeds by reaction of lactam units with the polymer carboxylic groups (reaction [36]):

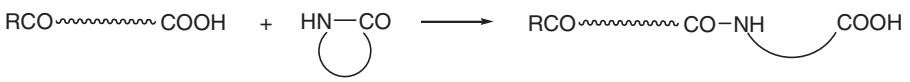
It is remarkable that in polymerizations initiated by carboxylic acids, the acid is incorporated in the polymer chain, differently from the reaction initiated by strong acids, where the strongest nucleophile is the amide group. An alternative mechanism involving the formation of a mixed anhydride of the acid and the amino acid and subsequent intramolecular rearrangement has been hypothesized.[7] This reaction pathway has been invoked in order to account for the experimental data showing the presence of basic groups (i.e., amine groups) in polymers of seven-, eight-, and nine-membered lactams.[110,111] The proposed mechanism,[54] indeed, implies the formation of anhydride functionality and a terminal amine group:

As soon as basic amine groups are produced, the aminolytic polyreaction between the $-NH_2$-terminated chain and the monomer, described in [9], may compete with the acidolytic reaction as propagation reaction. To a minor extent, the anhydride would also contribute to chain growth by bimolecular aminolysis:

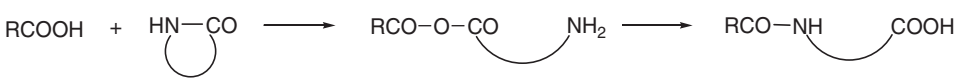
A detailed investigation[110] on the polymerization of ε-capro-, ζ-enantho-, η-caprylo-, and ω-lauro lactam initiated by aliphatic carboxylic acids has shown that propagation prevailingly proceeds via the reaction of the lactam with the carboxyl group and that CL polymerization is characterized by an induction period, unlike the polymerization of eight-, nine-, and thirteen-membered lactams. It has been proven that, with the exemption of CL, the reaction rate of the first lactam with the initiating carboxylic acid is the same as the rate of further lactam molecules to the carboxylic groups of the polymer. On the contrary, in the case of the seven-membered lactam, the first reaction proceeds much slower than the reactions of the second and further molecules. For instance, in lauric acid-initiated polymerizations, the ratio of the rate constants relative to eqns [35] and [36], k_n/k_1, has been found to be 8.4 for the seven-membered lactam and 1.1 and 1.0 for the eight- and nine-membered lactams, respectively. This can be rationalized by the statement that in the case of *trans*-lactams, the rates of initiation and propagation are comparable, while for *cis*-lactams (i.e., CL), they are not.

The presence of the induction period with CL has also been explained[57] by taking into account two propagation reactions, the acidolysis (reaction [35]) and the reaction with amine groups (reaction [9]), and has been related to the formation of basic groups. As a matter of fact, the generation of amine groups increases to a certain level but with very different rates. In the case of ε-capro-, ζ-enantho-, and η-caprylolactam, their concentration attains a constant level at low conversion and the aminolytic polyreaction becomes significant with increasing extent of polymerization. On the other hand, in the seven-membered lactam, due to the existence of the induction period, the formation of basic groups proceeds even at 50% conversion.[110]

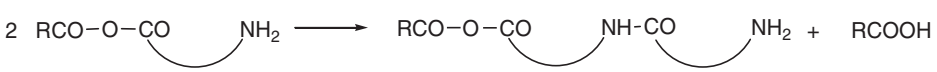
Namely, the acidolytic polymerization of η-caprylolactam at 220–280 °C not only proceeds at high rates, much higher than that shown by CL, but also is a little dependent on the acidity of the initiator. Since the hydrolytic process proceeds at comparable rates, the major contribution to monomer consumption has been attributed to the acidolytic reaction [35], neglecting reaction [9].[112]



[36]



[37]



[38]

N-substitution slows down the polymerization rate even in the acidolytic mechanism, as a consequence of the lower rates of transacylation of the lactam as compared to the linear amide, due to the insufficient flexibility of the lactam ring in the formation of the activated complex. Only *N*-benzoyl lactams, together with highly strained rings, raise the rate of acidolytic polymerization by more than three orders of magnitude.[80]

The polymerization initiated by amines is faster than the acidolytic process remaining, in any case, rather slow.[113] For example, the polymerization of CL at 230 °C, initiated by benzylamine (0.106 mol kg^{-1}), is faster than that initiated by caproic acid (0.120 mol kg^{-1}), affording the conversions of 70% and 20%, respectively, after 50 h (**Figure 13**).[83]

The initiating activity of amines increases linearly with their pK_b, but it is also a function of their structure (e.g., secondary amines are less efficient than primary amines). The aminolytic polymerization proceeds by nucleophilic attack of the amine group on the lactam molecule:

[39]

[40]

However, the process is not so simple, implying several types of reactions. The aminolytic CL polymerization exhibits an induction period and its initial rate is proportional to the amine concentration, while the maximum rate of polymerization is proportional to the square root of the amine concentration. The decomposition of the tetrahedral intermediate in this case as well as in the cationic and hydrolytic polymerization, affords amidine and water. The presence of the induction period has been assumed to be associated with slow amidine formation, while the progressive increase of the polymerization rate has been related to the further contribution of the formed carboxylic groups.[57]

4.14.7 Anionic Polymerization

After the early description of Joyce and Ritter,[6] Hanford and Joyce[114] were the first to discuss in 1948 the mechanism of the anionic polymerization of lactams assuming a chain growth via amide anions, which had to be abandoned later on. Only in the early 1960s of the last century, the teams of both Wichterle *et al.*[115] and Champetier and Sekiguchi[116] established the true mechanism involved in these lactam polymerizations.

Since then, the anionic polymerization of lactams has been studied in depth and excellent and exhaustive works have been published; among them are the fundamental reviews of Šebenda, Sekiguchi, and Reimschuessel, already mentioned in part in Section 4.14.1.[7–9,12,117]

The anionic route is the fastest process for producing polyamides, its activation energy being rather low. In bulk polymerizations, the lower temperature limit is the lactam melting temperature, together with the solubility limit of the polymer into the molten monomer. The anionic synthesis, performed in molten lactam, may be accomplished either below or above the melting point of the polymer (i.e., 220 °C for PA6 and 185 °C for PA12). In the first conditions, the reaction mixture, initially liquid, turns turbid at the cloud point and then solidifies in the course of the polymerization. The beginning of solidification is considered the moment at which the growing chains attain a critical length that enables their crystallization, forming spherulites insoluble in the monomer.

The anionic process is the only method allowing the ROP of the stable five- and six-membered lactam rings, 2-pyrrolidone and 2-piperidone. Obviously, as already mentioned, only N-unsubstituted lactams can be polymerized by the anionic mechanism because of the required presence of the hydrogen atom on the amide group.

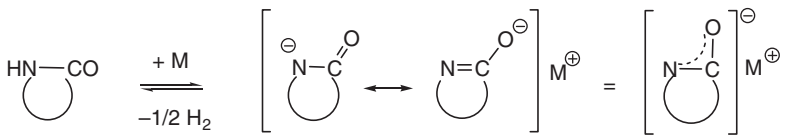
A great confusion sometimes arises from the literature owing to the nonuniform terminology adopted for the various reactive species. Thus, the terms catalyst, cocatalyst, chain initiator, initiator, coinitiator, precursor, activator, coactivator, and accelerator are indifferently used. In the present chapter, the notation 'initiators' will be used for identifying the ionic lactam salts (i.e., the alkali metal lactamates) capable of starting the anionic polymerization of lactams in suitable conditions. Their 'precursors' will be the basic compounds (e.g., the alkali metals) capable of producing the initiators, while the term 'activators' will be used to denote the species, acting as the source of nonionic growth centers able to run the polymerization in more favorable conditions (high rates and lower temperatures).

4.14.7.1 Reaction Mechanism

The anionic polymerization of lactams is initiated, under anhydrous conditions, by generation of the lactam anion. Any strong base capable of producing the N anion of lactam may be effective in initiating polymerization. The polymerization process carried out in the presence of initiator only, that is, a basic substance providing the lactam anion, is regarded as 'nonactivated polymerization' (or 'nonassisted polymerization'), while polymerization process carried out by adding an activator (e.g., *N*-acyl lactam) is designated as 'activated polymerization' (or 'assisted polymerization').

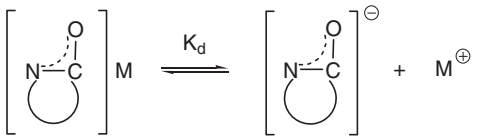
4.14.7.1.1 Preinitiation

This step involves the formation of the free lactam anion by ionization of the alkali metal salt of the lactam (lactamate), generally produced by treatment of the lactam with a strong base, such as an alkali metal M [41] (see Section 4.14.7.2):



[41]

The negative charge in the lactamate and in the free lactam anion is, as in the case of the lactam cation, delocalized on the amide group in virtue of the resonance stabilization by conjugation with the carbonyl group. The lactamate acts as the source of free lactam anion, which is the active species of the polymerization. The concentration of such free lactam anion is a function of the dissociation constant of the lactam salt [42] and [43], being equal to the concentration of this latter only under conditions of complete dissociation:



[42]

$$K_d = \frac{[L^-][M^+]}{ML} \qquad [43]$$

Lactamates, and also the salts of polymer amide groups, may be involved in complex equilibria with formation of various aggregates, ion pairs, free ions, and triple ions.[9] In virtue of this fact, the dissociation constant must take into account the participation of the various types of ions. Thus, the concentration of the free lactam anion $[L^-]$ may be written as

$$[L^-] = \left(K_d[ML]_0 + \frac{K_d^2}{4}\right)^{1/2} - \frac{K_d}{2} \qquad [44]$$

where $[ML]_0$ is the initial lactamate concentration.

The contribution of the free lactam anion increases with temperature, starting to be predominant above 150 °C. Only at higher temperatures, the alkali metal lactamates can be considered completely dissociated. When the lactamate is weakly dissociated, the concentration of active species $[L^-]$ may be approximated to vary with the square root of the salt concentration,[118] as in [45]:

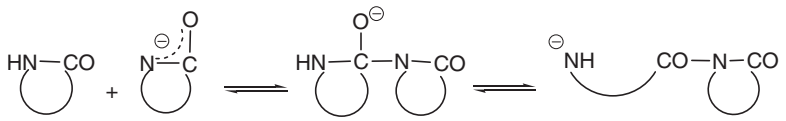
$$[L^-] \approx \left(K_d[ML]_0\right)^{1/2} \qquad [45]$$

In the molten lactam medium, without other solvating or complexing species, the lactamate dissociation depends on both the lactam properties (i.e., acidity, dielectric permittivity, donor–acceptor capability, substituents) and the electropositivity of the metal as well (Section 4.14.7.2). For example, higher lactam permittivity, such as in ω-laurolactam as compared to CL, makes easier the salt dissociation (see **Table 7**).[119]

4.14.7.1.2 Initiation in nonactivated polymerization

The lactamate (i.e., the lactam anion) is a very strong nucleophile (see **Scheme 4**). Thus, it is easily acylated by the lactam, although the acylating ability of the latter is poor, with the amide group being stabilized by resonance. The lactam anion reacts with the monomer by a ring-opening transamidation reaction forming *N*-acyl lactam structures carrying primary amine anions (disproportionation reaction).

Assuming a free ion mechanism,[117] the imide anion is formed, in the first slow step, by nucleophilic attack of the lactam anion on the carbonyl of the lactam molecule, via formation of a tetrahedral intermediate [46]:

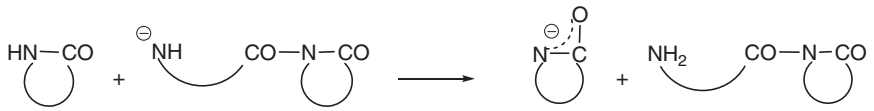


[46]

Table 7 Dissociation constants (K_d) of lactam salts in their respective lactams with different acidity (pK_a at 25 °C) and relative permittivity (ε)

Ring size	Lactam	pK_a	$\varepsilon_r(T)$	T (°C)	$-LogK_d$ $Li^+ L^-$	$Na^+ L^-$	$K^+ L^-$	$Me_3N^+ L^-$	References
5	2-Pyrrolidone	24.5	27.10	31			0.80		14
6	2-Piperidone	26.7	17.49	45		3.89	3.58		14, 57
			13.14	120	7.5	6.31	4.44	3.35	14, 57
7	CL	27.2	12.55	150	4.25	3.98	3.73		14, 57
13	ω-Laurolactam	27.2	35.00	160		2.38			14, 57

The amine anion is highly reactive, unlike the lactam anion, as it is not stabilized by resonance, and rapidly undergoes proton exchange with a lactam molecule, yielding an imide dimer (*N*-acyl lactam) and regenerating a lactam anion [47]:



[47]

The result of these two combined reactions is the disproportionation between two amide groups (present in lactam and in lactam anion) to give an amine and an acyl lactam moiety (in the *N*-acyl lactam species). Since the neutralization reaction is extremely fast, the initial rate of disproportionation may be written as

$$v_d = \frac{d[NH_2]}{dt} = K_d[L]\left(K_d[ML]_0\right)^{1/2} \qquad [48]$$

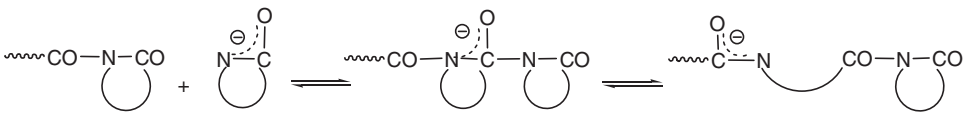
The rate of disproportionation depends on several factors: nature of counter ion and reaction medium, lactam ring size, substituents, and structure of the resulting linear monomeric unit. An N-substituted lactam, for instance, may react with the lactam anion with a rate significantly higher than that of the initial reaction [46], depending on the size and the electrophilicity of the substituent (e.g., *N*-benzoyl lactams are very reactive). As a consequence, specific types of N-substituted lactams are used as activators in the activated anionic polymerization (see Section 4.14.7.4).

On this basis, the *N*-acyl lactam (imide dimer) formed in [47] is highly reactive toward the lactam anion and represents the initiating species necessary for the onset of the polymerization. In fact, while the amide linkage in the lactam monomer is not sufficiently reactive (i.e., not enough electron deficient), the presence of the exocyclic carbonyl group in the *N*-acyl lactam increases the electron deficiency of the amide group and, thus, the acylating ability.

Since the concentration of imide dimers builds up slowly, an initial induction period of very low, if any, polymerization rate is observed. As a consequence, the use of rather high reaction temperatures (255–285 °C) is required and only the more reactive lactams, such as CL, undergo polymerization by strong bases alone in a nonactivated process. As a matter of fact, the formation of the imide growing centre is the controlling step of the polymerization process. In this respect, the nonactivated polymerization can be considered as having an autocatalytic character.[48] When an acyl lactam is added at the very beginning of the polymerization, the induction period is absent[7] and the anionic ROP can be performed at much lower temperatures (e.g., for CL at 130–180 °C)

4.14.7.1.3 Propagation

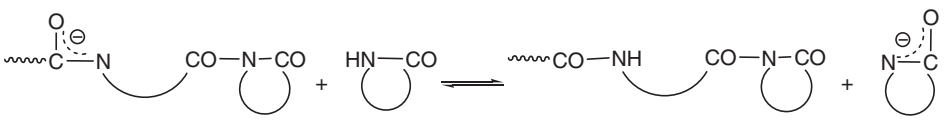
The *N*-acyl lactam embodies the strongest electrophilic group in the system and the most susceptible site to be attacked by the nucleophilic lactam anion. Thus, the neutral N-acyl lactam acts as the growth centre at the chain end. Propagation proceeds, according to the free ion mechanism, by repeated nucleophilic attack of the lactam anion on the endocyclic carbonyl of the imide group, via formation of the tetrahedral bicyclic intermediate [49]:



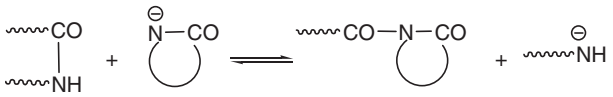
[49]

In contrast to the imide anion formed at the slow initial stage [46], the amide anion is more stable and reaction [49] is appreciably faster. The polymer amide anion participates in the ionization equilibrium with the lactam molecule, thus regenerating the lactam anion [50]:

The combination of these two reactions results in the incorporation of a monomer unit into the polymer and the regeneration of both the active end group and the lactam anion. As soon as the polyamide chain is formed, additional reversible reactions occur. The polymer amide groups may be involved in disproportionation reactions as well, forming acyl lactams and amine end groups [51]:

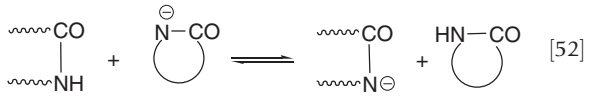


[50]

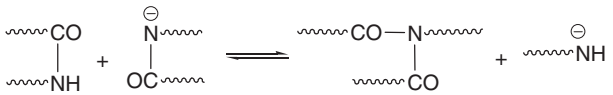


[51]

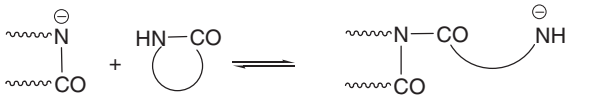
Furthermore, the presence of amide N anions along the polymer chain, derived from equilibrium reactions with lactam anions in the strongly basic medium [52], may produce diacylamines [53] and polymer branching [54]:



[52]



[53]



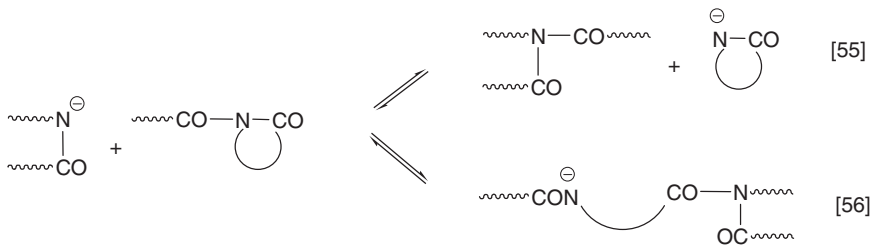
[54]

Transacylation reactions between polymer amide anions and acyl lactams (N-acylations) (Scheme 11) may cause depolymerization or incorporation of a lactam unit when the exocyclic [55] or the endocyclic carbonyl groups [56] are involved, respectively.

4.14.7.1.4 Role of counter ion

The nature of counter ion does affect not only the degree of dissociation of the corresponding lactamates but also the whole polymerization rate, entering in the propagation reactions and influencing also the extent of side reactions.[120] Indeed, aside from the free ion mechanism described above, alternative propagation pathways have been proposed involving the cation participation in ion pairs and complexes: the lactamolytic mechanism put forward by Sekiguchi[116,121,122] and the ion-coordinative mechanism suggested by Frunze *et al.*[123,124]

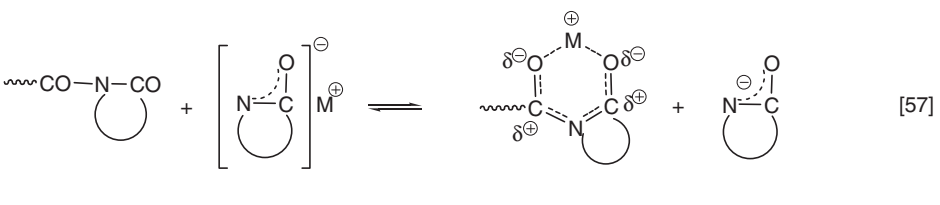
The lactamolytic mechanism (Scheme 12) assumes a transfer of the alkali metal cation from the activated monomer species to the imide group at the end of the growing chain and its coordination to the carbonyls of the imide [57]. The reaction proceeds via formation of an alokoxide-type anion by nucleophilic attack of the lactam anion on the endocyclic carbonyl, proton exchange with monomer, and, as the final step, rearrangement with ring opening [58]. Sekiguchi derived this mechanism from some experimental evidences. Indeed, he studied the conductivity behavior of the polymerization mixtures of CL,[125] 2-piperidone, and 2-pyrrolidone[126] and found



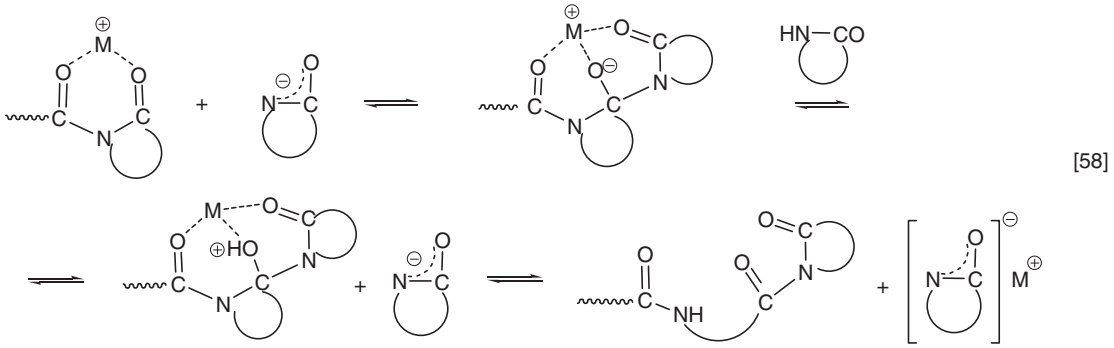
[55]

[56]

Scheme 11 Transacylation reactions between polymer amide anions and acyl lactams.



[57]



[58]

Scheme 12 Propagation pathways based on lactamolytic mechanism.

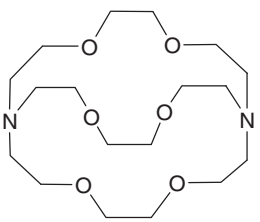
that, after the addition of *N*-acyl lactams to the lactam salts, the conductivity increased for CL and 2-piperidone and decreased for 2-pyrrolidone. The increase in conductivity has been attributed to a higher concentration of free ions resulting from reaction [57]. The coordination of the cation would increase the concentration of the free lactam anion and enhance the reactivity of the imide group to nucleophilic attack [58].

Since the ion-pair bonding is fairly weak, lactams with high dielectric permittivities (e.g., 2-pyrrolidone) are incapable of forming the complex by reaction [57]. Moreover, every condition entailing a high degree of dissociation of the lactam salts determines this reaction to be less and less important.[8] However, there are probably no simple relationships between conductivity and interaction of lactamates with growing centers, since dissimilar behaviors have been observed for different lactams.[9]

Frunze *et al.*[123] proposed the participation of ion pairs of lactam salts in the propagation step and suggested an ion-coordination mechanism. According to this mechanism, a complex between the lactamate and the two carbonyl groups of the growing center is formed (**Scheme 13**).

The contribution of free lactam anions and ion pairs would vary as a function of reaction conditions, nature of counter ion, and structure of monomer and chain end. The mechanism hypothesized by Frunze *et al.*[123] is somehow similar to that suggested by Sekiguchi, from which it differs by the fact that it does not necessarily assume free lactam anions besides ion pairs. Arguments may be formulated in support of each mechanism. However, both of them have some difficulties to accommodate all the observed phenomena in a satisfactory way. For instance, as a matter of fact, the occurring of side reactions greatly alters the course of the polymerization reaction, also preventing the formation of living polymers, which would be implied by all assumed mechanisms.

In any case, it may be asserted that free ions play a decisive role at high temperatures and in media of high permittivity, while at low temperatures and in low polar media, the involvement of ion pairs is more influential. A significant increase in dissociation (i.e., conductivity) and in the rate of polymerization of some lactams has been observed[8] by addition of the cryptand Kryptofix[2.2.2], namely 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]-hexacosane (**26**) to 2-pyrrolidone and 2-piperidone:



26

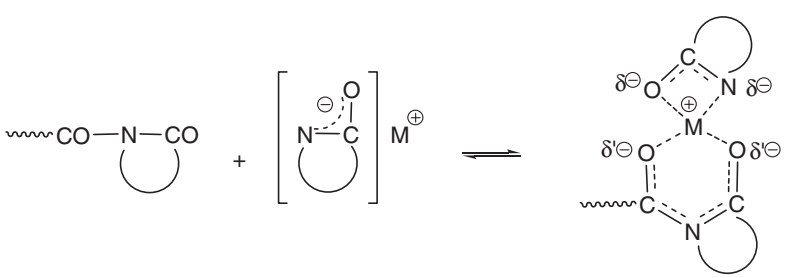
This effect has been shown to be more effective in media of low permittivity, which are more sensitive to a gain in dissociation. Indeed, addition of cryptand has only doubled the rate of polymerization for 2-pyrrolidone,[127] while it has enhanced the rate by two orders of magnitudes for 2-piperidone.[126] The same influence has been found in the anionic polymerization of CL conducted in THF at low temperature (25 °C).[128]

4.14.7.2 Side Reactions

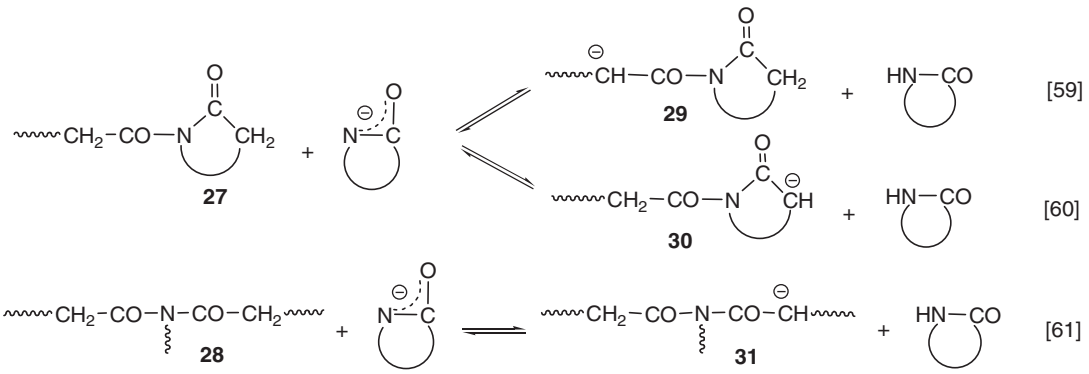
Due to the high reactivity of the species involved in the anionic polymerization, a series of side reactions can take place, namely when using high polymerization temperatures and long polymerization times. The lactam anion and the propagation centers, *N*-acyl lactams and diacylamines, can initiate a variety of reversible and irreversible side reactions in which both the growth centers and the monomer anions are consumed. The strongly basic conditions, as described in this section, promote polymer branching and β-keto compounds, yielding to a considerable number of side products and chain irregularities.

The presence of side products and structural irregularities in the final polymer can be monitored by UV spectrophotometry, as most of them are able to strongly absorb in the UV region. As pointed out by Šebenda,[117] in the case of anionic PCL, the absorption maxima in the ultraviolet region between 250 and 300 nm are directly proportional to the total amount of products derived from the imide groups. Namely, most of the irregular structures arising from keto compounds are responsible for the UV absorption in that region. Therefore, an easy method to have a rough idea of the extent of side reactions in the anionic polymerization of CL is to measure the UV absorption spectra of anionic PA6, as often adopted in the literature.[46,129] It is worth emphasizing here that the fast kinetics involved in the activated anionic polymerization of CL at low temperatures, when adopting the 'very fast' activating compounds explored in the last two decades, is capable of drastically limiting the formation of by-products. In this case, indeed, the UV spectra performed on formic acid solutions of anionic PCL samples have shown the structural irregularities to be almost absent.[130]

The origin and the evolution of structures derived from side reactions have been extensively reviewed by Šebenda,[7] studying essentially the polymerization of CL in slow activated conditions. A survey of them is hereafter reported.



Scheme 13 Propagation pathway based on the ion-coordinative mechanism.



Scheme 14 Formation of carbanions.

4.14.7.2.1 Formation of carbanions

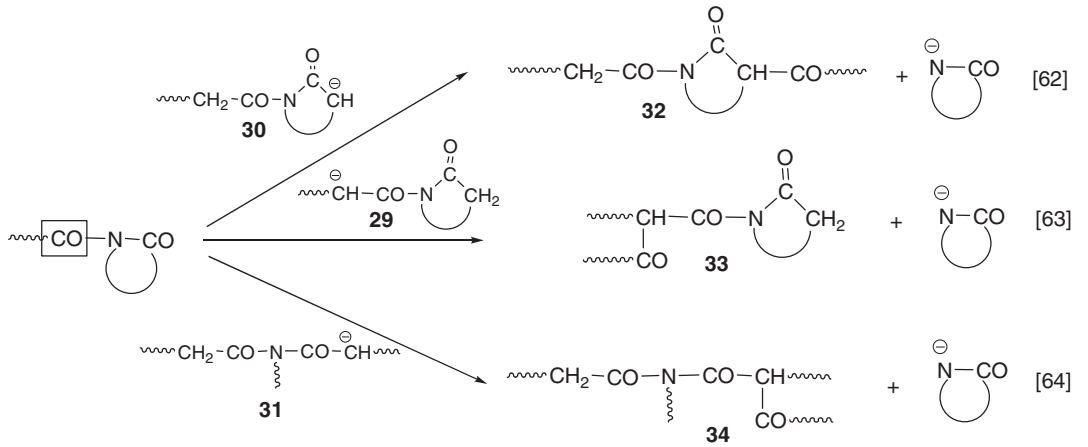
The acidity of the hydrogen atoms in α position, to the carbonyls of the imide group in the *N*-acyl lactam growth center, is comparable to that of hydrogen in the amide group. As a consequence, in the presence of a strong base (e.g., the lactam anion), the ring imide group (**27**) having at least an α-hydrogen to carbonyl, after the established equilibrium with the lactam anion (**Schemes 14**), can undergo Claisen-type condensation reactions, similar to the condensation of esters and ketones.

Analogous behavior is given by diacylamine branching points (**28**), as shown in [61]. The concentration of these carbanions is low. Nevertheless, C-acylations and, only in some specific cases, O-acylations[9] are competitive reactions with regard to the propagation step [49].

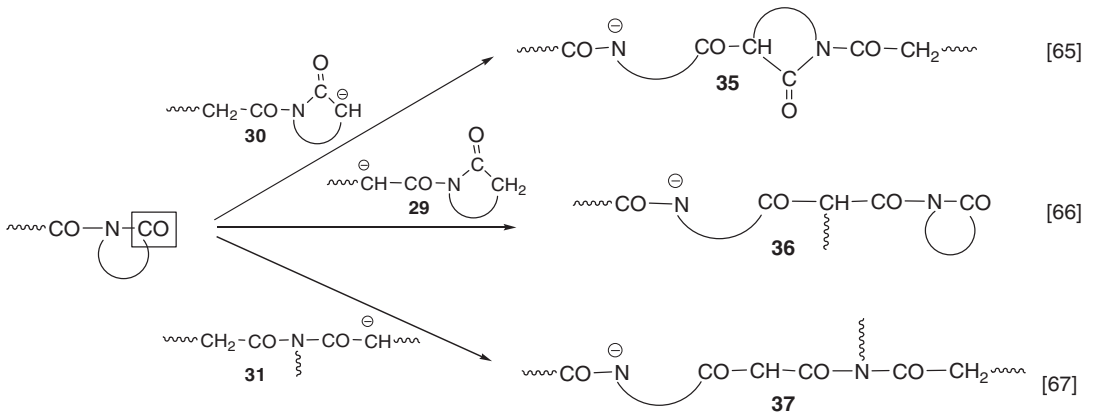
4.14.7.2.2 Formation of β-ketoimides and β-ketoamides

As shown in **Scheme 14**, three types of acid hydrogens exist, yielding to three reactive sites for C-acylation. In this respect, two are the most relevant carbonyl sites: the exo- and the endocyclic carbonyl in *N*-acylated lactams (**29** and **30**), respectively, not considering the branched structure (**31**). As a result, six (in total) or, more probably, four possibilities arise, originating six (four) different β-ketoimide structures.

The C-acylation reactions on the exo- and endocarbonyls are illustrated in **Schemes 15** and **16**, respectively. In the



Scheme 15 C-acylation reactions on the exocyclic carbonyl group.



Scheme 16 C-acylation reactions on the endocyclic carbonyl group.

case of CL, the acylation of the exocyclic methylene on the endocyclic carbonyl has been reported to be the fastest.[131] Reactivities of the different acid methylenes and those of carbonyls are related to many factors:[9,127] the lactam properties (e.g., ring size and substituents), the presence and the nature of activator, the initial ratio of initiator and activator concentrations, the permittivity of the reaction medium, and the reaction temperature. The nature of counter ion may play an important role too.

The concentration of the keto groups in the polyamide depends on the initial concentrations of the catalytic components (and, thus, on the basicity of the medium), temperature, and the polymerization time. In the anionic polymerization of CL at high temperatures (250–280 °C), it has been reported[132] that approx. 0.5–1 keto groups per activator molecule (*N*-benzoyl-CL) are formed very quickly. At a low effective basicity, the majority of keto groups are formed during the first minutes, while at higher medium basicity, most of the keto groups are formed in the latter stages of the process.

For the activated polymerization of CL, conducted in THF at 25 °C (using equimolar concentration of potassium ε-caprolactamate and *N*-propionyl-CL (EtCOCL)), it has been found[131] that the rates of C-acylation ([62], [63], [65], [66]) are comparable to those of propagation [49] and the rates of N-acylation ([55], [56]) are slightly lower.

Indeed, the overall activation energies of polymerization and C-acylation reactions have been estimated to be very close (40 and 30 kJ mol^{-1}, respectively)

Neutral β-ketoimides are strong acylating agents and may be involved in a number of complex reactions, acting as growth centers and leading to either branched or linear chains. β-Ketoimides may be converted to β-ketoamides (2-oxoamides), by nucleophilic attack of the N anion on the carbonyl of the imide group, following the general scheme of eqn [68]:

[68]

In the case of reaction with the lactam anion, the *N*-acyl lactam growth centre is regenerated [69]:

β-Ketoimides and β-ketoamides decrease the concentration of active species present in the initiating system. The formation of a ketoimide structure by the Claisen-type condensation reaction consumes two molecules of the initial growth centers (*N*-acyl lactams). Moreover, both β-ketoimides and β-ketoamides having an α-hydrogen are many orders of magnitude more acid than the amide groups, due to the high resonance stabilization given by conjugation with two carbonyls. Thus, they contribute to a decrease in the concentration of lactamates (**Scheme 17**)

The final result is a decrease in both active species and the polymerization rate. As a consequence, a decrease in the rate of the imide C-acylation is observed as well. Indeed, C-acylations are initially very fast, until subsequent side reactions start to consume the β-ketoimides and a temporary equilibrium is attained.

The presence of ketoimide/ketoamide groups has been demonstrated using model experiments and also isolation of aminoketones formed by total hydrolysis of the polymer. It is noteworthy that α,α-disubstituted lactams, lacking α-hydrogens, cannot undergo this type of secondary reactions. In the case of α-monosubstituted lactams, the pattern of side reactions is fairly different: for example, the ketoimide structures obtained by the Claisen-type condensation (see **32** and **35** in **Schemes 15** and **16**) have no acid hydrogens; thus, the concentration of lactam anions is decreased at a lower rate.

4.14.7.2.3 Condensation and decomposition of β-keto compounds

Like other β-carbonyl derivatives, the β-ketoimides and β-ketoamides are very reactive under basic conditions and at high temperatures, and are considered as the key intermediates in a series of complex secondary reactions with formation of water, carbon dioxide, ketones, amines, and rather stable heterocyclic structures (**Scheme 18**).[9] Indeed, condensation reactions involving β-ketoamides [72] may lead to uracil structures (**38**), while β-ketoimides may give hydroxypyridinone structures (**39**) [73]. It is remarkable that these heterocyclic

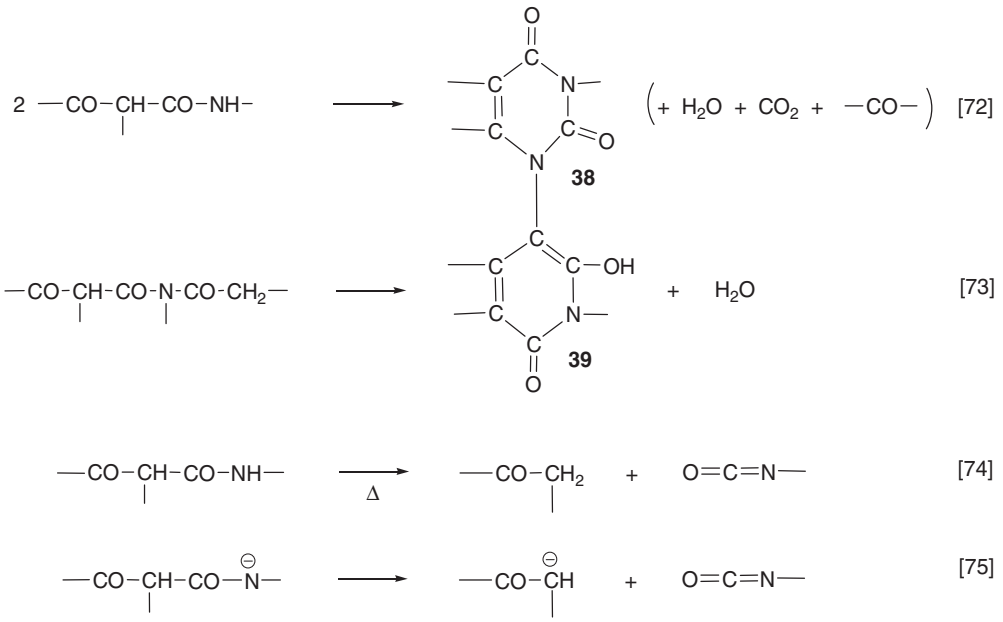
[70]

[71]

Scheme 17 Reaction of b-ketoimides and b-ketoamides with lactamate anions.



Scheme 18 Condensation and decomposition reactions of b-ketoimides and b-ketoamides.

compounds may act as branching and cross-linking points. On the other hand, the thermal [74] or base-catalyzed decomposition [75] of β-ketoamides can afford ketones and isocyanates. Isocyanates may act as efficient precursors yielding, in subsequent reactions, additional growth centers, such as *N*-acyl lactams (see Section 4.14.7.5).

4.14.7.2.4 Hydrolytic reactions

An important consequence of these side reactions is the presence of water, irrespective of the fact that anionic polymerization starts in anhydrous conditions. Water is able to hydrolyze *N*-acyl lactams, β-ketoamides, β-ketoimides, and the imide branching points via fast base-catalyzed reactions.[7] During these hydrolytic reactions, carboxylates, amine groups, ketones, carbon dioxide, and carbonate are formed (Scheme 19).

4.14.7.3 Initiators

The lactam anion in the form of lactam salt (lactamate) can be obtained by *in situ* reaction with alkali metal compounds, or prepared *ex situ* and then introduced in the polymerization mixture. Some confusion may arise about the terms often used in the literature to identify the various compounds mentioned in previous sections (initiators, or catalysts, or precursors). In this chapter, we prefer to consider the lactamate as the true initiator and the alkali metal compound as the precursor. A great number of precursors are able to generate

lactamates (Scheme 20) and have been widely described in the literature,[8,10] essentially with reference to the polymerization of CL.

As already highlighted in the partial list of Scheme 20, various groups of compounds may act as precursors:[8] alkali metals; alkali metal hydrides, oxides, hydroxides, alkoxides, halides, carbonates; alkali metal salts of organic acids; alkyl aluminums; alkali aluminum hydrides and their alkoxides; quaternary ammonium salts; guanidium salts of lactams, etc.

The nature and concentration of the initiator play a crucial role in the nonactivated anionic polymerization, where the growing centers are formed in the slow reaction [46] between the monomer and the lactam anion bringing about the presence of some induction periods. On the other hand, the evaluation of the specific action of a given initiator in the activated lactam polymerization is more complex, since it cannot be taken in consideration apart from the activator used. It is necessary to consider here the dual system initiator/activator. It seems that the activation energy for the anionic ring-opening polymerization of CL is almost independent of the activator used,[133–135] whilst it is probably a function of the initiator nature.

At high temperatures (150–200 °C), the initial rate of activated polymerization of CL is proportional to the concentration of free lactam anions, increasing with the square root of the dissociation constant (K_d) of the lactamate.[57] For alkali metal lactamates, the value of K_d increases as a function of the electronegativity of cation. At higher temperatures (above 200 °C), the dissociation of the alkali metal lactamates (e.g., caprolactamates) is considered complete; consequently, the rate of polymerization becomes independent of the nature of the cation. Cations of transition metals (e.g., Cr^{3+}) and other metals (e.g., Al^{3+}), exhibiting high values of electronegativity, have very low dissociation constants. Thus, the corresponding lactamates hardly dissociate even at high temperatures.

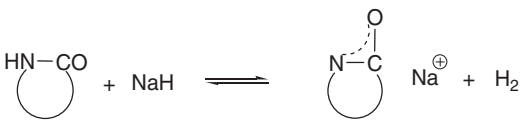
Accordingly, the activity of the alkali metals follows the order of electropositivity, with the only exception of Li:

$$Na^+ < Li^+ < K^+ < Cs^+, \text{ and } Me_4N^+$$

In fact, lithium, despite its highest ionization energy, shows[46] a higher activity than does sodium as lactamate in initiating CL anionic polymerization. All quaternary ammonium salts of a given lactam exhibit more or less the same activities, decreasing only slightly with the increasing dimensions of the alkyl and/or phenyl substituents, due to restricted mobility and decreased ionization potentials:[8]

$$Me_4N^+ \geq Et_4N^+ Me_3PhN^+ > Bu_4N^+ > (PhCH_2)Et_3N^+$$

The use of sodium salt of the lactam (e.g., Na ε-caprolactamate) has been the most common choice of initiator in lactam polymerization and the most widely reported in literature. In order to prepare the sodium salt, it is possible to have the monomer reacting with Na metal or with strong bases yielding lactamates in irreversible (with NaH) or reversible reactions (e.g., with CH_3ONa, $t\text{-}C_4H_9ONa$, and NaOH). The use of the strong hydride NaH is the fastest way, implying only liberation of molecular hydrogen from the reaction mixture [76]. The use of alkoxides and hydroxides requires the removal of alcohol or water by distillation:



[76]

It has been reported[136] that in the nonactivated polymerization of CL, the sodium salt (CLNa) prepared *in situ* by reaction of the lactam with sodium methoxide (CH_3ONa) is less active than the sodium caprolactamate prepared *ex situ*. Heterogeneous precursor/initiator systems may be used and have been experimented. A potassium–graphite intercalate (KC24) has been compared to the potassium caprolactamate, showing that the nonactivated polymerizations with KC24 were slower, proceeded with an induction period, and gave a polyamide with low molar mass.[137]

The organomagnesium compounds, that is, the Grignard reagents, proved[138–140] to be very effective in the deprotonation of the lactam monomer giving rise to lactam magnesium bromides. They have been specifically tested in the activated polymerization and copolymerization of CL using 'fast' *N*-acyl lactam activators.[141] In recent years, CL magnesium bromide (CLMgBr) has been used more and more as initiator, for a variety of reasons, the most relevant being its stability and ease of handling as compared to sodium metal or sodium hydride as precursors of NaCL. Moreover, its lower nucleophilicity related to the $MgBr^+$ cation ends up in a better processability window, lower

level of side products, and marked suppression of cyclization reactions during polymerization that, in addition, is less sensitive to the presence of water. For these reasons, lactam magnesium bromides are widely adopted in RIM (referred to as Nylon-RIM),[142] reactive extrusion,[143] and centrifugal molding.[144]

CLMgBr can be easily prepared in laboratory by reaction of the lactam with ethylmagnesium bromide:

[77]

Due to their large use, both ClNa and CLMgBr are, at the present time, commercially available. Explanation of the activity of CLMgBr takes into account the capability of $MgBr^+$ to be coordinated to the growing center (*N*-acyl lactam, see Section 4.14.7.1.4) and form a complex with the polymer functional groups. Indeed, the complex formation between magnesium cations and amide anions in the polyamide chain minimizes or prevents cyclic oligomer formation, presumably hindering some polymer chain conformations favorable to the cyclization reaction. Namely, the formation of cyclic dimer is strongly limited or suppressed.[145] Studies on model compounds[146] seem to support the formation of coordination sites stable up to 200 °C. The coordination capability of some counterions and the complex formation between them and the monomers, on the one hand, or between them and the growing chains, on the other hand, have already been suggested in literature.[46,51,122,147]

Chemistry and kinetics of adiabatic homopolymerization and copolymerization of CL using CLMgBr, in combination with isophthaloyl-bis-caprolactam as activator, has been studied in depth.[140,148] It has been shown[148] that the value of the activation energy for homopolymerization using CLMgBr is much lower than that using sodium caprolactamate (30 vs. 73–61 kJ mol^{-1}).

By varying the lactamate counterion in the polymerization of CL, a comparison regarding the formation of side products has been made.[9] At high temperatures, the content of diaminoketone units formed during C-acylation side reactions is almost the same for sodium, potassium, and lithium ε-caprolactamate but much lower when CLMgBr has been used (**Table 8**).

When the presence of side reactions has been studied[10] in the two systems, CLNa/*N*-benzoyl-CL and CLMgBr/*N*-benzoyl-CL with or without the addition of α,ω-dibenzamido-poly (propylene oxide) (PPO), it has been shown that, in the absence of PPO, the content of side structures using CLMgBr is slightly less as compared to CLNa, while in the presence of 20 wt.% of polyether, the side reactions are almost completely suppressed.

More recently, sodium bis(2-methoxyethoxy) aluminum hydride ($NaAlH_2(OCH_2CH_2OCH_3)_2$, structure **40**, available in toluene solution under the commercial name of Synhydride©), has been extensively used in replacement of the more dangerous lithium aluminum hydride as reduction agent in the chemical industry and, specifically, in the polymerization of CL at temperatures below 170 °C:

Table 8 Content of the diaminoketone units anionic PA6 prepared at 225 °C with 0.051 mol kg^{-1} of various lactamates and 0.153 mol kg^{-1} of *N*-benzoyl caprolactam

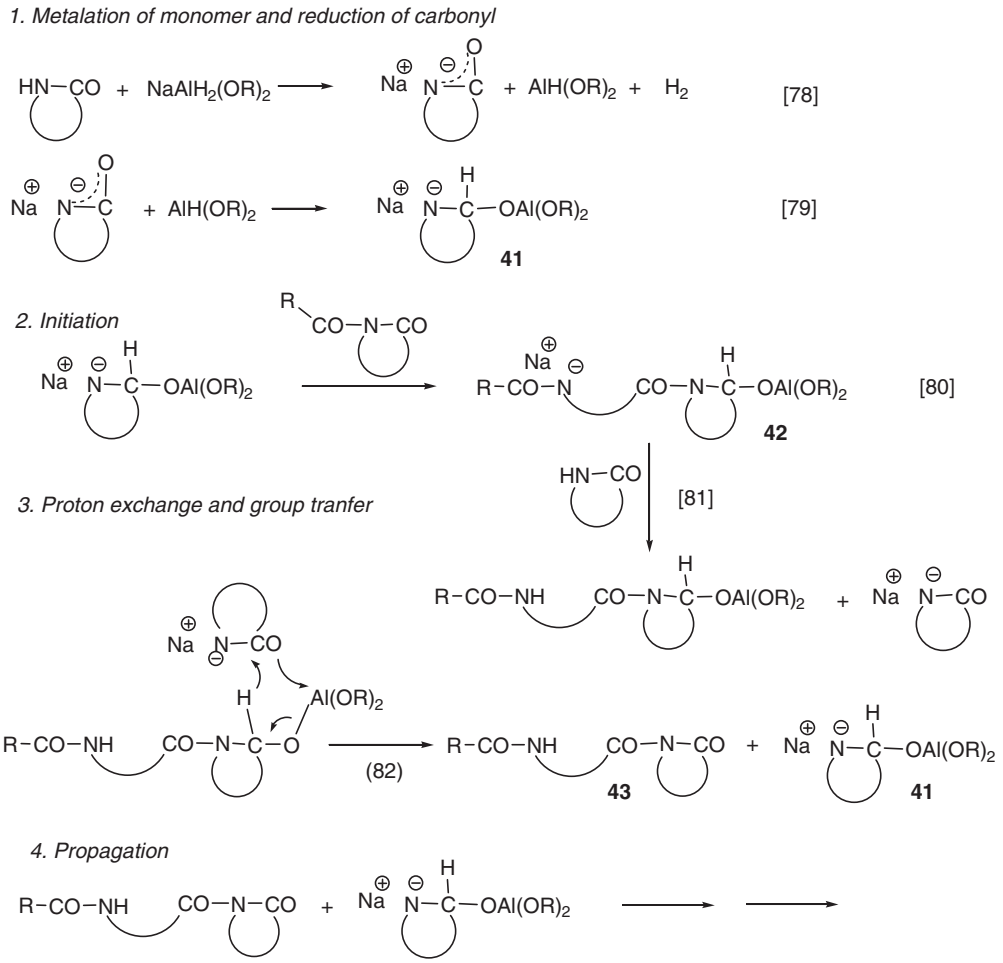
40
Synhydride

While other strong bases, such as $LiAlH_4$ and BuLi, behave similarly to NaH in the deprotonation of monomer, yielding the classical anionic mechanism previously illustrated, lithium dialkoxyaluminum hydrides behave differently. The anion obtained by the reaction of CL with lithium dialkoxyaluminum hydrides is less nucleophilic than the classical lactamate anions.[149,150] A new mechanism has been suggested[151] for this type of polymerization where different active species are involved.

According to the proposed mechanism (see **Scheme 21**), the reaction of CL with sodium dialkoxyaluminum hydride gives rise to the sodium lactamate and dialkoxyaluminum hydride $AlH(OR)_2$ [78]. Then, the reduction of the carbonyl function by the latter produces the sodium salt of 2-(dialkoxyaluminoxy)-l-azacycloheptane (**41**) [79]. The initiation [80] in the presence of *N*-acyl lactam (in activated polymerization) proceeds by nucleophilic attack of the acylated carbonyl leaving the 2-(dialkoxyaluminoxy)-l-azacycloheptane moiety at the chain end (**42**). After proton exchange with the monomer [81], the reduction of the lactamate anion immediately proceeds by displacement and concerted transfer of both the hydride and dialkoxyaluminum groups from the terminal function [82]. Following this process, the initiating species **41** is regenerated, while an acyl lactam function is reformed at the chain end (**43**). This pathway has been regarded as a new propagation step, but it is still open to discussion.

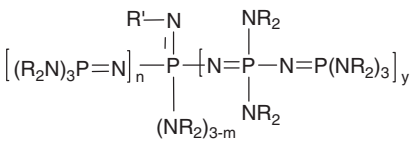
A similar mechanism has been encountered with the family of initiating species derived from metal dialkylaluminum hydrides and strong bases (NaH, BuLi) associated with reducing agents [R_2AlH, R_2BH, RMgBr, R = alkyl].[152] A few nonionic bases have been reported to initiate the ROP of lactams via the anionic mechanism. Pentamethylguanidine, in combination with the *N*-benzoyl lactam activator, is able to start polymerization of CL and η-caprylolactam.[153] Differently from what occurs using standard initiating systems, an induction period is observed. At 175 °C, the polymerization rates are appreciably lower than those



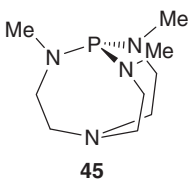
Scheme 21 Mechanism of e-caprolactam anionic polymerization initiated by Synhydride.

found in the activated polymerization of these lactams initiated by their alkali metal salts.

The unconventional nonionic species, poly(aminophosphazene)s (e.g., P4-*t*-Bu, 44) and the bicyclic 'superbase' protophosphatranes, $N[CH_2CH_2N(CH_3)]_3P$ (45), discovered recently,[154,155] have been reported to mimic the classical strong base precursors in lactam polymerization with the added advantage of the tolerance to moisture:[156]

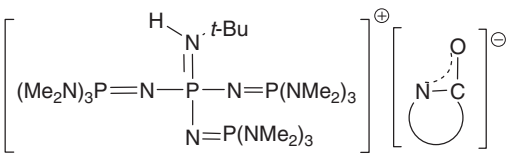


P4-t-Bu 44



45

A detailed investigation on the ROP of CL using a poly (aminophosphazene) (the P4-*t*-Bu 44) carried out using solid-state cross-polarization magic angle spinning ^{13}P NMR (CP-MAS) showed the conversion to the protonated form of P4-*t*-Bu and the similtaneous formation of the CL anion (46):[156]



46

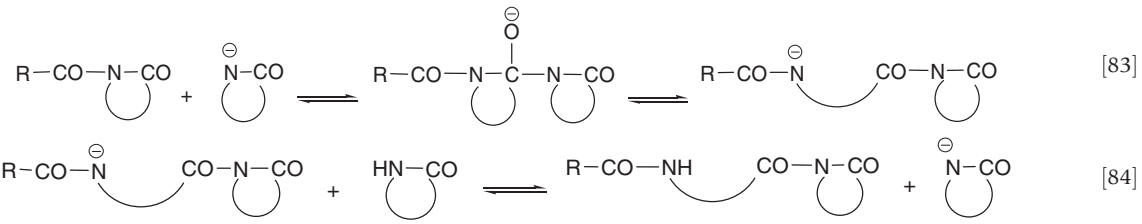
4.14.7.4 Activated Anionic Polymerization

The use of strong bases alone is a limiting factor in the anionic lactam polymerization since high polymerization temperatures and relatively slow reaction rates are necessarily implied; side reactions are, therefore, unavoidable. Moreover, only the more reactive lactams, such as CL and ζ-enantholactam, readily polymerize in nonactivated reaction conditions. The less reactive lactams, such as 2-pyrrolidone and 2-piperidone, are much harder to polymerize because the formation of the imide dimer is more difficult. These limitations can be overcome if the imide is generated by reaction of

the lactam with an acylating agent (e.g., an acyl chloride, anhydride, isocyanate, or monocarbodiimide).

When *N*-acyl lactam structures are introduced in the system from the very beginning of the reaction or formed *in situ* from appropriate precursors, the anionic polymerization is defined 'activated'; the rate of the initiation step is much higher and the reaction temperature can be considerably lowered.

Indeed, as already described, reaction [49] is much faster than reaction [46] by virtue of the higher reactivity of imide as compared to the amide group. When introducing *N*-acyl lactam activators, reaction [46] is no longer necessary and an immediate chain initiation is obtained:



Indeed, apart from some specific effects linked to the different nature of R substituents in the acylated lactam, reaction [83] is the same as reaction [49]; consequently, the activator addition allows to avoid the slow self-initiation step, obtaining immediately the fast propagation reaction. In other words, the initiation of activated polymerization corresponds to the fast propagation step in the nonactivated lactam polymerization.

Working in milder conditions for shorter times brings about the relevant advantage to reduce or even minimize the side reactions, yielding more regular macromolecular chains. Of course, the structural quality of the resultant polymer is also a function of the specific type of activator used (Section 4.14.7.5).

In the activated anionic ROP of CL in the bulk, the short cycle times make the reaction amenable to RIM processing (Section 4.14.13.3). Furthermore, fast polymerization conditions more advantageously offer the possibility of operating in quasi-isothermal conditions using, for instance, emulsion or suspension processes where a good dispersion of the reaction heat can be easily achieved (Section 4.14.13.2).

As mentioned above, in the activated anionic ROP of lactams, the induction period is suppressed and the polymerization rates are enhanced,[7] as shown for CL in **Figure 14**. The rate of the reaction between the *N*-acyl derivatives and the corresponding lactamates significantly varies as a function of the lactam ring size. There is, for example, a remarkable difference between the activation energies relative to the reaction of CL derivatives and those pertaining to higher lactams.[131] The parameters of the Arrhenius equation for the overall consumption of *N*-propionyl lactam in the reaction with the potassium salt of the given lactam, with reference to CL, η-caprylolactam, and ω-laurolactam, are reported in **Table 9**.[127]

In general, in CL polymerization, an equivalent concentration of activator (A) (*N*-acyl lactam or *N*-carbamoyl lactam) and initiator (I), in terms of its functional groups, is the best compromise among polymerization rate, overall conversion, degree of polymerization, high polymer yield, and polyamide properties (see Section 4.14.10.3).

Monomer conversion increases with the concentration of the activator, provided that a suitable initiator concentration is chosen.[144,148,157,158] A relevant difference between nonactivated and activated processes pertains to molar masses and their distribution. In the nonactivated polymerization, the number of growth centers and polymer chains increases as long as lactam anions are present. Since the growth centers formed at the very beginning attain a higher molar mass compared to those formed in the final stage, the molar mass distribution is expected to be quite broad. At sufficiently high temperatures, at which the lactamates are completely dissociated, the final molar mass is the consequence of both the polymerization–depolymerization equilibrium and the presence of side reactions, approaching a value proportional to the square root of initiator concentration.[7]

In the activated polymerization, the number of polymer chains (N) is determined by the concentration of the activator, with the formation of additional growth centers by disproportionation being much slower [46]. In theory, apart from some deviations caused by reversibility of the reaction, the number of polymer chains would be equal to the number of activator molecules. For CL, this number can be expressed in mol kg^{-1} and calculated by

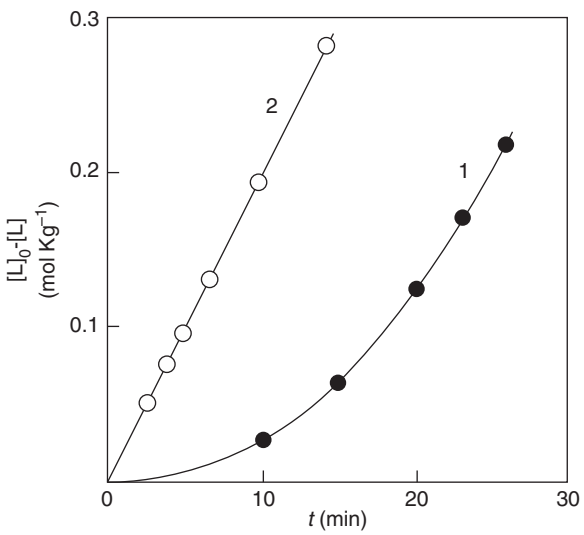


Figure 14 Anionic polymerization of CL with sodium caprolactamate (0.083 mol kg^{-1}) at 160 °C (curve 1) or with equimolar concentration of sodium caprolactamate and *N*-acetyl-caprolactam (0.0177 mol kg^{-1}) at 100 °C (curve 2). $$N = 10 \cdot \gamma/\mathrm{DP}\cdot 113 \qquad [85]$$

or

$$N = 10 \cdot \gamma/M_n \qquad [86]$$

where γ is the polymer yield (in %), M_n is the number-average molar mass (in g mol^{-1}), DP is the degree of polymerization, and 113 is the CL molar mass.

Actually, the polyamide molar masses are almost always higher than the predicted values. This is mainly due to the lowering of the number of growth centers due to side reactions and to the cross-linking between polymer chains, for example, by Claisen-type condensation reactions, which are more and more relevant as the medium basicity and the polymerization temperature increase.[129] In **Figure 15**, taking the 'slow' activated anionic polymerization of CL as an example, the number of polymer molecules formed per initial activator molecule, $[N]/[A]_0$, is plotted as a function of the initiator (sodium ε-caprolactamate) concentration. This ratio has been found always to be lower than unity, that is, polymer molar masses are higher than expected on the basis of the above assumption, sharply decreasing with the increasing basicity of the reaction medium.[129] The dependence of the $[N]/[A]_0$ ratio on [I] is a straight line, which when extrapolated gives the theoretical value of 1 at the origin.

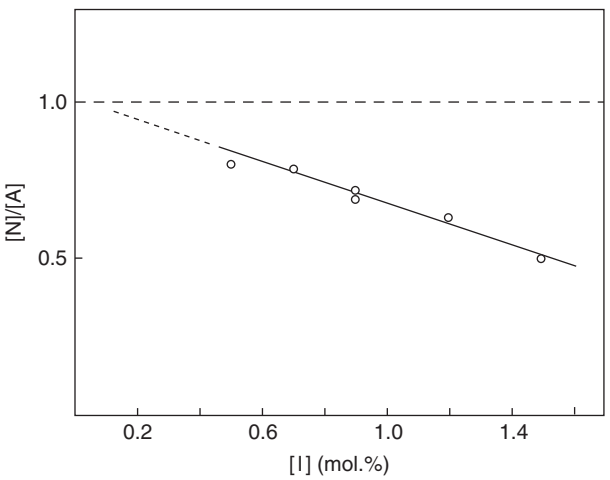

Figure 15 Number of polymer molecules (M) formed per activator molecule (A), as a function of initiator concentration, in the polymerization of CL conducted at 155 °C using equimolar concentrations of sodium ε-caprolactamate (I) and AcCL (A). Reproduced from Alfonso, G. C.; Chiappori, C.; Razore, S.; Russo, S. In *Reaction Injection Molding, Polymer Chemistry and Engineering*; Kresta, J. E., Ed.; ACS Symposium Series No. 270; American Chemical Society: Washington, DC, 1985; Chapter 11, p 163.[129]

A peculiar situation is met in the polymerization at temperatures below the melting point of the polyamide when depolymerization and side reactions are largely reduced and the disproportionation reaction is appreciably slower. In this case, even at equimolar concentrations of initiator and activator, the polymerization proceeds essentially by the reaction of lactam anions with a constant number of growth centers, resulting in a narrower molar mass distribution ($M_w/M_n < 2$).[159] Moreover, since bifunctional activators may be safely used under specific conditions without any formation of cross-linked structures, very high molar masses can be obtained.[140,159,160]

Of course, the monomer conversion, the degree of polymerization, the molar mass distribution, the presence of side reactions, and, thus, the microstructure of the resultant polymer, as already mentioned, are strictly related to the nature of the activator used (Section 4.14.7.4). It has been estimated that the rates of the first steps of propagation, C-acylation, and N-acylation of polymer amide groups (Section 4.14.7.2) depend on the nature of the exocyclic acyl group (i.e., the type of *N*-acyl lactam). In fact, it has been found[131] that, in CL polymerization in THF at 25 °C using an equimolar concentration of potassium ε-caprolactamate and EtCOCL (0.081 mol l^{-1}), the initial rate of propagation is 8.9×10^{-6} mol l^{-1} s^{-1}, that of C-acylation is 4.7×10^{-6} mol l^{-1} s^{-1}, and that of N-acylation is 3.0×10^{-7} mol l^{-1} s^{-1}. On the contrary, when using *N*-benzoyl-CL (0.055 mol l^{-1}) instead of EtCOCL, both the initial propagation and the N-acylation reactions are significantly faster, by two orders of magnitude, being 2.3×10^{-4} and 2.9×10^{-5} mol l^{-1} s^{-1}, respectively, while the rate of C-acylation remains lower (4.0×10^{-7} mol l^{-1} s^{-1}).

The introduction of 'very fast' activators, that is, *N*-carbamoyl lactams, in the above system (Section 4.14.7.5.3) has allowed to drastically reduce the polymerization time:[157,160] by choosing the appropriate initiator/activator ratio, 20–30 s is sufficient to reach polymerization completion with the attainment of a very high polymer yield. The overall polymerization time is obviously linked to the concentration of the specific activator used. Working at low temperatures for shorter times brings about the relevant advantage of reducing or even minimizing the side reactions, yielding more regular PA6 chains when compared to the use of slow activators.[160] The activated anionic polymerization, taking place in very short times, has also opened other opportunities in the vast panorama of polymer modifications. In recent years, attempts have been made to use this polymerization technique for the preparation of compatibilized blends of PA6 with other polymers (*in situ* polymerization and *in situ* compatibilization), as well as grafted copolymers starting from premade polymers with pendant functionalities such as ester, imide, maleic, or isocyanate groups acting as macroactivators (see Section 4.14.7.5.5). The main role of these functional groups on the macroactivator chain is to act as growing centers, forming *N*-acyl lactams by reaction with the lactam monomer and, subsequently, producing a graft copolymer that may be used as compatibilizer.

4.14.7.5 Activators

4.14.7.5.1 Overview

As mentioned in the previous section, an activator has the function to increase the polymerization rate supplying from the very beginning of the polymerization reaction the nonionic growth centers that start a faster initiation [83]. The activator significantly influences not only this initiation step but also the overall course of the polymerization and the whole polymerization rate.

As a matter of fact, the effects triggered by the activator are complex and hardly predictable *a priori*. Surely, remaining linked to the growing polymer chain, it can affect the reaction medium (e.g., its dielectric permittivity, and the dissociation of the initiator) and can change its basicity during polymerization favoring or limiting the side reactions (e.g., Claisen-type condensation and transamidation reactions, causing branching and cross-linking). All characteristics of the resultant polyamide can be considered strictly dependent on the nature and concentration of the activator or, better, of the dual system initiator/activator, influencing the polymer yield, the molar mass distribution, the presence of structural irregularities, the extent of cross-linking, the degree of crystallinity, and, as in the case of PA6, the polymorphism.

The number of possible activators for the lactam anionic polymerization is extraordinarily large. In Scheme 22, some examples of the various types of activators are reported. The activators can be monofunctional or multifunctional and can be divided in two main categories:

1. *Direct activators*. Compounds bearing the *N*-acyl lactam structure, that is, *N*-acyl-substituted lactams with electronegative substituents capable of increasing with the acylation ability of the endocyclic acyl group. Direct activators are essentially the *N*-acyl lactams (of general structure **47**) and *N*-carbamoyl lactams (**48**).
2. *Precursors*. Substances forming the *N*-acyl lactam functionality *in situ* by the reaction with lactam or lactam anion, thus generating the growth centers (e.g., anhydrides, acyl halides, esters, and isocyanates).

It is noteworthy that, very often, the CL derivatives (e.g., *N*-acyl-CLs) are employed as activators also in the homopolymerization of other lactams (e.g., ω-laurolactam). The activity of the activators based on N-substituted lactams generally increases with the increasing electronegativity of the substituent and is decreased by steric effects (Figure 16).

The number of polymer molecules that are formed (*N*) differs substantially for each specific activator, being much lower than the expected value of 1, due to the reduction of growth center concentration caused by side reactions (Section 4.14.7.2) When the polymerization is carried out below the polyamide melting temperature, this decrease of growth centers takes place for the most part at the beginning of the process, in the homogeneous stage. In CL polymerization initiated by 0.044 mol kg^{-1} of sodium ε-caprolactamate, $[N]/[A]_0$ is 0.82 with benzoyl-CL (BzCL) and 0.091 with phenyl-carbamoyl-CL (PCCL).[9]

4.14.7.5.2 N-acyl lactams

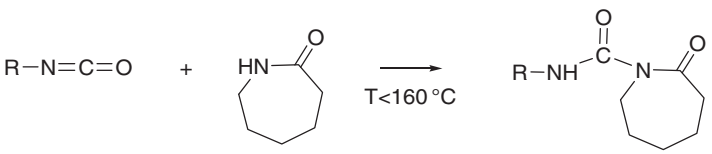
The *N*-acyl lactams (**47**), e.g., *N*-acetyl-CL (AcCL), N-propionyl-CL (EtCOCL), and *N*-bis-isophthaloyl-CL (IPBCL), are the first type of activators that have been used and their role on chemistry and kinetics has been examined in depth, essentially in the anionic polymerization of CL, in combination with sodium ε-caprolactamate or CLMgBr as initiator.[127,131,133,134,138,140,144,148,161–163] Obviously, the structure of the *N*-acyl lactam has a relevant influence on the polymerization rate, the side reactions, and the polymer yield. Typically, the activation energy for CL polymerization is about 70 kJ mol^{-1}.[10]

Highly electronegative substituents (e.g., benzoyl) increase the reaction rate of the lactam anion, while bulky acyl (e.g., 2,2-dimethylpropanoyl) groups decrease the reaction rate due to steric hindrance. For example, in CL polymerization, the rate of the reaction [83] with BzCL proceeds 40 times faster than that with EtCOCL.

4.14.7.5.3 N-carbamoyl lactams

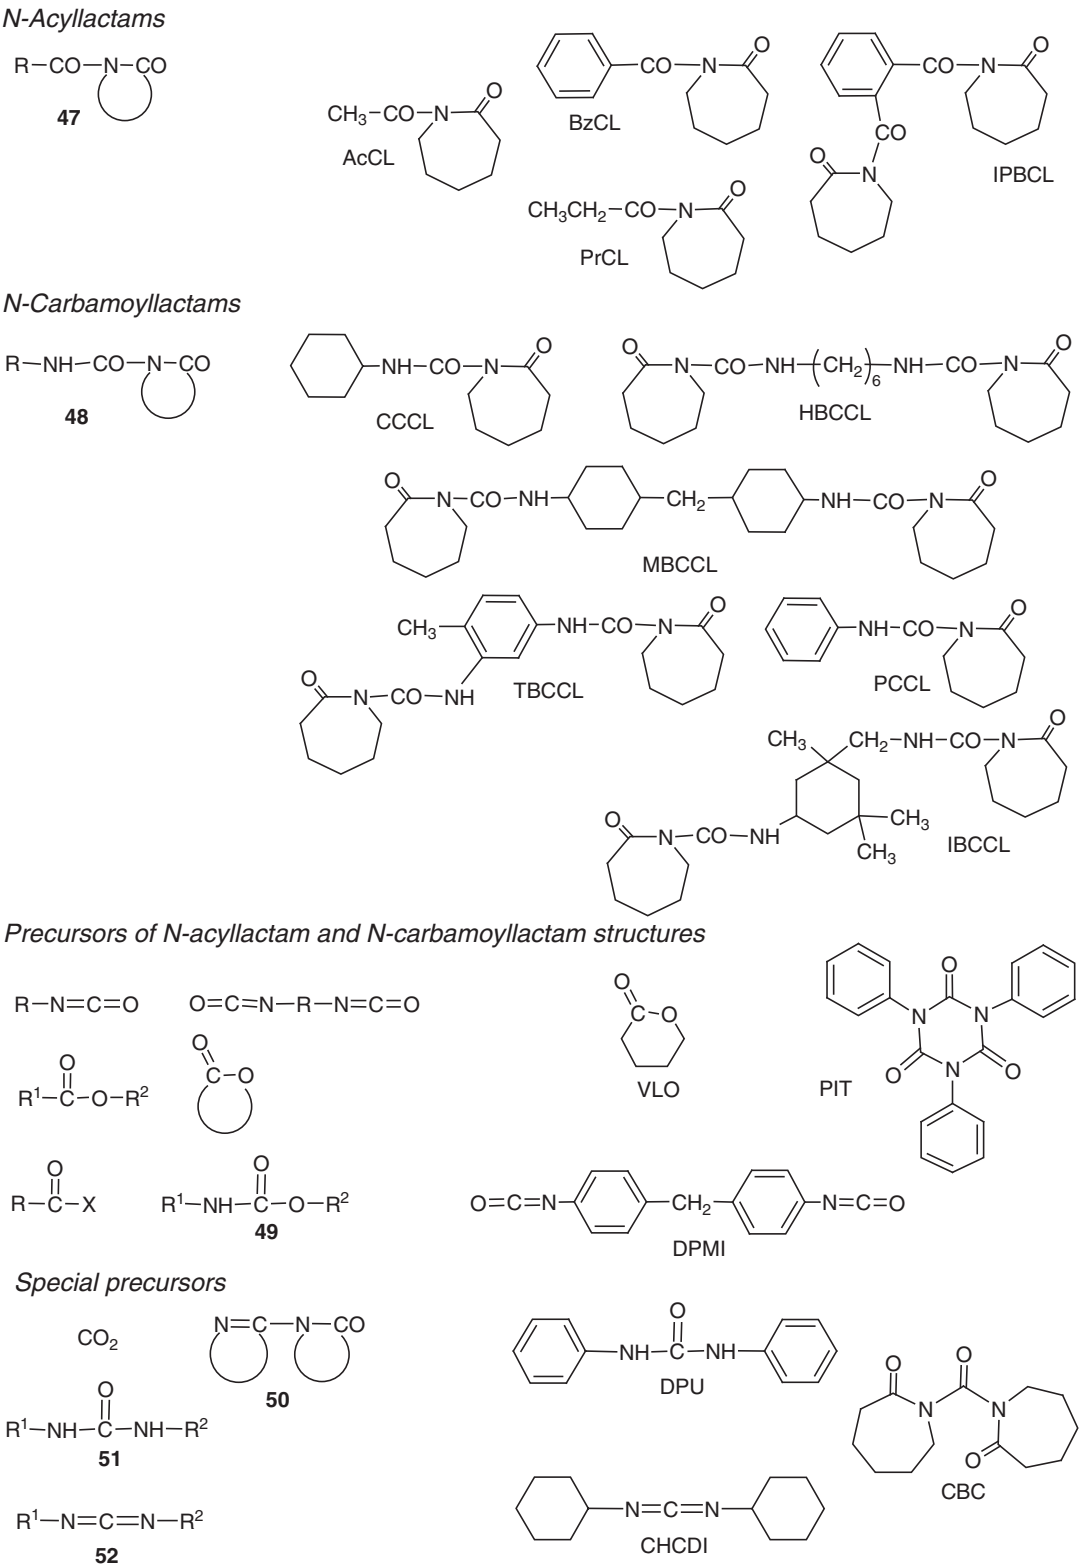
By far, the *N*-carbamoyl lactams (**48**) have proved to be the most efficient activators among those investigated, acting much more rapidly than do the *N*-acyl lactams.[160] A reason is the acidity of the carbamoyl group, significantly higher than that of lactam. Examples of monofunctional activators are PCCL and cyclohexyl carbamoyl-CL (CCCL), and examples of bifunctional ones are isophorone-bis(carbamoyl-CL) (IBCCL), 4,4′-methylene-bis(cyclohexyl carbamoyl-CL) (MBCCL), 2,4-toluene-bis(carbamoyl-CL) (TBCCL), and hexamethylene-1,6-bis (carbamoyl-CL) (HBCCL) (see Scheme 22).

The *N*-carbamoyl lactam can be prepared by reaction of lactam (generally CL) with carbamoyl precursors, e.g., the corresponding isocyanates [87]:



[87]

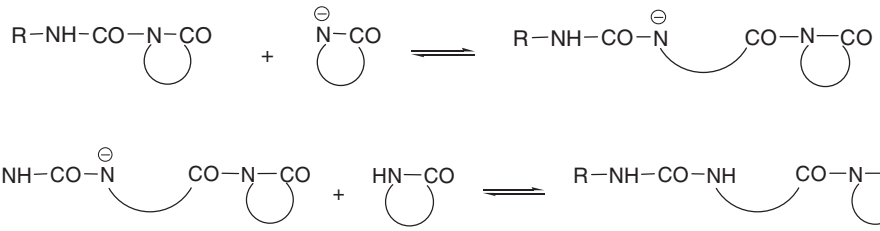
For instance, CCCL can be easily synthesized by reacting cyclohexyl isocyanate with CL under reflux in boiling anhydrous toluene and then removing the solvent by vacuum distillation. It is important to take into account that, contrary to the thermally more stable *N*-acyl-CLs, *N*-carbamoyl-CLs are



Scheme 22 Some examples of activators and precursors.

cleaved to give again free isocyanates and CL upon heating at 160–180 °C.[164,165]

Actually, it must be remarked that the isocyanate precursors (monofunctional, bifunctional, and also the trimer, PIT) can be used even directly without previous blocking with lactam, as they can react *in situ* with the monomer.[138] The propagation reaction using *N*-carbamoyl derivatives differs from that with *N*-acyl lactams in the first step (eqns [88] and [89]):



[88]

[89]

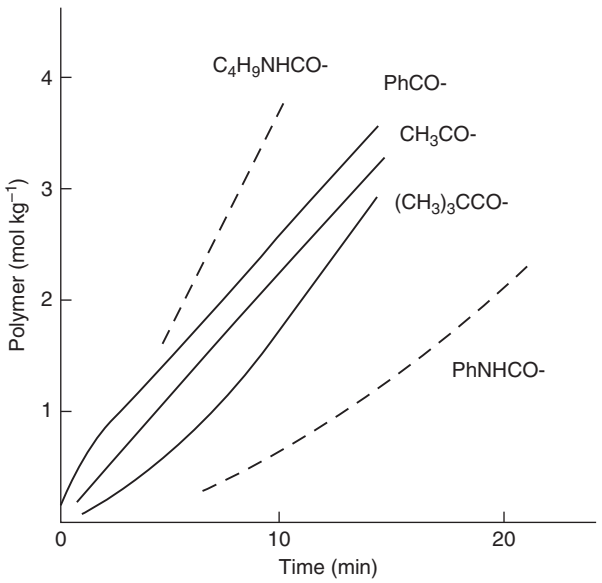


Figure 16 Effect of substituents in some *N*-acyl lactam (plain line) and *N*-carbamoyl lactam (dashed line) activators in the polymerization of CL with equimolar concentration of sodium ε-caprolactamate (0.0177 mmol kg^{-1}). Reproduced from Šebenda, J. In *Comprehensive Polymer Science*; Eastmond, G.; Ledwith, A.; Russo, S.; Sigwalt, P., Eds.; Pergamon Press: Oxford, UK, 1989; Vol. 3, Chapter 35, p 511,[9] with little modifications.

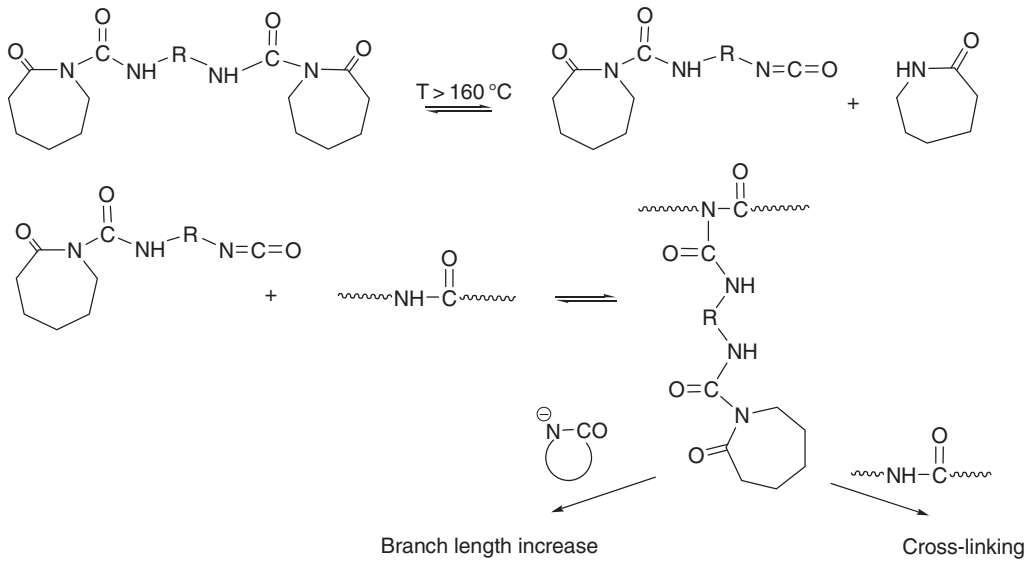
In fact, the resulting polyamide chain has a propagating end with an *N*-acyl lactam moiety and the other end with the structure of a disubstituted urea. On the contrary, using *N*-acyl lactams, the end groups are amides.

In general, aliphatic *N*-carbamoyl lactams (or aliphatic isocyanates) are more efficient activators than are their aromatic counterparts, using alkali metal ε-caprolactamates as initiators.[10] The cyclohexyl isocyanate and CCCL are indeed considered among the fastest ones.

The carbamoyl lactams can be successfully used in the 'very fast' anionic polymerization performed at relatively low temperatures, below the melting point of the resultant polyamide, in quasi-adiabatic or quasi-isothermal conditions (see Section 4.14.10 for the synthesis of PA6).

Several aliphatic carbamoyl-CLs are very fast activators and are able to reduce the polymerization time to less than 60 s for CL, even down to 18 s,[166] when the reaction conditions are optimized. With bifunctional activators, the increase of activator concentration brings about an increase of polymerization rate and conversion, as well as a major content of the cross-linked fraction.[157,167,168]

Indeed, at temperatures exceeding 160 °C, the deblocking reaction takes place, resulting in free isocyanate groups that can react with an amide functionality in the polymer chain to form a branch point (**Scheme 23**). Although these types of reactions occur for both mono- and difunctional carbamoyl-CL activators, the effect is more significant with difunctional activators owing to the fact that all chain ends remain active after



Scheme 23 Deblocking reaction and branch point formation.

branching enabling a further branch growth and a second branching reaction, resulting at the end in a 3D network structure.

The cross-linked fraction in anionic PA6 (determined as the percentage of polymer insoluble in 2,2,2-trifluoroethanol) increases with the increasing concentration of the bifunctional activator and with the [A]/[I] ratio, for example, when using the system HBCCL/CLNa. At the concentration ratio 0.60/0.30 (in mol.%), ~85% of cross-linked PA6 has been found, while at 0.45/0.90 and 0.15/0.60, the values were 9.7% and 3.5%, respectively.[157]

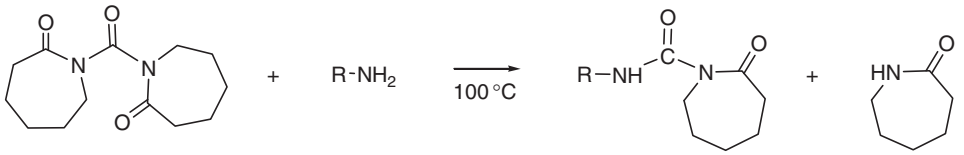
CCCL has been found to be particularly suitable for the anionic polymerization of CL in isothermal conditions at 150–170 °C, resulting in a PA6 in very high yields and almost completely free of structural defects (Section 4.14.10).[130] Indeed, the UV absorbance of PA6 prepared using CCCL as activator has shown a much lower content of structural irregularities and side products compared to those synthesized with other *N*-carbamoyl-type activators (**Figure 17**).

4.14.7.5.4 Precursors and special activators

4.14.7.5.4(i) Carbonyl bis-caprolactam

An isocyanate-free route to obtain carbamoyl derivatives implies the use of carbonyl bis-caprolactam (CBC®), a nontoxic solid compound commercialized by DSM and generally used as chain extender, coupling, and cross-linking agents.[169,170]

At temperatures around 100 °C, carbonyl bis-caprolactam can react with a primary amino group to give CL and *N*-carbamoyl-CL:[171]

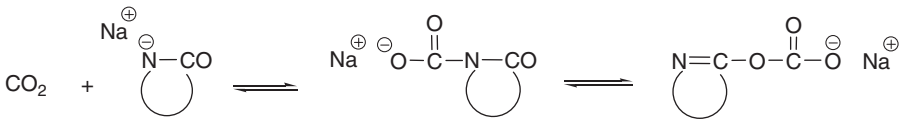


[90]

The carbonyl bis-caprolactam has been successfully employed for the first time as activator in CL polymerization in the 1990s by Mateva *et al.*[172–174] in combination with sodium ε-caprolactamate as initiator, for the production of PA6 and its copolymers. CBC capability as coupling agent also allows the preparation of hybrids, for example, inserting polyhedral oligomeric silsesquioxanes (POSS) in the PA6 matrix (POSS-PA6) by anionic polymerization.[175]

4.14.7.5.4(ii) Carbon dioxide

Carbon dioxide too has been used as activator in anionic lactam polymerization. In particular, it has been successfully employed in the polymerization of 2-pyrrolidone by Roda *et al.*[176,177] The introduction of gaseous CO_2 into the polymerization feed containing monomer and initiator causes the formation of two possible carboxylate growth centers, an N-carboxylate or an O-carboxylate (carbonate) [91], being not yet clarified which one has to be considered the most probable:



[91]

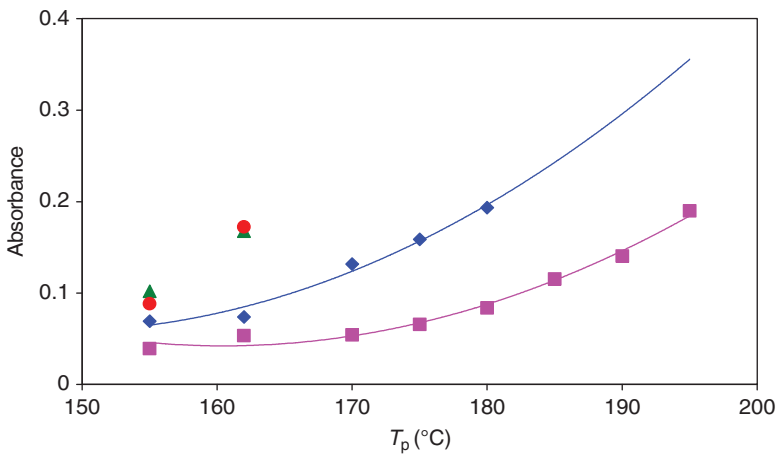


Figure 17 UV absorbance at the band maximum (270–280 nm) for polyamide samples polymerized using the following: ■, CCCL; ◆, HBCCL; ●, MBCCL; and ▲, IBCCL. Reproduced from Ricco, L.; Russo, S.; Orefice, G.; Riva, F. *Macromolecules* **1999**, *32*, 7726.[130]

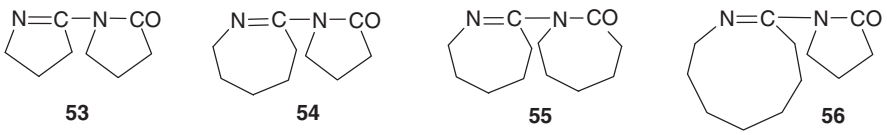
4.14.7.5.4(iii) N-iminolactams

Lactam anionic polymerization can be accelerated also by the addition of *N*-iminolactams (**50**), which have proved to exert a more efficient activity compared to carbon dioxide. A number of derivatives containing the acylamidine structure have been synthesized and tested, such as 1-(1-pyrrolin-2-yl)-2-pyrrolidone (**53**), 1-(1-azacyclohept-1-en-2-yl)-2-pyrrolidone (**54**), 1-(1-azacyclohept-1-en-2-yl)-1-azacycloheptan-2-one (**55**), and 1-(1-azacyclonon-1-en-2-yl)-2-pyrrolidone (**56**):



53 **54** **55** **56**

All of them have been studied in the anionic polymerization of CL, initiated with alkali metal lactam salts,[178] and have found a more suitable application in the polymerization of 2-pyrrolidone at 30–50 °C, initiated by potassium 2-oxopyrrolidin-1-ide.[179,180]

4.14.7.5.4(iv) Carbamates

Carbamates (**49**) can also be used as activators, yielding the *N*-carbamoyl lactam structure by reaction with lactamate (**Scheme 24**). The reaction has shown to hold an activation energy of 90 kJ mol^{-1}, comparable to that of *N*-acyl lactam and an order of magnitude lower than that of *N*-carbamoyl lactams.[10]

4.14.7.5.4(v) Esters and lactones

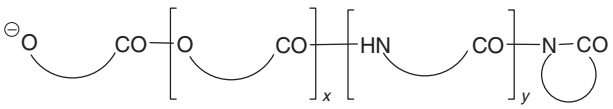
Aliphatic and aromatic esters show an activation effect in the anionic lactam polymerization[161,181] through a fast acylation of the lactam anion (already at 150 °C) with the formation of the corresponding *N*-acyl lactam growth center and of an alkoxy anion as by-product [92]. The reaction is followed by neutralization of the alkoxy anion [93]:

[93]

Similarly, lactones behave as efficient activators [94],[182] generally more active than the linear esters, with an apparent activation energy of about 80 kJ mol^{-1}:

[94]

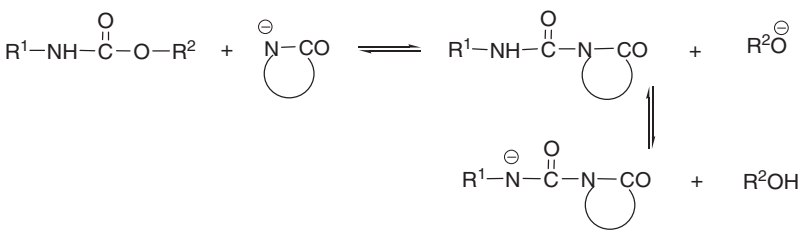
However, it must be taken into account that, in this case, the *N*-acyl lactam moiety acts as a growth center for the lactam polymerization, while the oxy-anion can initiate the lactone polymerization. Indeed, some lactones behave as activators if present at concentrations of up to 5 mol.%, while they act as comonomers at higher concentrations yielding copolymers poly(ester-co-amide)s (**57**) (Section 4.14.12.3):



57

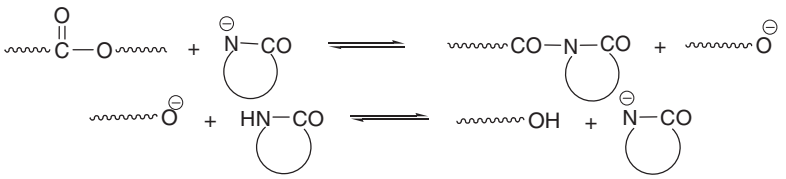
It has been demonstrated[181] that δ-valerolactone (VLO) and ε-caprolactone (CLO) are converted into the corresponding

[92]



Scheme 24 Reaction of carbamates and lactamates.

homopolymers in the first stage of the polymerization process and it is the ester group of the polyester chain that reacts with CL generating the growth centers for the formation of polyamide chains. Indeed, it is possible to accomplish the CL polymerization in the presence of poly(ε-caprolactone), acting with the esters groups in the macromolecular chain acting as indirect activators via transacylation reactions:[183]



[95]

[96]

With VLO and CLO, the polymerization has been shown[181] to proceed via a pseudo-living character (proved by the linear dependence of the degree of polymerization on the degree of conversion) and has been explained by the unusual balance between growth center formation, chain propagation, and side reactions. It has been calculated that less than 15% of the originally introduced lactone was responsible for the growth center formation.

A different behavior is correlated with the use of γ-butyrolactone, which does not homopolymerize and acts as a classical activator leading to a slower polymerization, lower polymer yield, and lower degrees of polymerization, mainly due to the presence of side reactions and the absence of transacylation reactions.[181]

It is noticeable that using the above lactones (e.g., VLO and CLO) as activators in the polymerization of CL, high degrees of conversion and high degrees of polymerization are achieved even for a 10-fold excess of activator over initiator (e.g., CLMgBr).[181]

4.14.7.5.4(vi) *N,N′-disubstituted ureas*

Disubstituted ureas (**51**), such as *N,N′*-diphenylurea (DPU), *N*-butyl-*N′*-phenylurea, and *N,N′*-dibutylurea, can be present in the anionic polymerization of CL either as additional activators referred to *N*-acyl lactams or as individual activators.[184]

As a matter of fact, urea moieties, as already mentioned, are present in anionic polymerizations activated by *N*-carbamoyl lactams or their precursors and in the synthesis of block copolymers when NH_2-terminated prepolymers are functionalized by isocyanates. When the substituted ureas are used as activators, two initiation mechanisms are possible. In the first route (**Scheme 25**), the thermal dissociation of the urea gives amine and isocyanate, followed by addition of the latter to lactam:

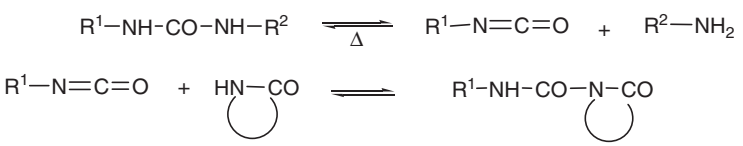
while in the second route (**Scheme 26**), the urea directly produces acylation of the lactam (or the lactam anion):

The number of reactions involved by *N,N′*-disubstituted ureas in the anionic polymerization of CL is relevant and their effects on the resulting polyamide are complex. The rate of the urea-activated process is an order of magnitude lower than that activated by *N*-acyl lactams.

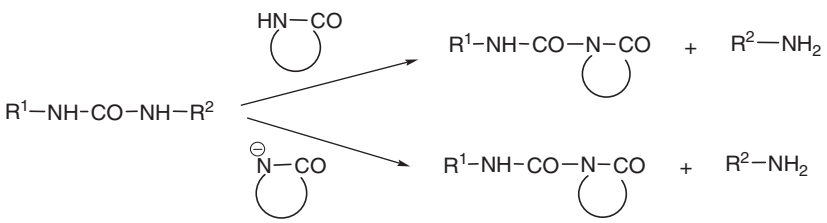
It has been found[184] that in the case of CL, using its sodium salt as initiator and ureas as activators, the polymerization rate increases with the increasing relative acidity of the latter. The acidities of the dialkylureas are similar to that of the monomer, while those of aromatic ureas are much higher. Thus, the polymerization rates change following the sequence: *N,N′*-diphenylurea > *N*-phenyl-*N′*-butylurea > *N,N′*-dibutylurea.

It is remarkable that, contrary to what typically happens when using *N*-acyl lactams and *N*-carbamoyl lactams, the number of polymer chains formed from each urea molecule has been found to be in all cases higher than unity, being approximately 1.3, thus showing that additional growth centers are generated.

Interesting results have been attained using urea as an additive in the anionic polymerization of CL activated by AcCL: a strong acceleration of the polymerization rate has been



Scheme 25 Thermal dissociation of substituted ureas and subsequent blocking of isocyanate group.



Scheme 26 Direct acylation of lactam or lactamate by substituted ureas.

observed, more than would have been expected from their independent activity. This synergistic effect has been ascribed to both the suppression of side reactions by controlling the system basicity (due to the urea intrinsic acidity) and the formation of additional growth centers.[184]

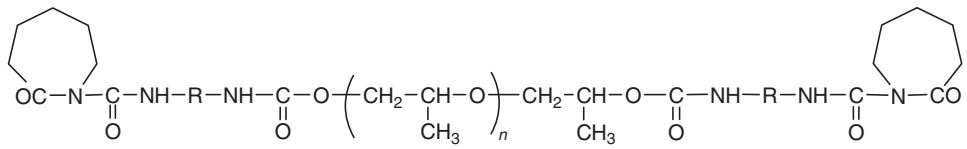
4.14.7.5.4(vii) Carbodiimides

Carbodiimides (**52**) have been used in a stable liquid system[185] in which the activator (e.g., the N-cycloalkyl carbodiimide, CHCDI) and the initiator (e.g., sodium ε-caprolactamate) are present in an aprotic solvent (e.g., 4,4,5-trimethylimidazolidin-2-one) and mixed with the monomer during processing. Such a system has the major advantage of permitting prolonged storage of the reactants and is particularly well suited for the liquid molding of polyamide composites. It has been successfully employed in the polymerization of ω-laurolactam (Section 4.14.11.3).[186]

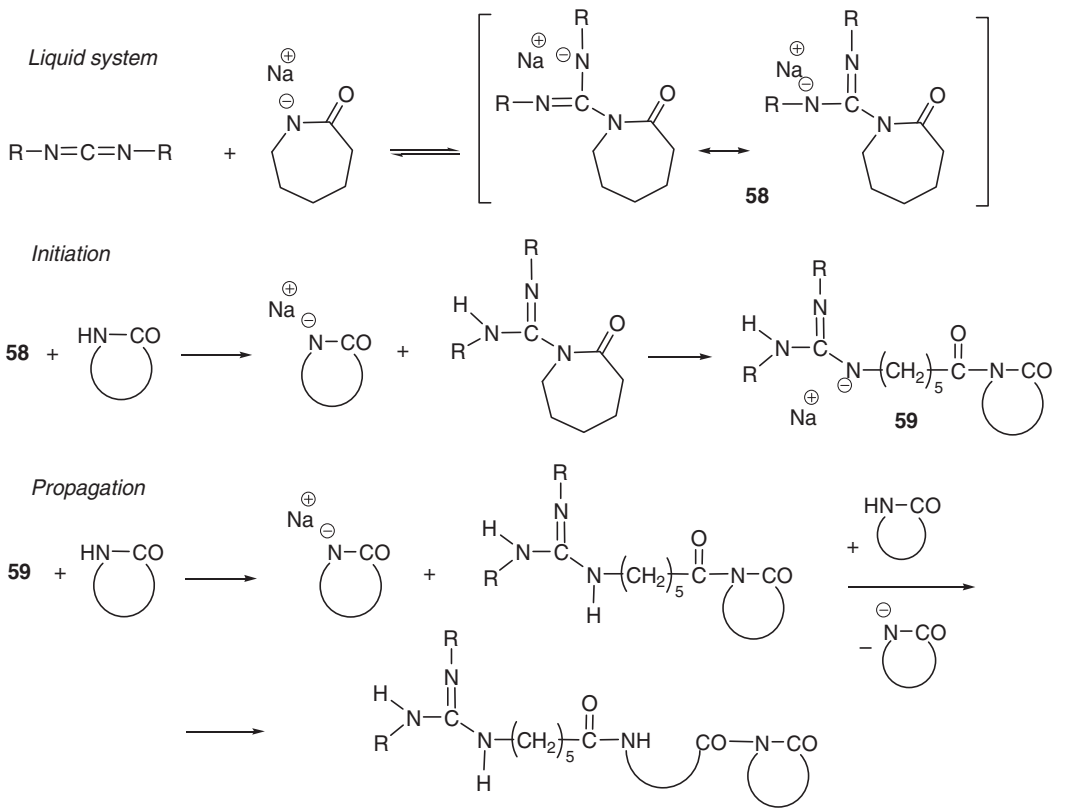
The reaction between the above carbodiimides and the sodium caprolactamate takes place in part in the liquid system, producing a resonance-stabilized guanidine anion (Scheme 27). In the initiation of the polymerization, the guanidine anion reacts with the lactam monomer by a proton exchange reaction giving the lactam anion, the actual polymerization initiator. Then, acylation of lactamate occurs, causing cleavage of the CO–N bond with ring opening and reformation of the N anion in the guanidine derivative. The strong resonance stabilization of N anions favors the addition of monomer. Then, repeated proton exchange reactions and nucleophilic additions constitute the subsequent propagation step.

4.14.7.5.5 Macroactivators

When a functional group capable of behaving as an activator or a precursor is linked to a polymer chain, the latter is identified as macroactivator or polymeric activator. The anionic polymerization of lactams using macroactivators is a suitable method for the synthesis of block copolymer (Section 4.14.12.4) incorporating, for example, soft blocks in the main polyamide block. Hydroxy-terminated polymers, such as polyethers (e.g., PPO) with terminal –OH groups, can be reacted with diisocyanates (e.g., isophorone diisocyanate) leaving a free isocyanate group linked to the polymer. This isocyanate-terminated polymer can be used directly as macroactivator or may be previously blocked by reaction with CL to obtain the carbamoyl lactam derivative (**60**):

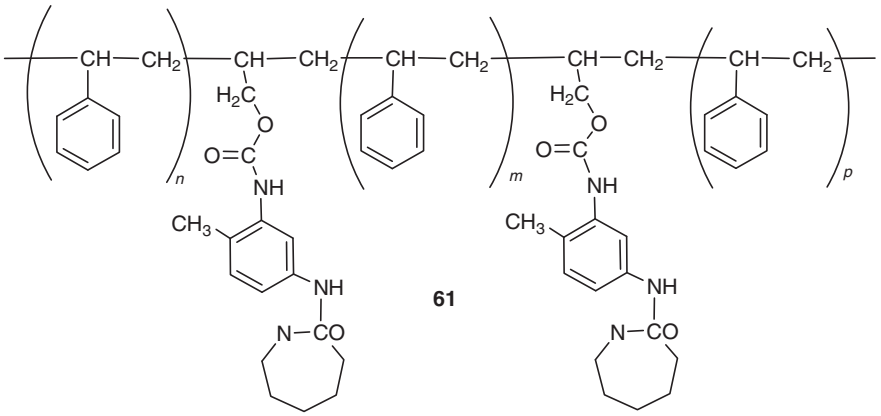


60



Scheme 27 Reaction pathway of the carbodiimide – sodium caprolactamate liquid system.

Following a similar approach, various polymeric activators bearing pendant functionalities can be synthesized in order to give rise to graft copolymers. For example, a macroactivator with pendant ester,[187,188] or imide,[189] or isocyanate,[190] or maleic anhydride groups[191] can be prepared in order to obtain the growth of grafted polyamide chains onto the macroactivator backbone. In another example, in order to obtain a PS-*g*-PA6 graft copolymer, a macroactivator formed by an isocyanate-bearing polystyrene (PS) backbone has been prepared using a copolymer of styrene and 3-isopropenyl-α,α-dimethylbenzene isocyanate, synthesized by radical polymerization.[192] To overcome the drawbacks associated with to the use of isocyanates, the synthesis of a macroactivator with pendant *N*-carbamoyl lactam moieties seems a better method. Following this approach, poly(methyl methacrylate) (PMMA)- or PS-based macroactivators have been prepared by copolymerization with comonomers bearing *N*-carbamoyl caprolactam functionalities **(61)**:[193]



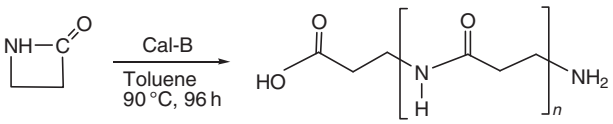
61

4.14.8 Enzymatic Polymerization

Poly(β-alanine) (PA3) cannot be obtained by chemically initiated ROP of the unsubstituted azetidin-2-one (β-lactam), but only by anionic isomerization polymerization of acrylamide.[194] The latter synthesis, however, generally leads to structurally irregular polyamide 3.[195] On the contrary, the polymerization of β-lactams may be accessible by novel enzymatic routes.

Enzymatic polymerization has emerged in the last few decades as a field of considerable interest and commercial promises. It proceeds with high regio-, enantio-, and chemoselectivity under relatively mild conditions. So far, enzymes have been used to synthesize polyesters, polysaccharides, polycarbonates, polyphenols, polyanilines, vinyl polymers, and poly(amino acid)s.[196,197] Namely, the lipase B of *Candida antarctica* (Cal-B, a serine hydrolase) immobilized on polyacrylic resin (Novozyme 435) has proven to be a very versatile catalyst in terms of reaction conditions and acceptance of various substrates. For example, this enzyme has been successfully used to synthesize polyesters.[198–202] However, little has been reported so far on the synthesis of polyamides catalyzed by enzymes.[203]

The enzyme-catalyzed ROP of azetidin-2-one to give unbranched poly(β-alanine) has only recently been achieved.[204] The synthesis has been conducted in toluene at 90 °C using Cal-B, immobilized on Novozyme 435 [97]:



[97]

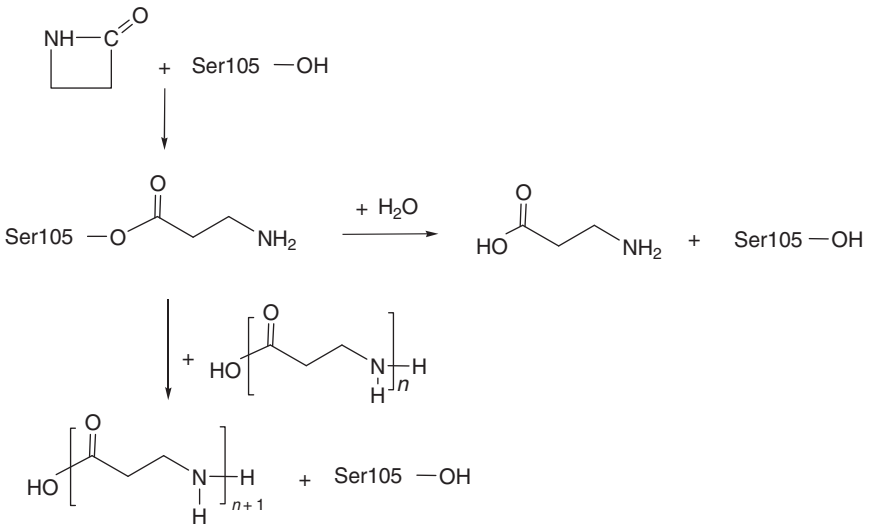
Linear poly(β-alanine) of low molar mass has been obtained. The rather low-average DP of the polymer (DP = 8) has been related to its poor solubility in the reaction medium. The proposed mechanism (**Scheme 28**) involves the participation of water. Indeed, although the reaction is carried out under essentially anhydrous conditions, water is never removed completely, as it is always present as the structural water of the enzyme.

The polyamide formation initially follows the enzymatic acylation of Ser105 by β-lactam. The reaction of the acyl-enzyme intermediate with water releases β-alanine, and the reaction with the growing oligomer yields poly (β-alanine). It has been shown that this mechanism is applicable only to ß-lactam and not to ß-alanine polymerization.[205]

4.14.9 Spontaneous Polymerization

The spontaneous polymerization of lactams, also referred to as 'autopolymerization', identifies the process in which no initiator is intentionally added. It has been observed to occur only at high temperatures and proceed at very low reaction rates. Purified anhydrous CL has been reported to start a slow polymerization after heating for a considerable time above 250 °C.[206]

The same is valid also for η-caprylolactam at 240 °C[207] and ω-laurolactam at 280 °C.[208] The polymerization mechanism has not been completely clarified and many doubts yet remain on the consistency of the hypothesis that has been postulated. Amine groups and structures easily hydrolyzable to carboxyl groups (e.g., imides) have been found to be present in the polymerization product.[207] A considerable amount of cyclic oligomers have also been detected. Aminoacyl lactams, formed



Scheme 28 Reaction pathway in the enzymatic formation of poly(b-alanine) from unsubstituted azetidin-2-one.

by a disproportionation reaction similar to that occurring in the cationic polymerization, have been assumed to be present.[209] Polymerization has been suggested to proceed by bimolecular aminolysis of aminoacyl lactams and/or aminolysis of lactams. The intramolecular cyclization of the aminoacyl lactams has been assumed to give rise to the cyclic oligomers. The activation energies for the autopolymerization of CL, η-caprylolactam, ω-laurolactam, and for the autocopolymerization of the pair CL–ω-laurolactam have been calculated.[210]

However, it must be underlined that a small amount of water still remains in lactam monomers even after a drying procedure. This content of residual water may be the agent able to initiate lactam polymerization.[211]

4.14.10 Anionic Polymerization of CL

4.14.10.1 Overview

The anionic lactam polymerization will be herein described with reference to the most important and most studied member of the class, CL. Since its discovery, CL anionic polymerization has been explored in depth under a great variety of experimental conditions that very strongly affect the development of the reaction and the characteristics of the resultant polymer. The complexity of the role played by the various reacting species and their mutual influence, together with the effects of both the polymerization temperature and the reaction rate on kinetic evolution and established equilibria, has not enabled so far to draw a clear and general picture of CL anionic polymerization, especially when it is carried out in bulk. A first classification of its polymerization can be based on the overall kinetics of the reaction, which can be depicted as 'very fast', 'fast', or 'slow' depending on somewhat arbitrary evaluations. Generally speaking, it can be assumed that a 'very fast' polymerization reaches completion in less than 60 s, while a 'slow' process can take several minutes and even some tens of them. 'Fast' polymerizations are those running for intermediate times, that is, ~1–2 min. Several factors can influence the polymerization rate of CL in the bulk: (1) nature of activator and its concentration; (2) nature and concentration of initiator; (3) initial polymerization temperature T_0; and (4) isothermal, nonisothermal, or adiabatic conditions, with the specific temperature profiles of these latter. 'Very fast', 'fast', or 'slow' processes, on the other hand, strongly affect structure and properties of the resultant anionic PA6. Namely, a proper choice of the initiating pair (activator and initiator), together with suitable experimental parameters ($T_0 \leq 170\,^{\circ}C$, quasi-isothermal conditions), allows to obtain PCL almost completely free of structural defects, such as branching or cross-linking, and color centers.

The activated polymerization of CL, carried out in the bulk, can run almost adiabatically due to the high rates and the poor heat exchange with the surroundings. A temperature rise of up to 52 °C is theoretically predicted and experimentally observed when polymerization starts at 150–155 °C and is followed by crystallization.[11] In quasi-adiabatic conditions, with 'very fast' activators and a starting temperature of ~155 °C (increasing up to ~205 °C), low residual monomer content, low cyclic oligomers, and high molar masses of the resultant polyamide have been achieved.[160] Since the occurrence of side reactions, such as Claisen-type condensations (Section 4.14.7.2), is not only caused by the strong basicity of the reaction medium but also highly favored by the temperature increase due to the lack of dispersion of the polymerization heat, much more interesting results have been obtained by the 'very fast'-activated polymerization run in quasi-isothermal conditions.[130]

Indeed, in quasi-isothermal polymerization processes carried out at relatively low temperatures (150–160 °C) with 'very fast' activators, the presence of side reactions is minimized. A comparison of different polymerization processes, using various types of activators is shown in **Table 10**. The polymerization times and the UV absorbances (Section 4.14.7.2) of polymers synthesized using various types of activators (i.e., slow, fast, and very fast) are reported.

The high reaction rates derived from the use of 'very fast' activators made it possible to realize a quasi-isothermal

polymerization of CL in suspension or in emulsion with a good dissipation of the reaction heat. This topic will be described in detail in Section 4.14.13.2.

Furthermore, the fast cycle times of the activated anionic ROP made this latter amenable to RIM processing, where the anionic PCL and its copolymers have foreseen for several years the potential for their most widespread industrial applications (Section 4.14.13.3). In the following sections, a description of what now appears well established will be provided, with some specific mention of the most reliable kinetic approaches to describe anionic bulk polymerization of CL, as well as the relevant role of initiator and activator concentrations in terms of monomer conversion, high polymer yield, content of cyclic oligomers, and side products. Namely, the formation of cyclic oligomers and higher cyclic species during the anionic polymerization will be described in detail in the light of very recent findings.

4.14.10.2 Kinetic Approaches in the Bulk Polymerization

As shown in other sections of the present chapter, the anionic ROP of CL in the bulk involves a great number of reversible and irreversible reactions (including side reactions) in which, depending on the chosen experimental conditions, the active species are continuously destroyed and reformed. Therefore, any kinetic approach, based on an oversimplified scheme of the reaction chemistry involved in order to model the polymerization pattern, will lead to very questionable conclusions.

So far, after many attempts to apply mechanistic models to interpret anionic polymerization kinetics of CL with very limited success,[148] the above models have been almost completely abandoned in favor of phenomenological approaches, among which the most successful has been the autocatalytic model of Malkin *et al.*[212]

Malkin's model has been put forward to describe the nonisothermal kinetics of both CL and ω-laurolactam anionic polymerizations in bulk, monitoring the temperature rise inside the reactor. The heat balance is given by the following differential equation:

$$\frac{dT}{dt} + \left(\frac{UA}{cm}\right)(T - T_w) + \left(\frac{\Delta H_p}{c}\right)\frac{d\lambda}{dt} = 0 \qquad [98]$$

where T is the temperature inside the reactor; T_w is the wall temperature; U is the overall heat transfer coefficient; A is the surface of the reactor available for heat exchange; c is the specific heat of the reacting system; m is the total mass; ΔH_p is the enthalpy of polymerization ($-140\ kJ\ kg^{-1}$ for CL); and λ is the degree of conversion.

Hence

$$\frac{d\lambda}{dt} = -\left(\frac{c}{\Delta H_p}\right)\left[\left(\frac{dT}{dt}\right) + \frac{(T - T_w)}{\tau}\right] \qquad [99]$$

$\tau\ (= cm/UA)$ is the time constant of the system and is evaluated from a separate set of experiments. For strictly adiabatic conditions, the term $(T - T_w)$ of eqn [99] is equal to zero. Applied to both nonisothermal and quasi-adiabatic polymerization conditions, Malkin's model fits a more or less large amount of data for the activated CL polymerization in bulk, on the basis of the following equation:

$$\frac{d\lambda}{dt} = k\frac{[A]^2}{[M]}(1 - \lambda)\left(1 + \frac{b\lambda}{[A]}\right)\exp\left(-\frac{E_a}{RT}\right) \qquad [100]$$

where $[A]$ is the activator concentration; $[M]_0$ is the initial monomer concentration; E_a is the activation energy ($63 \pm 6\ kJ\ mol^{-1}$); k is the front factor reflecting the reaction rate; and b is the autocatalytic term characterizing the intensity of the self-acceleration effect during chain growth.

Both k and b depend on the chosen activator. For $\lambda << 1$, that is, at the initial stage of polymerization, the value of k can be easily evaluated. Namely, Macosko *et al.*[135] have found that Malkin's model was in very good agreement with their data for both neat CL polymerization and its copolymerization with 16 wt.% of OH-terminated poly(propylene oxide) (PPG) end-capped with hexane-1,6-diyl diisocyanate (HDI).

A summary of Macosko's results is given in **Table 11**, adapted from Reference 213, while **Figure 18**, also taken from Reference 213, shows the adiabatic temperature rise data for the block copolymer formation and the excellent agreement with Malkin's model. The additional temperature rise at longer times is due to polymer crystallization, underlining that the two phenomena, polymerization and crystallization, can be kept well separated by choosing proper experimental setup, thus, avoiding any superposition effect.

The analysis of the thermal balance in transient conditions can be performed with acceptable accuracy on the basis of the simple equation [99] only when the Biot number, a dimensionless parameter used in transient heat transfer calculations, is much smaller than 1.[214] In that case, heat conduction inside the body is implied to be much faster than convection away from its surface, and thermal gradients in the body are negligible.

The autoacceleration in the activated anionic polymerization of CL has been tentatively attributed, as already mentioned (Section 4.14.2.2.2), to the much higher dielectric permittivity of the resultant polymer (PA6), as compared to that of the monomer.[75] This difference is not present in the anionic polymerization of ω-laurolactam. The permittivity difference seems to be linked to the different configurations of the amide group in the monomer (*cis*) and in the polymer (*trans*) for lactams having less than ten ring atoms.

4.14.10.3 Role of Activator and Initiator Concentrations

In the anionic ROP of CL, the influence of activator and initiator concentrations [A] and [I], respectively, as well as their ratio [A]/[I], has been extensively explored by Russo *et al.* both in 'slow'[129,215] and 'very fast'[157,160] polymerizations. Regardless of the chosen conditions, a 1:1 equivalent ratio between the functional groups of the activator and the initiator has always been found as a necessary prerequisite for optimizing high polymer yield and properties, as well as minimizing the formation of oligomers and side products.

As an example, kinetic data obtained from 'slow', quasi-adiabatic CL polymerization, using *N*-acetyl-CL as activator and sodium ε-caprolactamate as initiator, are given in **Table 12** taken from Reference 129, in terms of overall polymerization time t_p and the initial as well as the maximum rate of polymerization. For [A] = [I], an asymtotic decrease of t_p down to slightly more than 3 min for I = 0.9–1.5 mol. % was observed.

For the same 'slow' system and the same equimolar conditions, **Figure 19**, taken from Reference 215, shows additional data in terms of monomer conversion, high polymer yield, and content of both cyclic oligomers and side products. It is evident that the best balance is provided by A = I = 0.6–0.7 mol.% and that their nonequimolar ratios (filled circles in the figure) determine a lowering of the high polymer yield.

Symp.* **1986**, *6*, 207.[215]

Analogously, UV-absorbing species, which can be considered a useful indication of the relevance of side reactions, are already present to a much greater extent in the anionic PA6 samples prepared from nonequivalent concentrations of activator and initiator (**Figure 20**, lines a, b, c, d).[129] The red straight line in the same figure represents

UV absorption of anionic PA6 samples prepared with [A] = [I].

Similar results have been obtained[157] in 'very fast' polymerizing systems, using a bifunctional activator (HBCCL). For a molar ratio of [A]/[I] = 1:2 and I = 0.9 mol.%, t_p as low as 24 s has been found (see **Table 10**). Obviously, by increasing the concentration of initiator, that is, by increasing the basicity of the medium, a higher extent of side reactions is observed (**Figure 21**).[129]

4.14.10.4 Cyclic Oligomers and Cyclic Species

Besides linear homologs and high polymer chains, in polycondensation reactions and in the ring-opening polymerization of heterocyclic monomers, sizeable amounts of cyclic oligomeric species are frequently found in the polymerization products. Namely, in CL polymerization, the formation of low-mass cyclic species has great relevance in terms of reaction kinetics and mechanism, as well as polymer properties. Irrespective of the polymerization mechanism, the linear oligomer content is an order of magnitude lower than the corresponding value for each cyclic species and its formation is usually not taken into consideration.[216]

In contrast to CL hydrolytic polymerization, in which a thermodynamic equilibrium is established in most cases among linear macromolecular chains, monomer, and higher (cyclic and linear) oligomers, the anionic route is very often under stringent kinetic control. In this respect, the residual monomer content, which is ~7–8 wt.% in hydrolytic polymerization, can be far below the value predicted on the basis of thermodynamic considerations (~3 wt.%) and, depending on the reaction conditions chosen, found to be as low as ~1 wt.%[217] or even less,[160] as shown in **Figure 22**.

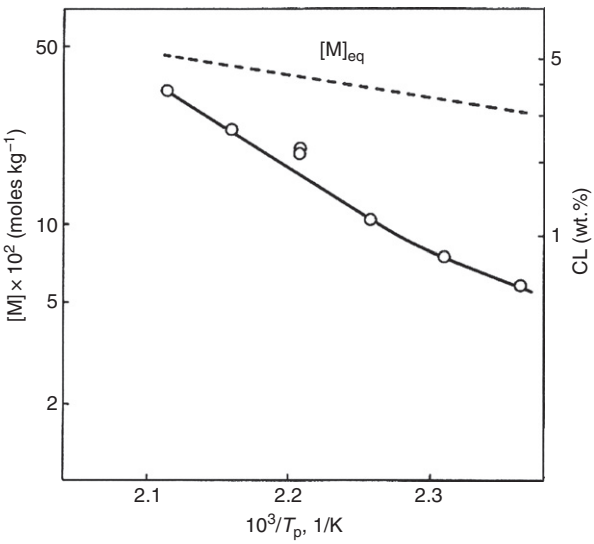

Figure 22 Residual CL content (experimental points) and equilibrium monomer concentration ($[M]_{eq}$, data from Reimschuessel, H. K. In *Ring-Opening Polymerization*; Frisch, K. C.; Reegen, S. L., Eds.; Dekker: New York, 1969; Chapter 7, p 303.[11]) as functions of $1/T_p$. Reproduced from Russo, S.; Biagini, E.; Bontà, G. *Makromol. Chem. Macromol. Symp.* **1991**, *48/49*, 31.[160]

Analogously, as far as higher cyclic oligomers are concerned, the most relevant reaction parameters able to affect their formation are the following:

1. quasi-adiabatic polymerization conditions or controlled polymerization temperature;
2. 'very fast' or 'slow' activators;
3. type and concentration of both initiator and activator; and
4. stoichiometric ratio of their active groups.

Each of the above parameters, alone or in combination with some of the others, can widely modify the overall content of cyclic oligomers and their relative composition. As pointed out by Roda,[10] when the total amount of extractables made of monomer, higher oligomers, and other low-mass species derived from side reactions (quite often present in anionic runs) exceeds 2–3 wt.%, both the processing and the end properties of PCL are negatively affected. Under suitable conditions, the anionic polymerization of CL can be performed in such a way to keep the above amount below that limit, thus avoiding expensive post-treatments of PA6 purification. As mentioned above and described in detail in Section 4.14.7.2, several side products in more or less relevant amounts are usually formed during the anionic polymerization of CL and contribute to make the description of the whole polymerization process very complex. Indeed, the concurrent presence of side reactions can not only affect the isolation, detection, and proper evaluation of cyclic oligomers but also interfere with their formation and reactivity.[7,9] It has been described in Section 4.14.7.2 that relevant amounts of low-molar-mass side species are produced if one or more of the following reaction conditions are established: (1) the reaction temperature exceeds ~170 °C irrespective of the polymerization conditions (isothermal, nonisothermal, or quasi-adiabatic runs); (2) the basicity of the reaction medium is too high due to the type and concentration of initiator; and (3) the polymerization rate is rather 'slow'. At present, the prevailing opinion is that the production of side products can be strongly limited only when the anionic polymerization of CL is carried out in the presence of both 'very fast' activators and quasi-isothermal conditions at $T_p \leq 170$ °C (preferably, at ~150 °C). Only the data from the above set of reaction parameters allow to evaluate the absolute and relative amounts of the main polymerization products (linear PA6 chains and rings) in a very accurate manner and in more detail, without the strong negative interference of side reactions.

As will be seen in the following, even the most recent studies on cyclic oligomer formation in CL anionic polymerization have been quite often carried out without considering the drawbacks and limitations outlined above and caused by experimental conditions, far from the optimum, that have been chosen. Only a few studies on cyclic oligomer formation during the anionic polymerization of CL have explored the role of activators and initiators, with specific attention to the kinetics and mechanism of individual cycle formation.[11,12,145,217] The above studies have attempted to correlate the extent of cyclics and some of the following parameters: (1) type and duration of the anionic polymerization (i.e., activated or nonactivated, 'very fast', 'fast', or 'slow'); (2) thermal histories during and after polymerization (e.g., annealing temperatures and times); (3) crystallinity degree of the resultant polymer; and (4) cyclization constants from equilibrium considerations.[218] However, a further word of caution is necessary, as the various interpretations of the experimental results have been based so far on extraction procedures and extractable analyses that have been questioned in recent years.[219] Following the recent findings of the latter researchers, the most widely used extraction techniques (by boiling water or boiling methanol) are not able to quantitatively remove the whole oligomeric fraction but only the lowest molar-mass species (monomer, dimer, and trimer). Of course, the extraction efficiency has been found to be progressively reduced as a function of the cycle size. Therefore, the content of cycles higher than the trimer, when evaluated by extraction techniques, can be underestimated and their relative ratios, namely those customarily referred to the cyclic dimer, affected by more or less relevant errors. Even the seldom used and time-consuming dissolution/precipitation methods do not allow a full recovery of cyclic oligomers except for cycles up to hexamer/heptamer. A sizeable amount of higher oligomers is retained, with the net result to remarkably affect conclusions and comparisons often present in the literature (kinetically driven processes vs. thermodynamic equilibrium data; agreement or disagreement with Jacobson–Stockmayer theory,[218,220,221] etc.). On these grounds, published data on cyclic oligomer formation during the anionic polymerization of CL, in addition to the role of the chosen conditions of synthesis ('slow' or 'fast' or 'very fast' polymerization, quasi-adiabatic vs. quasi-isothermal conditions), are also strongly dependent on the analytical procedure used (extraction, dissolution/precipitation, direct high-performance liquid chromatographic (HPLC) methods without sample isolation, etc.), as well as the upper limit of ring size chosen by the analytical setup.

No studies able to draw a general and conclusive picture of the relevant aspect of cyclic oligomer formation have been published so far. Ueda *et al.*[217] performed an HPLC analysis only up to the cyclic hexamer, after a 'slow' activated anionic polymerization carried out for very long times (between ~6.5 and 60 h) at 150 °C in conditions approaching the isothermal ones, followed by boiling water extraction for 5 h. Roda's group[145] performed a 'very slow' nonactivated polymerization at 190 °C for times between ~3 and 400 h in quasi-isothermal conditions, followed by repeated boiling methanol extraction and HPLC analysis up to the pentamer only. In previous years, Russo's group carried out both a 'slow' anionic polymerization of CL in quasi-adiabatic conditions[215] (initial T_p 155 °C; final T_p ~205 °C) and a 'fast' one in quasi-isothermal conditions at 160 °C, in bulk and in suspension, followed by boiling water extraction and HPLC up to the nonamer.[160] Most of the above studies and the few others already existing in the literature have shown a monotonic decrease of the individual cyclic oligomer content from the dimer to the highest species detected. However, in more recent years, when the new analytical procedures enabling to determine the exact content of individual oligomers have been applied to anionic PCL, a completely different trend has been found, at least for quasi-isothermally synthesized polymers.[222,223] Instead of a regular, monotonic decrease of the cyclic oligomer content as a function of its size, it has been found[223] that, as given by the matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) spectrum of **Figure 23** for a specific sample of anionic PCL, a sharp increase in the higher oligomer content from the hexamer up to the undecamer occurs with a maximum for this latter. After this maximum, higher cyclic oligomers up to $(CL)_{19}$ have been detected and their content follows a more or less regular decrease.

The cyclic undecamer (molecular mass 1244,8), present as the most abundant species in MALDI-TOF, has also been detected by Size Exclusion Chromatography (SEC) (**Figure 24**) as the maximum of a distinct peak in the low-molar-mass region, well separated from the high polymer trace. HPLC analysis of the cyclic oligomer fraction up to the undecamer for another anionic PA6 sample not previously

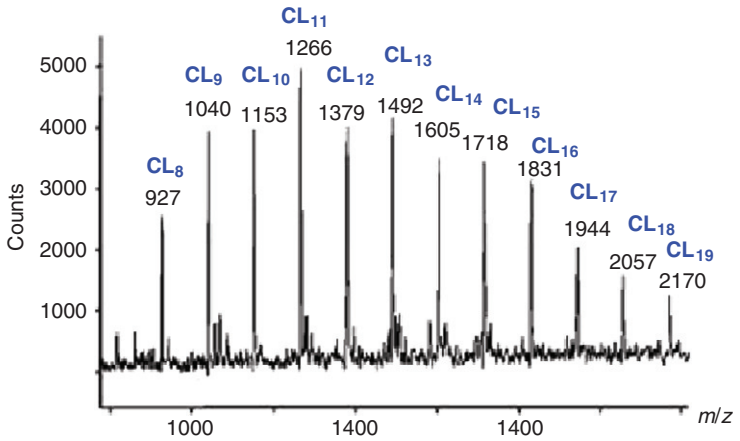

Figure 23 MALDI-TOF spectrum of an anionic PCL sample in the low-molar-mass region. The series of peaks at *m/z* values *n*113 + 23 corresponds to the Na^+ ions of the cyclic oligomers (C_x). Reproduced from Ricco, L.; Casazza, E.; Mineo, P.; *et al. Macromolecules* **2008**, *41*, 3904,[223] with little modification.

washed with methanol confirms the presence of unpredicted high concentrations of cyclics with a peak maximum corresponding for this sample to the nonamer, as given in Table 13 and Figure 25.

The series of intense peaks at *m/z* values *n*113 + 23 in MALDI-TOF spectrum corresponds to Na^+ ions of cyclic oligomers of PA6 from hexamer (peak at *m/z* 701) up to nonadecamer (at *m/z* 2170). Peaks due to species with higher molar mass are also present, but with very low intensity. The peaks indicated in the spectrum with # (at *m/z* values *n*113 + 39) are due to cyclic oligomers detected as K^+ species.

From the above data it is evident that, depending on the experimental conditions chosen for the anionic polymerization, the low-molar-mass peak, always present in anionic PA6 at 2–3 wt.% concentration and made of macrocycles from the octamer up to approx. $(CL)_{25}$, has a maximum that can be slightly displaced toward other mass values. The finding of the above peak just in recent years is probably linked to the experimental difficulties in the realization of SEC analyses of

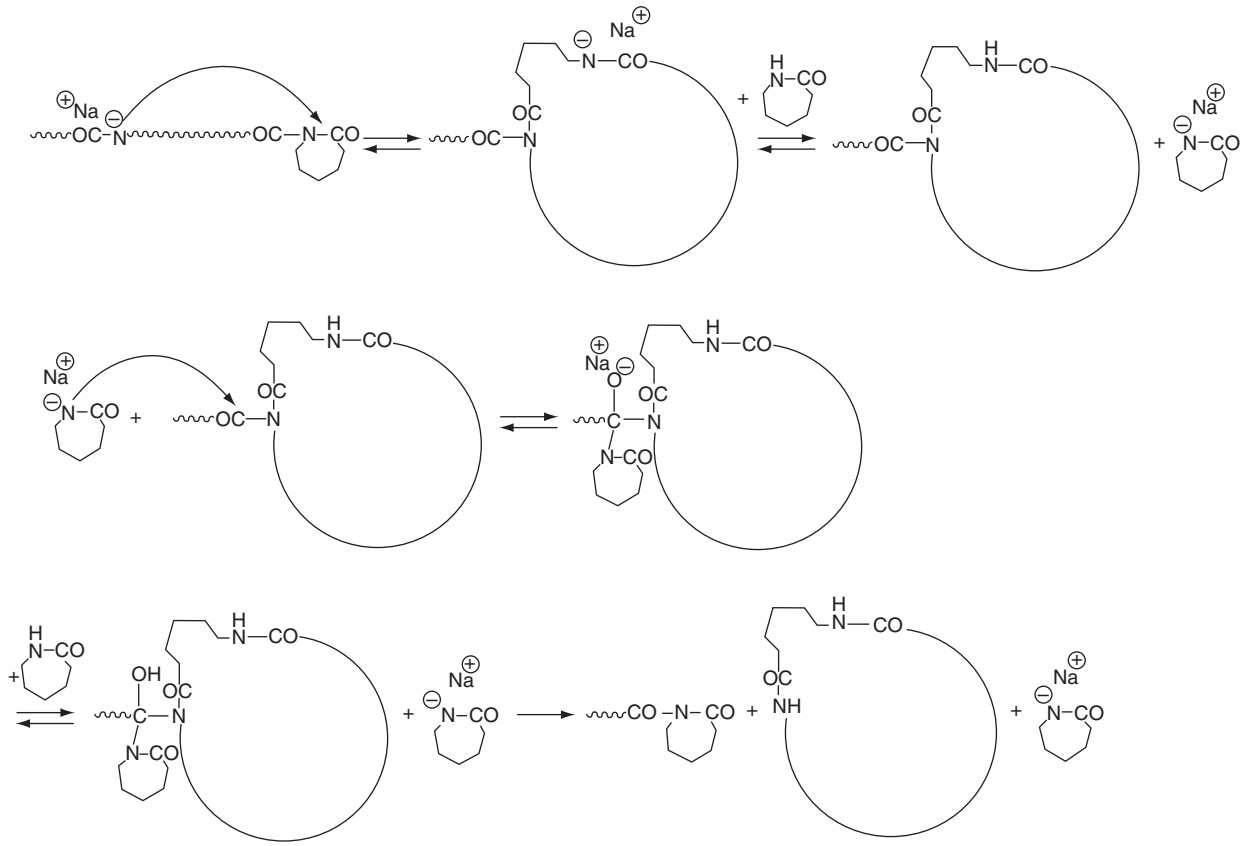
PCL, which were strongly affecting its molecular characterization for decades. Only in the last few years, the SEC problem of PA6 was satisfactorily solved by some groups, as described in Reference 159. For comparison, it may be useful to state that SEC analysis of hydrolytic PCL does not show any low-molar-mass peak but a relatively large plateau on the lower mass side of the high polymer peak. Future studies on the nature of this plateau, the masses of which more or less correspond to the anionic peak found by Russo's group, may be attempted in order to evaluate analogies and differences between the two mechanisms of ROP of CL. At present, thanks to MALDI-TOF data on 'fast' anionic PCL in quasi-isothermal conditions[222,223] without any previous oligomer separation from the high polymer fraction, together with SEC and HPLC results, it has been possible to find out a regularly decreasing trend of cyclic oligomer content up to the hexamer, together with a previously unknown peak made of macrocyclics rising from $(CL)_{7-9}$ up to $(CL)_{20-25}$ and with a maximum positioned as a function of the reaction parameters.

Among the first members of the cyclic oligomer series (up to the hexamer), which can be safely considered almost exempt from the extraction and/or analytical biases mentioned above, it may be interesting to describe how the cyclic dimer content depends on the different mechanisms of polymerization and the experimental conditions chosen. As compared to hydrolytic polymerization,[12] the cyclic dimer content in the extractables, derived from a 'slow' adiabatic polymerization,[215] increases from 10.2 wt.% (hydrolytic) to 23.5–44.5 wt.% depending on the experimental conditions, while in 'fast' quasi-isothermally polymerizing systems,[222] it has an intermediate value (17.2 wt.%). Referring to higher cyclics in the different experimental conditions of CL anionic polymerization, for instance, to the cyclic trimer, the $(CL)_3/(CL)_2$ molar ratio in 'fast' quasi-isothermal polymerizing systems[222,223] is almost the double (0.21), as compared to the 'slow' ones, either quasi-isothermal[217] (0.13) or quasi-adiabatic[220] (0.09–0.12). The corresponding value of the same ratio in hydrolytic polymerization, as given by Reimschuessel,[11,12] is 0.46. It is evident that the anionic polymerization of CL favors the cyclic dimer formation over higher cyclic oligomers. $(CL)_2$ is a very stable compound with a melting temperature (347 °C) much higher than that of the other cyclic homologs, a very poor solubility in most solvents, and strong intermolecular hydrogen bonds between NH protons and CO groups in the solid state.[15,16] Its formation in the anionic polymerization of CL is suspected to follow a different mechanism as compared to that of higher oligomers, as its final content in the reaction product is strongly influenced by activator and initiator concentrations, unlike those of the other cyclic oligomers.[224,225]

Ueda *et al.*[217] have recently suggested, as the most probable mechanism of cyclic oligomer formation in anionic PCL prepared by activated polymerization, a unimolecular backbiting reaction, depicted in **Scheme 29**,[223] as follows: an ionized amide bond is produced by proton abstraction along the polyamide growing chain, which is a highly probable event especially in the latter stages of anionic polymerization, invoked also to explain transamidation reactions, branching, and cross-linking, if any. If chain conformation allows the $-N^{\theta}-$ anion to approach its chain end (cyclic imide), it is possible to envisage its nucleophilic attack on the cyclic imide group in competition with that of CL anion. The generated loop, after the attack by the monomer anion, would form a cyclic oligomer and a linear chain. The segmental mobility of the growing chain in the more and more viscous reaction medium will control the formation of the individual cyclic species. So far it has been unclear, however, why formation of larger cycles, that is, $(CL)_{9-11}$, is favored over the smaller ones $(CL)_{4-8}$, although the cyclic dimer (to a greater extent) and cyclic trimer (to a lower extent) remain the most favored cyclic structures formed in the course of CL anionic polymerization.



Scheme 29 Possible mechanism of cyclic oligomer formation.

The role of LiCl[46,214,226] and $CaCl_2$[227] in the activated anionic polymerization of CL has been studied in detail by Russo *et al*. As far as cyclic oligomer formation is concerned,[226] a strong decrease in the cyclic dimer content as a function of added LiCl has been found. Higher cyclic oligomers, on the contrary, showed an increasing overall yield. A possible explanation is based on the extensive formation of complexed amide bonds, due to the strong ion–dipole interactions between the carbonyl oxygen atoms of the polyamide chains and Li^+, able to coordinate up to four C=O groups. The possibility of cyclic dimer formation necessarily needs to find pairs of adjacent amide bonds free of complexation, which is less and less probable as the LiCl concentration in the reacting system increases. Conversely, the formation of higher oligomers is not subject to such heavy restriction and is favored by the counterbalancing effect of system densification because of the salt. However, the overall effects of LiCl on the activated anionic polymerization of CL have a negative influence on both the kinetics and the thermodynamics.[46,214] $CaCl_2$,[227] on the contrary, does not show the above pitfalls but only a slight reduction of the high polymer yield and a much lower negative effect on polymerization enthalpy and entropy. Here again, strong ion–dipole interactions between Ca^{2+} and amide groups are responsible for the peculiar properties of the resultant PA6 (e.g., a higher Young's modulus), retained also in the present of moisture, at variance with LiCl.

4.14.11 Anionic Polymerization of Other Lactams

Out of the five to thirteen rings of unsubstituted lactams that can undergo polymerization, the only lactams, besides CL, intensively studied in terms of anionic ROP are 2-pyrrolidone and ω-laurolactam. Also 2-piperidone deserves some considerations in this respect, although it has been much less studied than the other two lactams.

4.14.11.1 2-Pyrrolidone

The potential industrial interest for poly(2-pyrrolidone) (PA4) in relevant fields of application (namely, textiles) arises from its excellent mechanical properties combined with a hydrophilic behavior similar to that of cotton. Other areas of applied interest may be those of membranes and biomedical devices. However, its industrial production has not yet been developed to any appreciable extent because of the many drawbacks existing in both its synthesis and its processing.

2-Pyrrolidone can be polymerized only by an anionic mechanism either in the bulk or in suspension, but so far the polymerization reaction has been less successful than that of CL and ω-laurolactam. First of all, a rather low ceiling temperature (~70 °C) allows the polymerization to be carried out at low T only. Optimum temperatures are in the range 40–50 °C. Within this set of temperatures, in the activated anionic polymerization in the bulk, after a very high rate

developing in a homogeneous system in the first few minutes, further monomer conversion has been found to be strongly limited by the phase separation of the polymer, its nucleation, and crystallization,[228,229] with predominant occlusion of the growth centers in the crystalline regions. As a consequence, the significant decrease of the polymerization rate has made impossible to reach very high conversions in a reasonable time.

Better results in the polymerization of 2-pyrrolidone have been obtained by Sekiguchi *et al.*,[230] when using quaternary ammonium salts as initiators. At 30 °C, PA4 of high intrinsic viscosity in high yields (>80%) has been obtained after prolonged polymerization time (24 h), using tetramethylammonium pyrrolidonate as initiator and *N*-acetyl-2-pyrrolidone as activator. The activity of the alkylammonium salts of the lactam has been found higher than that of alkali metal salts, and the following order has been drawn:

$$NMe_4^+ > K^+ > Na^+ > Li^+$$

Various alkylammonium pyrrolidine salts have been tested and the best results have been found with NMe_4NPy, while $BuEt_3NPy$ was the worst in terms of polymer yield and degree of polymerization. To explain these results, it has been suggested that the use of a sufficiently bulky counter ion allows the breaking of hydrogen bonds between polymer chains and creates local irregularities of the crystalline structure in the neighborhood of the reaction sites, assuring the access of the lactam anion.

Interesting additional results have been reported in polymerizations conduced at 25 °C for 72 h using esters, such as γ-valerolactone and *n*-butyl acetate, as slow activators.[230] Some lactones and polylactones have given PA4 with improved thermal stability. Indeed, upon heating, the ω-hydroxy acyl residue of the activator is cleaved forming again the lactone ring and liberating an amine group at the chain end, which can act as a chain-coupling agent giving rise to condensation reactions with the other chains.

The anionic polymerization of 2-pyrrolidone has also been accomplished employing carbon dioxide as activator.[177] The use of this gaseous activator has made possible to prepare a PA4 possessing a satisfactory thermal stability for fiber preparation and melt spinning.[231] Nonactivated anionic polymerization, on the contrary, enables high molar masses of poly (2-pyrrolidone) to be obtained, but at the expenses of much longer polymerization times.[232]

In general, a severe drawback is caused by the intrinsic thermal instability of the polymer that, at *T* close to the melting temperature, depolymerizes to its monomer. Although several thermal stabilizers have been suggested in the patent literature, the problem is still far from being satisfactorily solved. As far as the synthesis of the polymer is concerned, much better results have been obtained when 2-pyrrolidone has been anionically polymerized in suspension,[233] using its potassium salt as initiator, silicon tetrachloride as activator, possibly a surfactant (sodium dodecylsulfate), and *n*-heptane as the suspending medium. Limiting conversions and polymer molar masses have shown significant improvements (yield ~70%, intrinsic viscosity increase 45%) after 4 h reaction at 43 °C. The most relevant advantage has been the polymer shape, which, in contrast to the products of the bulk polymerization – a compact, rigid block of horny polymer-, was the bulk polymerization- a very fine powder, easily removable from the reactor.

A relevant aspect deserving attention is that both the bulk and suspension methods have been found to provide PA4 free of structural irregularities. This result is a clear indication that side reactions, responsible for the strong UV absorption and widely present in anionic PCL synthesized in the bulk (Section 4.14.10), are here minimized due to both the low polymerization temperature and limited conversions.

4.14.11.2 2-Piperidone

Thermodynamically speaking, 2-piperidone is slightly more polymerizable than 2-pyrrolidone, but kinetically less reactive.[8] The low kinetic polymerizability has been attributed to the concurrent crystallization of the growing chains and consequent physical termination as well as the relevance of side reactions, allowed to extensively occur because of the slowness of the polymerization. Activators have been found to be always essential for the polymerization of 2-piperidone. Relatively high molar masses of poly(2-piperidone) have been achieved only when quaternary ammonium salts have been used as initiators.[128] The resultant polyamide has a T_m of ~283 °C, higher than that of poly(2-pyrrolidone), ~260 °C, and is thermally much more stable than the latter. Therefore, melt spinning can be safely carried out and fibers with good characteristics are obtained.

4.14.11.3 ω-Laurolactam

In recent years, the anionic polymerization and copolymerization of ω-laurolactam has gained increasing attention for a well-balanced set of properties of the resultant polymers and copolymers. The main advantages of ω-laurolactam anionic polymerization are its low level of absorbed moisture, easily removable during heating and melting of the monomer at 150 °C, and the low content of residual ω-laurolactam due to a favorable monomer–polymer equilibrium.

A novel catalytic pair, made of an alicyclic carbodiimide as the activator and sodium caprolactamate as the initiator, has been recently developed[186]. It allows very long-term storage of the initiating species mixed together, an efficient control of the polymerization rate, and an accurate tailoring of polyamide molar masses. A time–temperature–transformation (TTT) diagram, very similar to that of thermosets, has been drawn[234] with the aim of studying the influence of their initiating species on polymerization kinetics and limiting conversions. At variance with the traditional set of initiators (e.g., sodium ε-caprolactamate) and activators (e.g., *N*-acetyl-CL) used by other authors, the novel catalytic pair is able to *in situ* generate a guanidine anion, which reacts very fast with the first molecule of ω-laurolactam, thus performing to the initiation stage of ROP. Propagation is then based on the subsequent reaction of monomer molecules with the active centers. A simplified scheme of the polymerization mechanism has already been described (**Scheme 27**, Section 4.14.7.5.4). Initial concentrations of patented activator and initiator species,[185] as well as their molar ratios, are able to control poly(ω-laurolactam) molar mass and, in general, end properties of the polyamide.

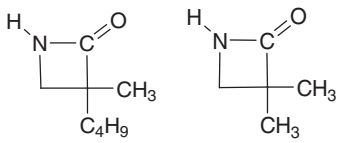
An interesting aspect that has been investigated[174] is the relationship between the anionic polymerization process and

PA12 structure formation in terms of polymorphic modifications α and β, the latter being the more stable one. Different initiators and different types of activation have been found to exert a deep influence on not only polymerization kinetics and thermodynamics but also the degree of crystallinity and the physical structure of anionic PA12.

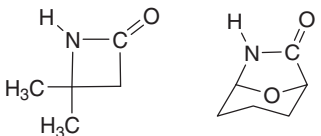
Significant changes of PA12 properties are achieved by copolymerization of ω-laurolactam with lactams of different ring size[235] or other monomers. The topic is covered in Section 4.14.12.

4.14.11.4 Substituted β-Lactams and Their Living Polymerization

The present status of the studies on β-lactam living polymerization has been described in great detail in a recent review of Hashimoto,[236] with specific attention to the anionic growth mechanism. Both Šebenda *et al.*[237,238] and Hashimoto *et al.*[239–241] have successfully synthesized uniform (i.e., the so-called monodisperse) polyamides from the substituted β-lactams (**62**, **63**, and **64**). Hashimoto *et al.*[242,243] have also obtained a uniform polyamide from the bicyclic oxalactam (**65**):



62 **63**



64 **65**

Šebenda *et al.*[237,238] have been the first to discover that the activated anionic polymerization of **62** has a living character, giving a polyamide of molar mass very close to the theoretical, predicted on the basis of the ratio monomer consumed/of activator added.

The roles of both the monomer structure and the reaction parameters in the achievement of living polymerization conditions for lactams have been analyzed by Hashimoto,[236] who found that a stringent control of the proton transfer reaction, restricted to that occurring from the lactam monomer to the anion of the growing chain, as given in [50], is essential for the attainment of living conditions.

No other active hydrogens, apart from that on the nitrogen atom, should in principle be present in the lactam molecule to avoid side reactions. The choice of mild polymerization conditions (e.g., room T_p, homogeneous solution, and low polymerization rates) goes in that direction too. Because of such experimental conditions, it is necessary to have highly reactive lactams, that is, those characterized by a high ring strain. Substituted β-lactams are very suitable in this respect. Furthermore, in order to carry out a homogeneous solution polymerization, selected polyamide solvents, capable of not interfering with the living species, are required. Hashimoto[239,240] made use of aprotic polar solvents (N,N-dimethyl acetamide, DMF, and DMSO) added with LiCl or LiCBr as the reaction media able to act as good solvents for polyamides derived from **63** and **64**. The activated anionic polymerization[239] of **63** in dilute solutions of DMAc + LiCl (5 wt.%) at 25 °C, keeping the initiator (K pyrrolidonate) concentration as low as 0.5 mol.% in order to decrease the polymerization rate and avoid the broadening of molar mass distribution, was completed in less than 20 min. M_w/M_n of the poly(β-lactam) was found to be < 1.1 and M_n was almost linearly proportional to monomer conversion (**Figure 26**).

Also the activated anionic polymerization[240] of **64**, under similar experimental conditions, gave a uniform polyamide, despite the α-active hydrogens of that monomer. The living character of the resultant polyamide has been proved[241] by adding further monomer to the reacting medium for a second-stage polymerization. The gel permeation chromatography (GPC) traces of the above poly(β-lactam) after the first and the second polymerization runs are depicted in **Figure 27** and fully support the living character of this polymerization. Therefore, it can be inferred that, by choosing sufficiently mild polymerization conditions, living polyamides can be obtained from monomers having α-active hydrogens also. The relatively low basicity of the lactamate anions in the chosen experimental conditions would prevent proton withdrawal from the neighboring carbon atom.

In general, several factors have to be taken into account in order to attain a living or a quasi-living polymerization of β-lactams. Monomers having a low rate constant of propagation are preferable for the synthesis of uniform polyamides. Drawbacks in the preparation of uniform polyamides from β-lactams are the very frequent occurrence of depolymerization and transamidation (at the acyl lactam chain end and on the polyamide chain), both causing broadening of molar mass distribution of the resultant polyamide. The latter reaction occurs more frequently at high conversion. Therefore, it is advisable to stop the polymerization at low to intermediate

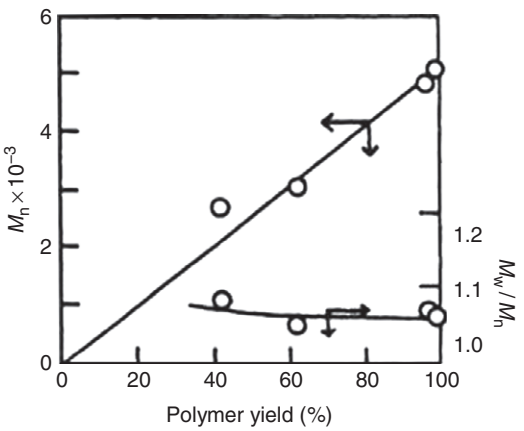


Figure 26 Values of M_n and M_w/M_n of the polyamide samples obtained from the anionic polymerization of **63**. Reproduced from Hashimoto, K. *Prog. Polym. Sci.* **2000**, *25*, 1411,[236] with slight modification.

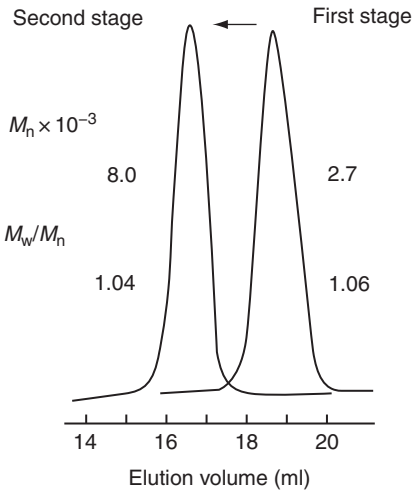

Figure 27 SEC profile of the polyamide obtained in two-stage polymerization of **64** at 258 °C. Reproduced from Hashimoto, K. *Prog. Polym. Sci.* **2000**, *25*, 1411.[236]

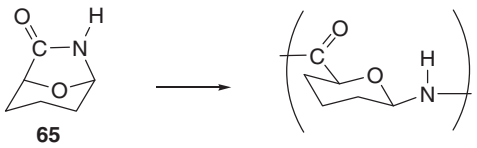
conversions in order to get a living or a quasi-living polyamide. Block and graft copolymers, macromonomers, telechelics, and multicomponent polymeric materials, all with well-defined design, have been prepared taking advantage of the living character of the above polymerizations. The excellent review of Hashimoto[236] exhaustively covers also these topics.

An interesting application of the above living polymerization has been suggested by Šebenda *et al*.[238] It takes advantage of the fact that the copolymerization of **62** with other lactams is still running in homogeneous solution even after enchainment of some monomer units of the second lactam, the polymer of which is insoluble in that medium. In this way, the rate of enchainment of any polymerizable lactam can in principle be evaluated under identical conditions.

Quite recently,[242] the anionic homopolymerization of a few substituted β-lactams and the copolymerization of some of the above pairs have been studied in order to prepare polyamide 3-derived polypeptides displaying biological properties. The solution polymerization or copolymerization, initiated by Li amide disubstituted with trimethylsilyl groups and activated with 4-*tert*-butylbenzoyl chloride, does not have living character. From that study,[242] some insights emerged into the reactivity of the above β-lactams in terms of their acidities, as well as electrophilicity of the imide end groups.

So far, apart from β-lactams, the other members of the lactam family characterized by larger rings have been unable to perform a living polymerization. The many stringent requirements that are necessary to fulfill for the development of a living system, that is, high ring strain, low polymerization temperature, solution homogeneity, low rates of polymerization, highly controlled proton transfer, no side reactions, limited conversions, and absence of depolymerization and transamidation reactions, have been so far satisfied only for some β-lactams (**62**, **63**, and **64**) and the bicyclic oxalactam (**65**). The latter is a racemic mixture of the corresponding enantiomers and can be anionically polymerized (e.g., in dimethyl sulfoxide at 25 °C) to ~80% yield of the resultant high-molar-mass polyamide,[243,244]



[101]

which should be considered a random copolymer of the above enantiomers. The intermolecular hydrogen bonds between the amide groups may be weakened to the point that justifies its very high solubility in several organic media. The kinetic polymerizability of **65** is very high, due to the high strain of internal bond angles, and its anionic solution polymerization[243] provides a living polyamide at least up to monomer conversions < 60% ($M_w/M_n = 1.1$, M_n directly proportional to conversion), with some broadening of molar mass distribution to ~1.2 at high conversions.

Also the corresponding optically active **65** has been polymerized under conditions similar to those outlined above.[236] The optically active polyamide has shown higher molar mass, higher melting point, and higher degradation temperature as compared to the polyamide prepared from the racemic **65**. Both polyamides are highly hygroscopic. They have been utilized for the preparation of hydrophilic membranes characterized by high water permeability and permselectivity, as well as for the design of multicomponent polymeric materials containing the polyamide block. In future, if proper experimental conditions (e.g., suitable solvents, temperatures, reaction rates, and conversions) would be chosen, other homo- and heterobicyclic lactams might yield living or quasi-living polyamides, opening interesting fields of application in many different areas.

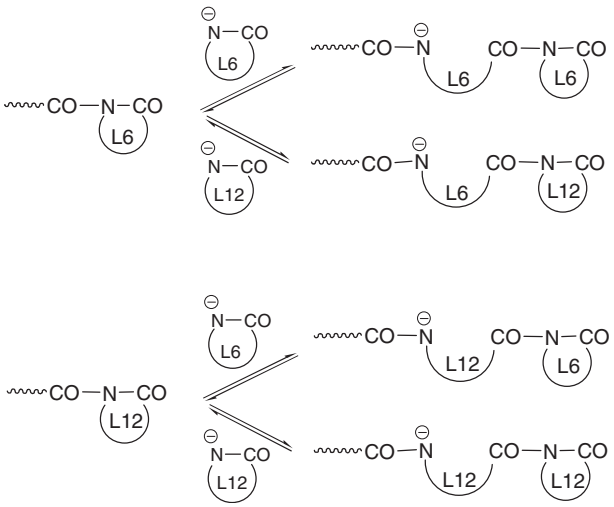
4.14.12 Anionic Copolymers

4.14.12.1 Introduction

Copolymers with at least one component that is a lactam are an interesting family of polymeric materials, whose properties strongly depend on the routes chosen for their synthesis. In this respect, anionic mechanisms offer unique opportunities to control sequence distribution and microstructure of the resultant copolymers. For some specific pairs, the anionic copolymerization is the only way to synthesize materials with tailor-made characteristics. In the following, some relevant examples of anionic copolymers will be given.

4.14.12.2 Copolymerization of CL and ω-Laurolactam

So far, the most studied lactam pair undergoing anionic copolymerization has been that based on CL and ω-laurolactam, the only other lactam industrially accessible. As already mentioned, the main aim has been to extend the range of PCL applications by tailored modifications of its properties, some of which (e.g., low impact strength at low T and high moisture uptake) show characteristics that need to be improved. In this respect, matching PA6 properties with those pertaining to PA12 by suitable copolymerization of the two monomers can lead to material improvement.



Scheme 30 Propagation stage of CL – w-laurolactam anionic copolymerization.

The anionic copolymerization kinetics of CL and ω-laurolactam, as well as the microstructure and the morphology of the resultant copolymers, is largely dependent on the reaction parameters, such as choice of initiator and activator, their stoichiometric ratio, quasi-adiabatic or quasi-isothermal conditions, and (initial) polymerization temperature. In the propagation stage, four competitive reactions (**Scheme 30**) of the two activated monomers (CL and ω-laurolactam anions) and the two nonionic growth centers (cyclic imides derived from CL and ω-laurolactam, respectively) are present[245] in competition with transacylation (exchange reactions) occurring between the amide groups of copolymer chains (**Scheme 31**).

Therefore, both thermodynamics and kinetics exert a control on copolymer formation, as well as its overall composition and microstructure. As mentioned before, initial temperature and possible temperature increase during polymerization, reaction time (often very high when slow or no activation is present), crystallization occurring after the end of polymerization or during it, absolute and relative concentrations of all reactants (lactams, initiator, activator, growing chains, and ionic species), complex equilibria of the various species, extent of Claisen-type side reactions, and so on make impossible to give a general, quantitative picture of the copolymerization reaction. Notwithstanding that, some relevant achievements have been obtained in recent years[144,245] and some findings well established. The most impressive kinetic information acquired is linked to the striking difference in the polymerization activity and in the role of the following two initiators: CLNa and CLMgBr. Roda's research group in Prague[245] found that the activated anionic copolymerizations (activator *N*-benzoyl-CL), initiated by CLNa, give rise to random copolymers, while those initiated by the Grignard reagent show a heterogeneous character. Indeed, a single melting

Scheme 31 Transacylation reaction between the amide groups of the copolymer chains.

endotherm and a single crystalline form have been found for the former initiating system in the whole range of copolymer compositions, while two melting endotherms and two types (α and β) of crystalline forms are displayed in the copolymers formed from 30 to 70 mol.% of CL in the feed with the latter set of catalytic species. The unusual behavior of the Grignard reagent has been explained on the basis of accurate analyses of copolymer microstructure composed by PA6 blocks (with a minor ω-laurolactam content) linked to sequences of CL/ω-laurolactam random copolymer. Most probably, PA6 is preferentially formed at the beginning of the polymerization, due to the much higher reactivity of CL as compared to ω-laurolactam. Only later on, random copolymers are formed from the remaining CL and the slowly reacting ω-laurolactam. Transamidation reactions, occurring to a very large extent when the polymerization is catalyzed by strong bases (CLNa), cause full randomization of the sequences and formation of a statistical copolymer only. CLMgBr is a much weaker base as compared to CLNa and, on the contrary, allows a much lower extent of transamidation reactions to occur. Long PA6 sequences are preserved and only a few links per chain with the copolymers are possible. The specific role of the Grignard reagent CLMgBr as initiator in anionic lactam polymerizations has been extensively discussed in Section 4.14.7.3. Its relevance is also under consideration in RIM applications, as mentioned in Section 4.14.13.3.

4.14.12.3 Copolymerization of Lactams and Lactones

The anionic ring-opening copolymerization of lactams and lactones has been studied in great detail by several research groups with the main aim to synthesize polyesteramides having potential biodegradable characteristics. Indeed, as remarked by Roda,[10] this is a rare example of copolymerization of rings obeying different mechanisms of homopolymer formation and giving rise to a copolymer using peculiar synthetic pathways.

Indeed, some lactones (such as CLO and VLO) can act as both activators of lactam anionic polymerization (up to ~5 mol.%) and comonomers at higher concentrations, while others (e.g., γ-butyrolactone) are only activators. Acylation of the lactone ring by the lactam anion (eqn [94]) is the initiation step, followed by a very rapid formation of polyester chains by growth reactions of the alkoxy groups and suitable lactone molecules. Taking into consideration the most studied monomer pair (CLO and CL), random or multiblock copolymer structures have been found, depending on the experimental conditions chosen for the synthesis. Copolymerizations initiated by CLMgBr and carried out in quasi-isothermal conditions (reactive casting in a 4-mm-thick mold at 150 °C) have been very successful in terms of copolymer yield, with a very low content of extractables (≤4%),[182,246] at variance with copolymerization runs initiated by CLNa giving extractable yields up to 40%. All copolymers with compositions ranging from 3 to 90 mol.% of CLO showed a random distribution of comonomer units, as supported by the close agreement of experimental T_g values and those calculated from the Fox equation.[247]

The exchange (transacylation) reactions between ester and amide groups in the copolymer chains have been considered responsible for the copolymer randomness, as they are very fast

and occur simultaneously with initiation and propagation steps under the experimental conditions chosen for the reaction. Once again, as we have seen in other sections of the chapter, the use of the Grignard reagent CLMgBr as initiator brings relevant advantages in both the synthesis and the properties of the resultant polymers.

As already mentioned, it is now well ascertained that at the beginning of the anionic copolymerization of CL and CLO, irrespective of the initiating system, it is the latter monomer that is more rapidly consumed, with the formation of poly (ε-caprolactone) homopolymer.

An interesting copolymerization experiment of the above monomers has been published by Scola et al.,[248] who applied a microwave process to convert them in the corresponding copolymers. The two monomers are suitable to effectively absorb the microwave energy due to the high values of their dielectric permittivities (∼14 at 100 °C for CL and ∼42 for CLO at the same temperature) and the additive dielectric properties of their mixtures. The rate of copolymerization is increased by the microwave process as compared to the purely thermal reaction because of more effectively activated molecular collisions and/or lower activation energy. Also in this case, only random copolymers have always been obtained, as supported by a single T_g found by Dynamic Mechanical Thermal Analysis (DMTA). The relevant yield increase and the much higher amide-to-ester ratios in the copolymers synthesized by the microwave-assisted process seem to suggest that a direct interaction between microwaves and molecular dipole moments more efficiently delivers the energy to amide groups (3–4 D) than to ester units (1–2 D), enhancing the reactivity of the former. Surprisingly, the microwave-assisted anionic homopolymerization of CL has not been mentioned in the literature so far, while its hydrolytic variant initiated by ω-aminocaproic acid has been studied.[89]

In more recent years, the anionic copolymerization of various lactams and lactones has been performed under reactive processing conditions, using a twin-screw extruder. By suitable sequential monomer feeding and temperature profiles, it has been possible to get diblock or triblock copolymers, while the simultaneous feeding of monomers always produced random copolymers.[249,250] In sequential feeding, the block lengths and, hence, the molar masses could be adjusted by controlling the feed rate.[251]

4.14.12.4 Block Copolymers and Other Copolymers

The anionic route is particularly suitable for synthesizing lactam-based block copolymers. CL and, to a much lower extent, ω-laurolactam have been the lactams more often used for the purpose. Polymeric activators (macroactivators) (Section 4.14.7.5.5) obtained from appropriately terminated prepolymers can give rise to di- and triblock copolymers or, when other functional groups acting as additional activating centers are present along the prepolymer backbone, even multiblock structures. The latter approach has been found particularly useful in RIM technology and will be discussed in detail in Section 4.14.13.3.

In order to obtain a good combination of end properties, numerous copolymers with a variety of nonpolyamide blocks have been prepared using polymeric activators and accomplishing the *in situ* anionic lactam polymerization. The main aim for synthesizing block copolymers of PA6 has been to improve its toughness, which is rather inadequate especially at low temperatures. Therefore, polymers, such as, polyethers,[252–255] poly(butadiene) (PBu),[256–259] and poly (dimethylsiloxane)[260,261] with suitably modified end groups, can be prepared and transformed into the corresponding polymeric activators. For instance, triblock copolymers with a soft PPO block in the main chain of PA6 or PA12 can be synthesized starting from macroactivators prepared, for example, by reaction of a PPG with isophorone diisocyanate. Further blocking with CL gives the *N*-carbamoyl-CL growth centers at the PPO chain ends.[262] Di- or triblock OH-terminated poly(ethylene oxide)/PA6 copolymers (PEO–PA6) have been synthesized along similar routes, using different macroactivators bearing tolylene-bis-carbamoyl-CL, or HBCCL, or cyclohexyl carbamoyl-CL growth centers, and the resultant morphological, thermal, and mechanical properties related to the conditions of synthesis have been studied.[255] PEO segments in the block copolymers showed amorphous characteristics, whereas a large fraction of unreacted PEO segments was crystallized in as-polymerized samples, with the notable exception of the products obtained using cyclohexyl carbamoyl activator. Among the various products obtained, the triblock copolymers showed the smallest PEO domains and the highest impact strength. Formation of chemical bonds at the interphase has been found as a necessary prerequisite for reaching optimum toughness. Similarly, a telechelic α–ω dihydroxy-poly(butadiene) reacting with a diisocyanate (e.g., 2,4- or 2,6-tolylene diisocyanate), blocked or not with CL, can be used as the polymeric activator to produce a triblock PA6–PBu copolymer, for example, by anionic casting polymerization in the presence of potassium ε-caprolactamate.[256–259] The final properties of the triblock PA6–PBu copolymer depend mostly on the length of the PBu block. A phase separation and an increased toughness (up to an order of magnitude higher as compared to unmodified PA6), as well as decreased Young's moduli and yield strengths, were generally found, together with higher contents of PA6 amorphous phase (and, thus, modified permeation properties).

Also cross-linked block copolymers, arising from three *N*-acyl lactam growth centers per PBu molecule, have been prepared and characterized.[263] Optimum values of impact strength, six times higher than the impact strength of PA6 homopolymer, have been found when 10 wt.% of PBu was used.

Diblock copolymers made of hydrogenated PBu and PA6 units (HPBu–PA6) have been synthesized in a similar manner (but hydrogenating the hydroxyl-terminated PBu) and used as compatibilizers in low-density poly(ethylene)/PA6 blends (PE/PA6).[264] The diblock copolymer exhibited a very relevant interfacial activity, with a reduction of particle size and an improvement of the interfacial adhesion between the incompatible phases. Also hydroxyl-terminated styrene–butadiene rubber (SBR) or poly(ε-caprolactone), after reaction with diisocyanates, were anionically copolymerized with CL in order to get block copolymers with improved mechanical properties.[265]

Graft copolymers can be obtained using macroactivators bearing pendant functionalities (Section 4.14.7.5), mainly for an end use as compatibilizers or to attain the *in situ* compatibilization in reactive blending. In this way, copolymers formed by a backbone of poly(propylene) (PP), PMMA, or PS, grafted

with polyamide chains, are easily obtained by the *in situ* anionic polymerization of lactams.

Thus, for instance, PP-*g*-PA6 copolymers have been obtained by reaction of isocyanate-bearing PP with CL (using, e.g., sodium caprolactamate as initiator),[266–269] and PS-*g*-PA6 have been anionically produced starting from macroactivators synthesized by copolymerization of isocyanate[192] bearing comonomers.

4.14.13 Industrial Applications

4.14.13.1 Introduction

Since the initial applications, essentially limited to the field of 'cast nylon' technology and centered on CL polymerization, the anionic polymerization of lactams has found in recent years several new industrial applications and many other fields have been tentatively explored or foreseen. In the 1980s, RIM and reinforced RIM (R-RIM) processes, previously involving for the most part polyurethane chemistry, seemed very suitable for the *in situ* anionic polymerization of CL in the mold.[270] The initial enthusiasm, however, had to face the complexity of the chemistry involved and the careful control necessary for keeping all reaction parameters under rigorous processability windows. Despite these difficulties, the extensive technological know-how acquired has provided new approaches, which may be extended in the near future to other fields, such as rapid prototyping. In general, in more recent years, some of the above processes, together with modern technologies, opened the route to new ideas, new applications, and new products. Some of them will be briefly outlined in the following.

4.14.13.2 Powdered Polyamides

The obtainment of fine powders of PCL, poly(ω-laurolactam), and their copolymers has attracted relevant attention in recent years for possible commercial utilizations in several fields. Cosmetic formulations, coating and graphic art applications, protein or enzyme immobilization techniques, rotational molding and sintering processes, and filtration devices in food and beverage industry are the major industrial fields where powdered polyamides are currently applied. Their use as stationary phase in chromatography has also been envisaged and introduced for some specific systems.

As compared to the other two techniques industrially utilized for the obtainment of polyamide powders, that is, low-temperature grinding and polymer dissolution/precipitation, anionic ROP of lactams (and, namely, of CL) offers great advantages in terms of much higher particle porosity, total absence of irregular edges and sinterized zones, controlled particle size, very narrow size distribution, and wide range of specific surface areas. Besides CL, ω-laurolactam has been so far the only other lactam considered in this respect, in terms of both ring-opening homopolymerization to polyamide 12 and its copolymerization with CL (PA6/12).

The anionic ROP of the above lactams has been carried out following three different approaches:

1. solution polymerization with phase-separated polymer avoiding its coagulation (dispersion polymerization);[271–276]
2. suspension polymerization in nonaqueous media as the continuous phase;[277] and
3. miniemulsion polymerization in hydrocarbons.[278]

Other, less common approaches can also been found in the open literature.[279] Due to the great potential of the above methods for the obtainment of polyamide powders, it is not surprising that many patents have been issued on these topics and several commercial products are already on the market.

The dispersion polymerization method, which in general needs suitable dispersants in order to avoid polymer coagulation, has been described in detail[271–276] and can be summarized as follows: the powdered PA6 formation is the result of very rapid steps governed by both the chemistry (initiation and growth of the polymer chains) and the physics of the polymerization process (precipitation, aggregation, and, finally, crystallization of the polyamide), steps that in part overlap. As a consequence, polymerization temperature; nature of the solvent; concentration of monomer, initiator, and activator; chemical nature and functionality degree of this latter; and molar ratio of the components of the catalytic pair all strongly affect not only the polymerization rate, the final conversion, and the chain length but also the polymer structure (linear, branched, and cross-linked) and its morphology.[280]

Studies on the suspension polymerization, focused on CL, have mainly been performed in oligo(isobutene) oils of different molar masses (and, therefore, viscosities) as the continuous phase.[277] CL was found partially soluble in the lower molar-mass oils and completely insoluble in intermediate- and high-molar-mass oils. Pure suspension polymerization without additional contributions from solution (dispersion) polymerization has been carried out using the oils of intermediate molar masses, which represent the optimum compromise between monomer insolubility and medium fluidity. Very high monomer conversions in very short times, excellent microstructural regularity of the polymer chain (evaluated by the UV method mentioned below), accurate control of its molar mass and fine-tuning of particle shape, size, and size distribution have been successfully achieved by fast activated anionic polymerization, using the blocked cyclohexyl isocyanate/sodium ε-caprolactamate pair in equimolar concentrations. A typical SEM micrograph is given in **Figure 28**.

By suitably tuning the reaction parameters, the particle coalescence phenomena can be minimized and particle size distribution becomes rather narrow. Also by this method, it is possible to strongly reduce the amount of microstructural defects, as evidenced by the sharp lowering of the UV absorbance peak between 270 and 280 nm, usually assumed to be linked to the presence of structural irregularities in the PA6 chain and roughly proportional to their overall content. The absorbance of the UV absorption peak maximum is as low as ~0.04, almost the same as that for hydrolytic PA6.

As mentioned above, a miniemulsion process has also been successful for the obtainment of powdered PA6.[278] The optimum conditions in terms of miniemulsion stability have been achieved by dissolving CL in polar solvents, such as DMSO, followed by *in situ* formation of sodium ε-caprolactamate and subsequent dispersion in an apolar phase, typically in a branched saturated hydrocarbon (e.g., Isopar M©), with the aid of a suitable surfactant. The anionic ROP starts when the initiator (*N*-acetyl-CL) is added to the reaction medium and

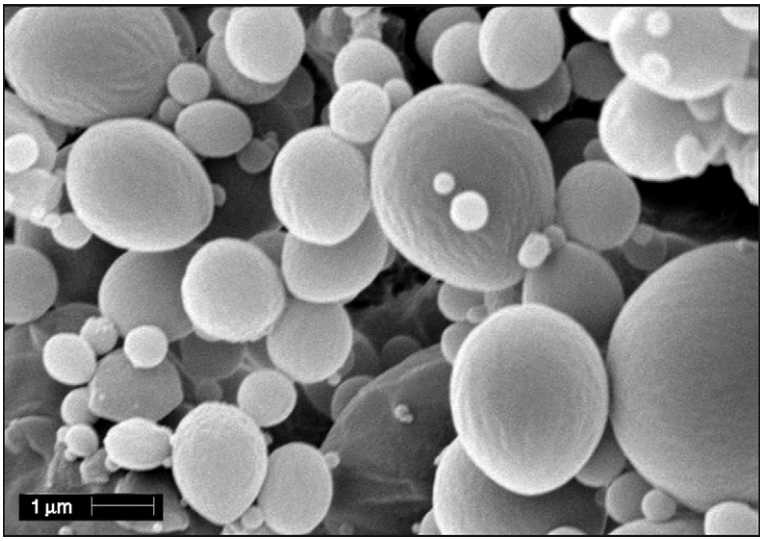


Figure 28 SEM micrograph of the PA6 particles obtained by suspension polymerization, as described in Ricco, L.; Monticelli, O.; Russo, S.; *et al. Macromol. Chem. Phys.* **2002**, *203*, 1436.[277]

polymerization T is reached. Ellipsoidal nanoparticles of PA6, obtained from the precipitation polymerization of CL inside the monomer/DMSO miniemulsion droplets, have been characterized by TEM. Their typical size is in the range of ~30 nm.

On the basis of the results obtained so far using the three methods mentioned above, a relevant conclusion can be drawn: the accurate temperature control (≤ 170 °C) permits to run polymerizations of CL in quasi-isothermal conditions and very efficiently contribute to the minimization of side reactions, the other relevant factor in this respect being the use of very fast activator/initiator pairs. Only the simultaneous effect of both factors, that is, temperature control and very fast catalytic systems, allows to reach both optimum process conditions and excellent polymer properties. The use of slow activators, such as *N*-acetyl-CL, on the contrary, strongly limits possible advantages of the method. Moreover, it should be taken into account that, in general, solution polymerizations (methods 1 and 3) are characterized by lower reaction rates as compared to suspension processes (method 2). On the other hand, these latter methods have to face more difficult and expensive purification procedures of the polyamide from the reaction mixture. The only other lactam-based polyamide synthesized in powder form in laboratory by a suspension process[233] is poly(2-pyrrolidone). A description of its synthesis is given in Section 4.14.11.1.

4.14.13.3 RIM, RTM, Rotational Molding, and Reactive Extrusion

As already mentioned in Section 4.14.13.1, the activated anionic polymerization of CL has undergone interesting industrial developments in the field of well-established monomer casting process, as well as in the more recent areas of RIM (RIM and R-RIM), resin transfer molding (RTM), and rotational molding. In addition, reactive extrusion processes, already explored since 1968,[281] are now gaining renewed attention for the easy preparation of nanocomposites and nanoblends, as described in the following.

Monomer casting, already described in some German and US patents prior to WWII, has been fully developed only since 1956, when several families of new initiators and activators allowed the anionic process to be industrially viable.[115] Due to its high crystallinity and high molar mass, cast PA6 has considerably greater modulus and strength, better wear, higher heat deflection temperature, better solvent resistance, better hygroscopic characteristics, and better dimensional stability as compared to the extruded or molded PA6 and PA6,6 materials. Additionally, a large variety of fillers can be easily added for more demanding applications. The very short polymerization times (2–20 min), as compared to those necessary to perform hydrolytic polymerization runs (12–24 h or more), the very low cyclic oligomer content (~2 vs. 8–12 wt.%), and the much lower initial polymerization temperature (130–170 °C vs. 230–280 °C) are the main advantages of this process.

Additional assets are the low cost of the mold, an almost unlimited range of shapes, and the weights of cast PA6 pieces up to several hundred kilograms. The anionic polymerization of CL in the bulk runs under increasing temperature profiles, even in quasi-adiabatic conditions for large cast volumes. For these latter systems, it is necessary to reduce the rate of polymerization by using slow initiating species and lower initial temperatures in order to avoid incomplete mold filling. To prevent sedimentation of fillers, when present, the reaction mixture is usually added with some polymeric thickener.

Like polyurethanes, in more recent years, PA6 has developed from monomer casting technology to RIM and R-RIM. So far, its only relevant commercial application and products are under the NyRIM© trade name. Indeed, this product is a multiblock copolymer formed from an oligooxypropylene or other elastomer and end functionalized with *N*-acyl lactam groups acting as polymeric activators (chain initiators) for the fast anionic polymerization of CL in the mold. The elastomeric blocks considerably improve the impact strength of the polyamide, thus making end products with the best combination of modulus, impact strength, and use temperature in comparison to any other unfilled RIM polymer. However, some disadvantages are also present: longer demold times and higher temperatures as compared to polyurethanes (PUs), the necessity of anhydrous conditions, and higher production prices.

Essentially, the process shows close similarities to polyurethane and polyurea RIM. Therefore, the machinery developed for these latter polymers and well known in the industrial practice can be readily adapted to NyRIM. The specific requirements of the RIM process applied to CL anionic polymerization have been summarized by Macosko[213] in terms of unit operations. The initiators typically used are sodium ε-caprolactamate or magnesium bromide ε-caprolactamate.

RTM applied to the anionic polymerization of CL is a result of implementation of RIM. A preformed reinforcing mat is placed into the mold where the reacting liquid mixture is injected. The continuous fiber or long fiber reinforcement is easily and fully impregnated by the reactants, which very quickly give rise to molded parts. These latter are characterized by stiffness and toughness much higher than the corresponding values coming from RIM or casting processes with short fiber reinforcement. Moreover, large percentages of fiber reinforcement are allowed by the RTM process.

Rotational molding (or rotational casting) provides hollow parts. The reactant mixture is introduced into a closed mold and rotation around one or two axes produces a uniform layer of PA6 on the inner surface of the cavity. Both RTM and rotational molding processes are advantageously realized with anionic PA6, while they are not practiced with polyurethanes.

Another potentially useful application is the continuous anionic polymerization of CL, which can be performed in twin screw extruders, taking advantage of both the very fast reaction kinetics and the broad limits of reactive system formulations. Recent findings[282] extended these potential applications to the field of nanocomposites, preparing organically modified montmorillonite (MMT) particles almost completely exfoliated and well dispersed in the polyamide matrix, with a sharp improvement of the mechanical properties (elastic modulus inserted up to +60% and tensile stress up to +15%). Another relevant application of CL anionic polymerization under reactive extrusion conditions is related to the *in situ* preparation of compatibilized nanoblends from immiscible/incompatible polymer pairs. For the system PP/PA6, as an example, the average size of the dispersed PA6 particles has been found in the 10–100 nm range.[283] No other blending method can achieve the same level of dispersion.

In general, *in situ* blending by reactive extrusion has been mainly explored in recent years in order to develop toughened PA6, although some studies have also been dealing with PA12 toughening[284,285] by anionic polymerization of ω-laurolactam in the presence of various rubbers. The results obtained so far are very promising and open wide possibilities of technically and economically feasible industrial applications.

4.14.13.4 Composites and Nanocomposites of Anionically Synthesized Polyamides

The anionic polymerization of lactams (mainly, CL) is less suitable than the hydrolytic process for the *in situ* preparation of their composites and nanocomposites. This is particularly the case when clays are used as reinforcing agents due to the presence of sizable amounts of water associated with clay as well as of mobile cations in most clay galleries and surfaces. Both agents contribute to the deactivation of the anionic active groups of the growing polyamide chains or, at least, exert a negative interference with them. In the field of clay-based nanocomposites, pristine MMTs cannot be well dispersed in CL because of the weak hydrogen-bonding interactions between the above components preventing intercalation or exfoliation. On the other hand, organically modified MMTs, which are very successful in the preparation of exfoliated nanocomposites based on clays and other polymers, seem to exert a severe inhibiting effect on the anionic ROP of CL, in addition to a rather poor interaction with it. Quite recently,[286] anionic PA6/MMT nanocomposites have been prepared by a novel two-step procedure able to overcome the above drawbacks, thus allowing full exfoliation of the pristine clay and large improvement of the nanocomposite thermal stability.

Another interesting field of application for PA6-based nanocomposites is that dealing with functionalized carbon nanotubes (CNTs), homogeneously dispersed in the polyamide matrix by *in situ* anionic ROP of CL. Usually, multiwalled carbon nanotubes (MWNTs), suitably functionalized on the surface to enhance hydrogen bonding with CL[287] or to create activators for its anionic ROP ('grafting from' method),[288] are characterized by a uniform and stable dispersion in the anionic PA6 matrix, thus increasing the crystallization temperature and enhancing the degree of crystallinity of the latter. Also single-walled carbon nanotubes (SWNTs) can be easily functionalized by CL attachment on their surface and subsequent anionic bulk polymerization using the above 'grafting from' technique.[289]

A third field where the anionic polymerization of CL has been applied to advantage is the *in situ* preparation of nanocomposites from nanosilica, uniformly dispersed in the monomer. Some recent publications[290–292] describe the fundamental steps of the synthesis and underline the most significant property improvements, especially when chemical bonds between surface-functionalized silica particles and anionic PA6 chains are formed.[291]

Biographical Sketches

Saverio Russo is a senior professor of industrial chemistry at Genoa University, Italy. He has been, and still is, project leader of several research programs supported by the European Union, Italian Ministry of University, and Chemical Companies. He has been working for more than 40 years in the field of macromolecular science and technology, mainly on *advanced polymeric materials: synthesis, characterization and applications.* Polyamide 6 by the anionic routes has been one of the major topics of his research. He is author of more than 250 scientific publications, mostly in international journals, and six patents. Prof. Russo has been member of the Scientific Committee of INSTM (Interuniversity Consortium of Materials Science and Technology) and director of its Section on Functional and Structural Polymeric Materials. He was the co-editor of four volumes of *Comprehensive Polymer Science*, Pergamon, 1989 and two supplement volumes (1992 and 1996). He was the organizer and co-chairman of two *IUPAC Symposia of Free Radical Polymerization: Kinetics and Mechanism*, in 1987 and 1996.

Elena Casazza studied organic chemistry and polymer science at University of Genoa, Italy, where she received her master's degree in chemistry and the PhD in chemical sciences and technology.

For a few years, she worked as a postdoc at Genoa University on macromolecular systems in the research group of Prof. Russo. Afterward, she joined industry in the field of the plastic materials where she has been working for more than 10 years within the Research and Development Department with managerial duties.

At present, she is involved in close scientific collaboration with Italian Universities and acts as a consultant for several chemical companies.

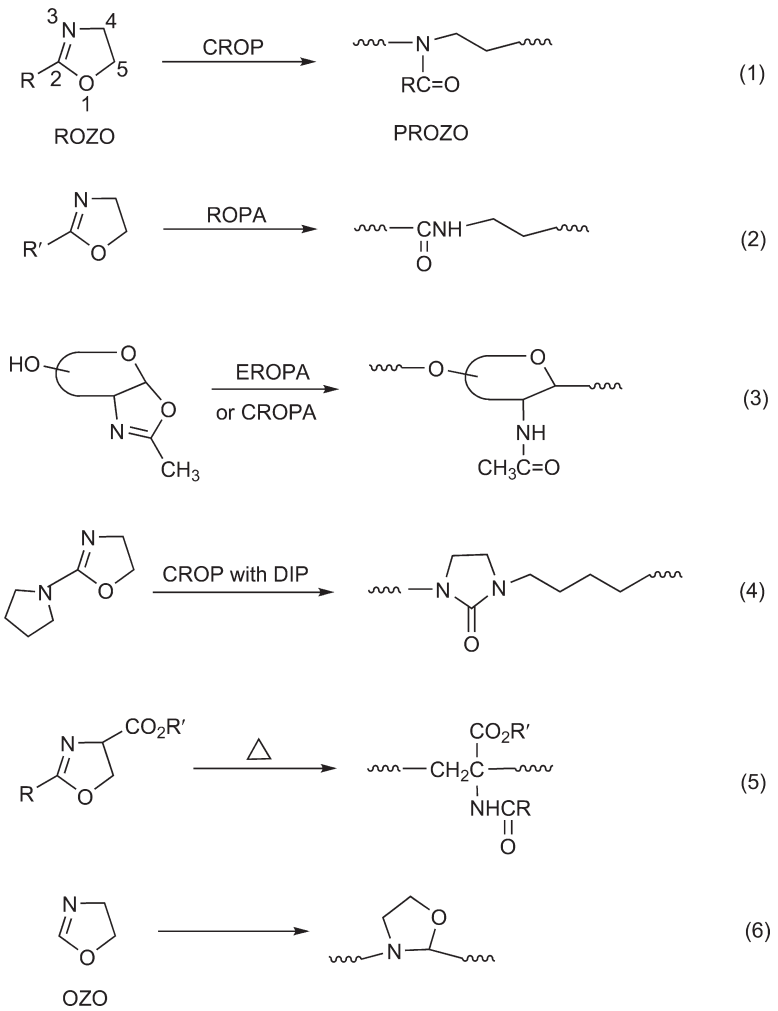
4.15 Polymerization of Oxazolines

S Kobayashi, Kyoto Institute of Technology, Kyoto, Japan

4.15.1 Introduction

Oxazolines are a family of cyclic imino ethers having a five-membered structure. Among the oxazoline family, 2-oxazolines (OZOs; IUPAC name: 4,5-dihydrooxazoles) with an *endo*-imino ether group (–C=N–O–) are most extensively studied so far in the polymerization chemistry. 2-Substituted-2-oxazolines (ROZO, reaction 1, **Scheme 1**) were first derived in the peptide chemistry of α-amino acid derivatives. In the polymer synthesis, pioneering works on the ring-opening polymerization of ROZOs were achieved in the mid-1960s by four independent groups.[1] A cationic catalyst or initiator induced the cationic ring-opening polymerization (CROP) of ROZOs to give poly(*N*-acylethylenimine)s (PROZOs) (reaction 1), during which the isomerization took place from the imino ether group of the monomer to a more thermally stable *N*-acyl group of the polymer.

After the above early studies, ring-opening polymerizations of OZOs have been conducted very actively and continuously for more than four decades, and various types of monomers and catalysts as well as polymerization modes have been developed. These results have been reviewed from time to time by several polymer scientists.[2] **Scheme 1** outlines the six reaction modes found, in which structures of monomers and product polymer units are given in a general form. Reaction 1 shows the CROP involving an isomerization of the –C=N–O– bond to an amide group –C(=O)–N– to produce an ethylenimine (EI) unit, the most well-known reaction mode. This mode of reaction constitutes a major part of the present chapter. Reaction 2 gives an amide unit, which is a mode of ring-opening polyaddition (ROPA) involving isomerization. Bis-ROZO monomers are often used in combination with bifunctional phenols or carboxylic acids for ROPA. Reaction 3 is a unique monomer as well as reaction mode involving isomerization found in polysaccharide synthesis with an enzyme catalyst (enzymatic ROPA (EROPA)) or a cationic catalyst (cationic ROPA (CROPA)). As shown in reaction 4,



Scheme 1 Major reaction types of oxazoline (OZO) monomers and their product polymer units in OZO polymerizations shown in general expression of structures.

depending on the nature of the monomer substituent and catalyst (initiator), CROP induces a double isomerization polymerization (DIP) during the polymerization to produce a new polymer unit. Reaction 5 involves ring opening of the monomer but affords a different polymer unit like a vinyl polymer under thermal reaction conditions. Reaction 6 does not involve the ring opening, undergoing the C=N reaction. Modes of reactions 5 and 6 are rather rare cases.

The polymers from the reaction (1) possess a PROZO structure, which can often be regarded as 'pseudopeptides' owing to the structure analogy and also to their nontoxic nature.[2,3] These characteristics often lead to 'smart' polymer materials like those quickly responding to external stimuli.

At the early stage of research, PROZOs were paid much attention as a convenient starting polymer for deriving linear polyethylenimine (LPEI), which is otherwise very difficult to prepare. It is because CROP of EI does not give LPEI but branched polyethylenimine (BPEI) (R = H, Scheme 2).[2,4]

This chapter is a comprehensive review dealing with polymerization of various OZO monomers to give a variety of polymers, polymerization reaction characteristics, and properties as well as applications of the product polymers.

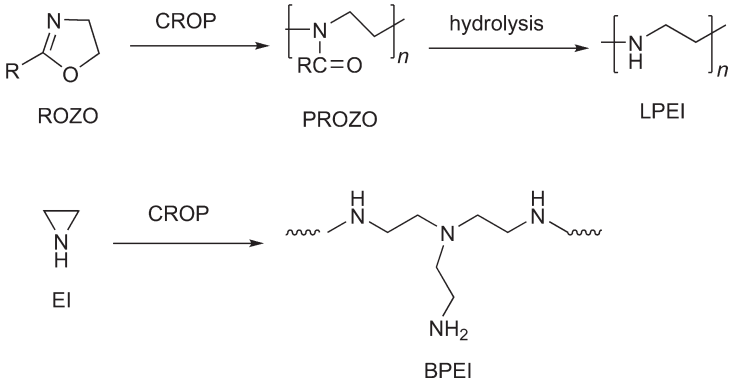
4.15.2 Cationic Ring-Opening Polymerization

4.15.2.1 Monomers, Catalysts (Initiators), Reaction Mechanism, and Monomer Reactivity

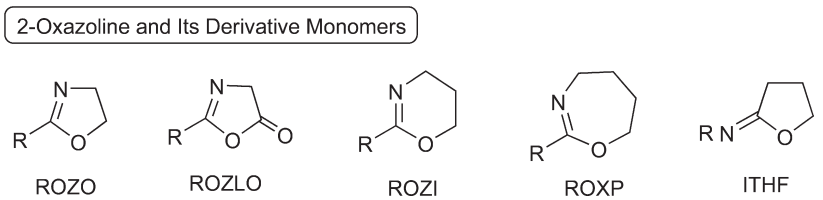
Typical examples of oxazoline monomers to be polymerized via CROP mode are shown in Scheme 3. Not only five-membered monomers of ROZO and 5-oxazolones (4,5-dihydro-1,3-oxazol-5-one, ROZLO) but also six-membered analogs (5,6-dihydro-4*H*-1,3-oxazines, ROZI) and seven-membered ones (4,5,6,7-tetrahydro-4*H*-1,3-oxazepine, ROXP) have been polymerized. 2-Iminotetrahydrofurans (ITHFs) are known as an *exo*-cyclic imino ether derivative of ROZO. CROP of ITHF was reported in 1963,[5] which was preceded by the studies on the CROP of OZOs.[1] Preparations of these monomers have been well known and documented.[2]

Concerning the structure of substituent R, numerous functional group-containing substituents have been investigated, functional groups being, that is, olefinic-, acetylenic-, phenolic-, hydroxyalkyl-, mercaptoalkyl-, carboxyalkyl-, amino-, aminoalkyl-, haloalkyl-, and other groups.[2,6] Some of these monomers act as a reactive or functional monomer.

As to catalysts or initiators, a variety of acid catalysts (protonic and Lewis acids), cationic species, and electrophiles have been



Scheme 2 Synthesis of linear polyethylenimine (LPEI) and branched polyethylenimine (BPEI).



Scheme 3 Monomer structures of 2-oxazoline family.

utilized and examined: typically, X of an electrophile RX = Cl, Br, I, *p*-toluenesulfonate (TsO), trifluoromethanesulfonate (TfO), etc. The nature of X affects the stability of oxazolinium ions and alters the polymerization mode (*vide infra*).[2]

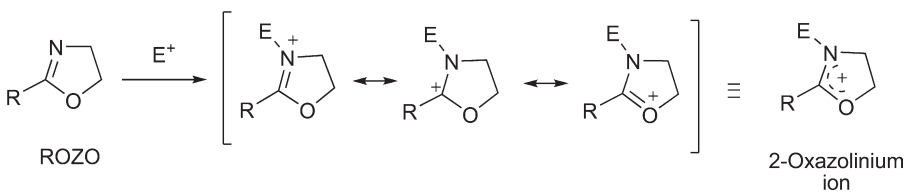
Since the imino nitrogen of OZOs is basic and nucleophilic, they readily react with an electrophile (E^+) to form oxazolinium species. Although the resulting cationic species are stabilized by resonance, they are reactive enough to be attacked by a nucleophile including OZO monomers (Scheme 4).

CROP of OZOs is generally given by using an initiator of R′X (Scheme 5). The nucleophlic attack to the 2-oxazolinium ion occurs selectively at its 5-position, which results in the isomerization of the imidate functional group (–C=N–O–) to a more stable amide group (–C(=O)–N–). Thus, CROP of ROZO is of 'cationic ring-opening isomerization polymerization' type. The CROP often proceeds in a living fashion due to a stable oxazolinium ion. The stable nature of the ions readily brings about the living CROP system.

The isomerization of the functional group gives an important feature on the CROP of ROZOs. The driving force for ROP of well-known monomers such as cyclic ethers, cycloalkene, lactones, and lactams is the release of ring strain (bond strain and tortional strain) during the polymerization.[7] However, the isomerization from the imino ether functional group to the more stable amide group gives an extra enthalpy gain, which was calculated to be 14 kcal mol^{-1}.[8a] This value seems even greater than the ring stain of the monomer since the ring strain of tetrahydrofuran is estimated as 5.5 kcal mol^{-1}.[8b] This enthalpy gain by the isomerization enables the ROP of a six-membered homolog of OZO, ROZI, although its ring strain is small.

Depending upon the nature of X^- (from a cationic catalyst or initiator) and of substituents R (R = H, alkyl, aryl, amino group, alkoxy group, etc., not only at 2-position but also at other positions), the polymerization mode becomes much varied. These affect the stability of the oxazolinium ion, and hence the reaction solvent also influences the reaction mode.

When OZO is allowed to react with an alkyl halide, an *N*-alkylated oxazolinium ion is once produced.[2] If the counter anion X^- is less stable (more nucleophilic), the ion receives a nucleophlic attack of the halide anion to produce the covalent *N*-2-haloethylamide. Therefore, a propagating species is of covalent type (Scheme 6). In the 1970s, from the results of polymerization mechanism studies, the covalent-type species was actually observed by ^{1}H NMR spectroscopy and confirmed as a stable propagating end.[2a–2e] The propagation reaction is a dipole (covalent-type species)–dipole (monomer) S_N2 reaction. This was supported by comparison of activation parameter values of the reaction with those of Menschutokin reaction like $Et_3N + EtI \rightarrow Et_4\ N^+\ I^-$, a similar dipole–dipole S_N2



Scheme 4 Structure and properties of 2-oxazolinium ion species.

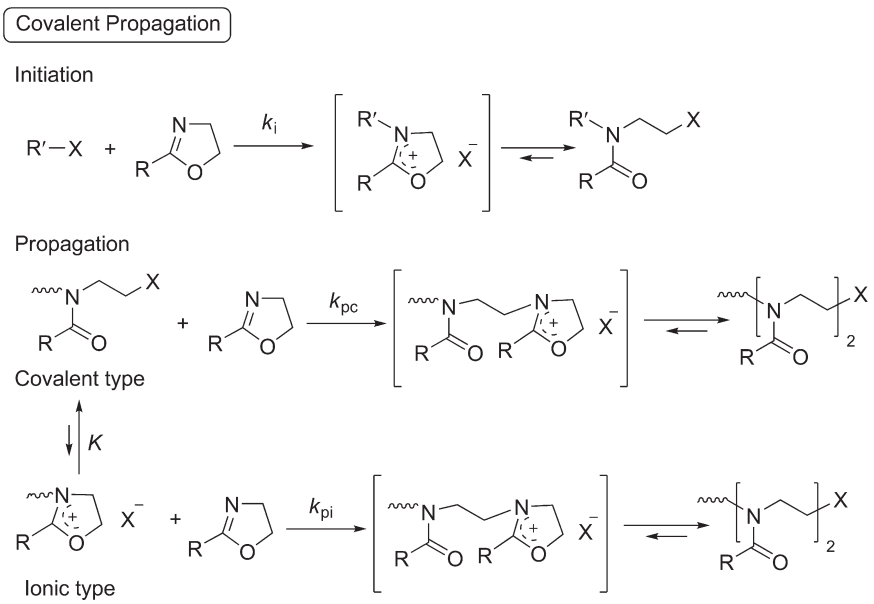
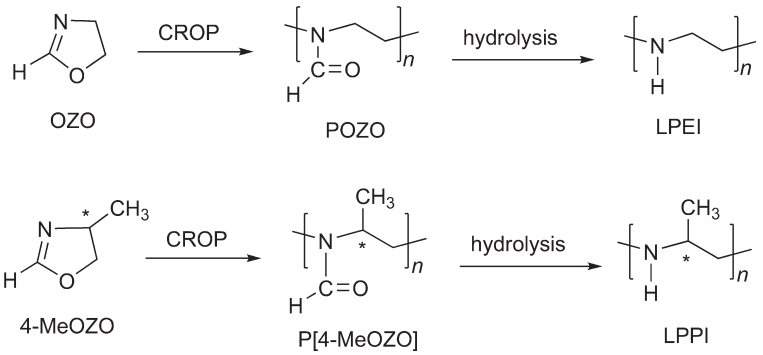


Scheme 6 A general scheme of cationic ring-opening polymerization (CROP) involving covalent propagating species in equilibrium with ionic propagating species.

reaction to form an ion, where the characteristics were indicated by both relatively lower enthalpy and entropy values of the reaction. In contrast to the covalent-type propagation, the ionic propagation is of an ion–dipole S_N2 reaction (Scheme 5), where relatively higher enthalpy yet higher entropy values of the reaction are normally observed. It is also highly possible that an equilibrium exists between the covalent type and the ionic type, the latter being formed via backbiting ionization of the former. The respective propagation reactions are given in Scheme 6; the propagation rate constants are denoted as k_{pc} (propagation due to covalent type) and k_{pi} (propagation due to ionic-type), respectively. An ionic type is normally much higher in reactivity than a covalent type. So, even though the covalent-type species is significant in amount, a major part of monomer may be consumed via the ionic-type propagation, because the rate of interconversion between the covalent type and the ionic type of the propagation end is much faster than the rate of propagation reaction[8c] (see also Scheme 8). If both propagations are involved, the propagation rate constants are in the following relationship:

$$k_{pap} = k_{pc} \times x_c + k_{pi} \times x_i$$

where k_{pap} denotes the apparent rate constant of propagation, and x_c and x_i are the molar fractions of covalent type and ionic type, respectively, that is, $x_c + x_i = 1$.[2a–2e]



Scheme 7 CROP of 2-unsubstituted OZOs and synthesis of LPEI as well as optically active linear poly(propylenimine) (LPPI) via hydrolysis of the *N*-formyl polymers.

Although ROZOs were extensively studied in the mid-1960s as shown in Scheme 5,[1] preparation of unsubstituted OZO was first reported in 1938,[9] and its CROP was achieved in 1972 (Scheme 7).[4] The OZO polymerization suggested the significance of POZO as a starting polymer for LPEI, due to the much easier hydrolysis of *N*-formyl group compared with that of *N*-acyl group.

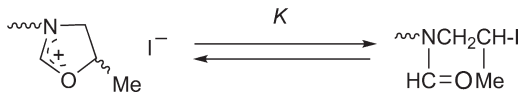
This method was extended to the preparation of optically active linear poly(propylenimine) (LPPI) via the CROP of 4-methyl-2-oxazoline (4-MeOZO) followed by the hydrolysis of the product polymer P[4-MeOZO] (Scheme 7).[10] The specific rotation of LPPI was $[\alpha]^{26}_{D}$ +105° (CH_3OH). 5-MeOZO also led to linear LPPI.[11]

So far, many mechanistic and kinetic studies have been reported to elucidate the monomer reactivity and type of CROP. Some of these data are shown in Table 1. The substituents at 2-position of monomers influence the type of the propagation species (ionic or covalent) and the monomer reactivity reflected by k_p values (rate constant of propagation given in Schemes 5 and 6). When the propagation species is ionic, k_p value is very different in the following order: H > Me > Ph. And, the nature of the counteranion (I^- or TsO^-) does not affect the CROP of MeOZO; the propagation is a reaction between an ionic propagating species and a dipole of monomer (Scheme 5). From the initiation reaction, the order Me > H > Ph > R_f accords with the basic strength of the monomer, which is reflected by the rate constant k_i values (data not shown) in Schemes 5 and 6, and also with the type of the propagating species; the higher the basic strength, the more ionic propagating species. However, the k_p value order is not simply in the basicity order of the monomer.

In the OZO polymerization, depending upon the counteranion, the covalent-type species by X = I showed a reduced k_p (about one-hundredth) compared with the ionic-type species by TsO^-, because the propagation is a dipole (covalent-type species)–dipole (monomer) reaction, formation of an oxazolinium ion is a rate-determining step (Scheme 6).

With a very strong nucleophilic Cl anion, propagation species of CROP of all monomers are of covalent type, whereas with the TfO anion, all the monomers proceed in the ionic propagation species, even though the monomers have a very strong electron-withdrawing perfluoroalkyl group. For reference, p*K*a of 2-methyl-2-oxazoline (MeOZO) is ~5, while that of 2-perfluoroethyl-2-oxazoline (R_fOZO) is ~2.[15]

Sometimes, equilibrium in the propagating ends exists between the covalent-type species and the ionic-type species, as they are interconvertible depending on the reaction conditions. The equilibrium is influenced by both the nucleophilicity and the leaving ability of halide ion and those of amide moiety, which are strongly influenced by the substituent of OZO. Actually, CROP of 5-methyl-2-oxazoline (5-MeOZO) with MeI initiator provided an interesting system, where the propagation species is present as both ionic and covalent species in equilibrium (*K*) as indicated in Scheme 8.[16] Concentration of both species much changed with temperature, and the ionic species were present around in one-third



Scheme 8 Both ionic and covalent propagating species are involved in equilibrium.

Table 1 Type of propagating species and propagation rate constants (k_p) of four counteranions

	Counteranion X⁻				
Monomer	*Cl* (k_p)[a]	*I* (k_p)[a]	*TsO* (k_p)[a]	*TfO*	*Reference*
OZO	covalent	covalent (0.18)	ionic (19)	ionic	12
MeOZO	covalent (0.03)[b]	ionic (1.14)	ionic (1.17)	ionic	13
PhOZO	-	covalent	ionic (0.02)[b]	ionic	14
R_fOZO[c]	-	covalent	covalent	ionic	15

[b] Calculated value from the experimental data.
[c] R_f: perfluoroalkyl group.

at 35 °C. Propagations occur from both species; at 40 °C in CD_3CN, k_p values due to the ionic type (k_{pi}) and covalent type (k_{pc}) were evaluated as 0.059 and 0.022×10^{-4} l mol^{-1} s^{-1}, respectively. With methyl *p*-toluenesulfonate (MeOTs) initiator, on the other hand, CROP of 5-MeOZO proceeded in all ionic propagating species.

Substituent effects on the monomer reactivity was quantitatively examined by performing CROP of 2-[*p*-(substituted) phenyl]-2-oxazolines by MeOTs initiator, where the substituents were H, CH_3, OCH_3, Cl, and NO_2. The k_p values of the monomers was in the following order: $OCH_3 > CH_3 > H > Cl > NO_2$. Hammett plots of the k_p values versus σ^+ values of the substituent gave a linear relationship, indicating that the monomer reactivity is governed by that of the oxazolinium propagating end.[14]

4.15.2.2 CROP: Various Reaction Modes

4.15.2.2.1 Monomers having heteroatom-containing substituents

Alkoxy or dialkylamino substituents were introduced into the 2-position (Scheme 9).[17–23] These OZO derivatives are not one of the classes of cyclic imino ethers, but 2-alkoxy-2-oxazoline is classified into a cyclic imino carbonate and *N,N*-dialkylamino-2-oxazoline into a cyclic pseudo-urea. These monomers polymerized to yield pseudo-polyurethane and pseudo-polyurea, respectively.

Contrary to the general living character of CROP of OZO, the polymerization of 2-ethoxy-2-oxazolines yields an oligomeric product (DP ~ 10) in a high yield as the chain transfer reaction involving the *exo*-attack of the propagating species occurs during CROP (Scheme 10).[17] The chain transfer was suppressed with a monomer having a bulky alkoxy substituent.

4.15.2.2.2 Double isomerization polymerization

All the above-mentioned CROPs involve isomerization one time during the polymerization (single isomerization polymerization (SIP)). However, the equilibrium in the propagating species between an oxazolinium halide and an *N*-haloethylamide brings an interesting yet complicated feature in the polymerization of OZO derivatives. A pseudo-urea is a compound having an –N=C(NR^2)–O– functional group, which is an isomeric form of urea. Then *N,N*-dialkylamino-2-oxazolines undergo CROP which was expected to give a pseudo-polyurea. However, the cationic polymerization of *N,N*-dialkylamino-2-oxazolines showed a unique polymerization behavior.

The cationic polymerization of 2-(1-pyrrolidinyl)-2-oxazoline (PyOZO) gave two different polymers by the selection of initiator.[18] With methyl trifluoromethanesulfonate (triflate) (MeOTf) or methyl *p*-toluenesulfonate (tosylate) (MeOTs), the polymerization of PyOZO yielded poly(*N*-(1-pyrrolidinecarbonylimino)ethylene) according to the usual CROP (SIP). On the other hand, the polymerization of PyOZO with RX gave poly ((1,3-diazolidin-2-one-1,3-diyl)tetramethylene) via DIP (Scheme 11).[19] In the latter polymerization, the OZO ring was opened and rearranged to a five-membered cyclic urea unit.

The polymerization mechanism of the SIP and DIP is explained as follows: In the initiation, *N*-alkylated oxazolinium salt is first formed. With the sulfonate initiator, the propagation via the oxazolinium species occurs to induce the SIP process, as the nucleophilicity of the counteranion is weak. When the counteranion of the salt is sufficiently nucleophilic as in the case of halides (X = Br, Cl), it catalyzes the rearrangement of the oxazolinium ion to 3-methyl-1-azonia-3-azaspiro[4.4] nonan-2-one salt, a spiro-structure, via a covalent-type alkyl halide species as an intermediate. This isomerization to form the spiro-intermediate is the key step of the DIP. Its formation is preferred since it is more thermodynamically stable than the oxazolinium ion, due to the more stable C=O bond than the C=N bond (Scheme 12). This spiro salt is sufficiently electrophilic to suffer the attack of the counteranion or the monomer. The attack of the counteranion exclusively occurs at the pyrrolidinium ring, and a covalent ethyleneurea species is generated selectively.[20]

The DIP has been extended to a bifunctional monomer, 1,4-bis(2-oxazolin-2-yl)piperazine (BOP), which yielded a linear polyurea, poly((1,3-diazolidin-2-one-1,3-diyl)ethylene) (PBOP).[21] When BOP was heated to 100 °C or above with methyl iodide or benzyl bromide in benzonitrile, the DIP proceeded and PBOP was obtained as brown needles whose melting point is 210 °C (Scheme 13).

It is very unusual that the polymerization of the bifunctional monomer of cyclic rigid structure gives linear polymer. The polymerization mechanism for DIP of BOP can be explained as shown in Scheme 14.

The polymerization of BOP with 2 mol% of MeOTf in benzonitrile at 150 °C, on the other hand, quantitatively produced an insoluble gel-like product after 100 h, whose IR spectrum showed the presence of urea and oxazoline groups. Obviously, two oxazoline moieties in BOP polymerized independently, which results in the branching and cross-linking of polymer.

A polymer having a high solubility was prepared from the SIP of 2-(1,3,3-trimethyl-6-azabicyclo[3.2.1]oct-6-yl)-2-oxazoline (TAOZO), although its DIP did not proceed. This polymer

was soluble in water as well as in common organic solvents.[22] The introduction of *o*-phenylene ring into the polymer main chain strongly reduced its solubility. The DIP of 2-(2-isoindolinyl)-2-oxazoline (IIOZO) with MeI produced an ethyleneurea-type polymer, which was partly soluble in chloroform.[23]

4.15.2.3 Microwave-Assisted CROP Reaction

Microwave irradiation is known to enhance the rate of various reactions. Normally, CROP reactions of ROZOs proceed relatively slowly, by taking some hours to complete the reaction. To accelerate the reaction, microwave irradiation method was applied and found very effective for the reaction, which has been extensively developed recently.[2j]

The first paper in 2004 reported that in comparison with the conventional thermal heating, CROP of 2-ethyl-2-oxazoline (EtOZO) by MeOTs catalyst in acetonitrile at 80–180 °C proceeded very fast under microwave irradiation to give PEtOZO in a living manner; rate acceleration was a factor of 350 (reaction time 6 h→ 1 min) with M_n up to 9000 and a polydispersity index (PDI) of 1.1–1.2. Side reactions were suggested by a slightly yellow coloration of the product solution. The homogeneous microwave irradiation allowed conducting the CROP in bulk or drastically reducing the solvent amount giving an opportunity of undertaking 'green chemistry'.[24]

The reaction rate of CROP of 2-phenyl-2-oxazoline (PhOZO) was similarly accelerated with MeOTs catalyst at 125 °C, showing a living nature to give PPhOZO almost quantitatively with M_n 10700 (PDI = 1.02) after 90 min. A strong microwave effect was suggested for a large rate enhancement. It is considered that microwave-assisted polymerization is a rapid, environmentally friendly method.[25] Whether or not the microwave effect actually exists was investigated by CROP of PhOZO initiated by MeOTs carried out under both microwave irradiation and conventional thermal heating. Then, it was concluded that the rate acceleration of CROP of PhOZO by microwave irradiation results from only the thermal effects.[26,27]

CROP on four monomers, MeOZO, EtOZO, PhOZO, and 2-nonyl-2-oxazoline (NonOZO), was studied by microwave irradiation with MeOTs initiator in acetonitrile at 80–200 °C. Rate enhancement was up to 400-folds, yielding the polymers whose degree of polymerization (DP) is higher than 300 with PDI < 1.20, exhibiting the living nature of the reaction. The fast, direct, and noncontact heating by the microwave irradiation permitted the CROP to be carried out in a highly concentrated solution or in bulk, which is a huge benefit.[28]

Microwave-assisted CROP of two monomers, EtOZO and PhOZO, was kinetically studied in acetonitrile with four initiators, benzyl chloride (BnCl), benzyl bromide (BnBr), benzyl iodide (BnI), and benzyl *p*-toluenesulfonate (BnOTs), to examine the effect on the reaction rate of the four different counteranions.[29] Values of the rate constant of propagation at 160 °C (k_p 10^{-3} l mol^{-1} s^{-1}) were for EtOZO: BnCl (2), BnBr (114), BnI (434), and BnOTs (350); and for PhOZO: BnCl (0), BnBr (2), BnI (7), and BnOTs (98). Percentages (%) of cationic propagating species were also determined by ^{1}H NMR for EtOZO: BnCl (0), BnBr (96), BnI (100), and BnOTs (100); and for PhOZO: BnCl (–), BnBr (0), BnI (25), and BnOTs (100). Namely, the CROP of EtOZO with BzCl and of PhOZO with BzBr proceeded via covalent propagating species in 100%. The nucleophilicity of X^- is in the order: $Cl^- > Br^- > I^- > TsO^-$ (see **Scheme 6**).

A variety of monomers were prepared by changing the structure of 2-substituent R, and their CROP was carried out with MeOTs initiator under microwave irradiation to give the corresponding polymers.[30] Table 2 demonstrates the structure of 12 substituents (R of ROZO) and the results of their kinetic study by k_p values (l mol^{-1} s^{-1}) in the parenthesis carried out at 140 °C in dichloromethane. The k_p values are in the range from 1×10^{-3} to 241×10^{-3} depending on the structure and substituent of ROZOs. An electron-rich aromatic group (furan) shows a higher polymerizability close to an alkyl substituent, whereas bulky groups decrease the k_p values. For reference as to temperature effect, the k_p values of MeOZO (2050×10^{-4} at 140 °C) can be interestingly compared with that (1.17×10^{-4} at 40 °C) in acetonitrile.[31]

4.15.2.4 Copolymerization via CROP-Mode Reaction

When the copolymerization between two ROZO monomers having a close reactivity is conducted, the reaction produces normally random copolymers. In such cases, copolymers with the average properties are expected, but production of copolymers with specific properties is less expected.

4.15.2.4.1 Block copolymerization

The living characteristic nature of CROP led to the development of a new concept in block copolymerization. Actually, AB-type block copolymers were first prepared with an appropriate combination of ROZOs and the product block copolymers were found to be an excellent nonionic polymer surfactant (**Scheme 15**).[3] This finding of amphiphilic copolymers from ROZOs for the new surfactants was based on employing MeOZO and EtOZO as monomers for hydrophilic segments, and 2-propyl (PrOZO), 2-butyl (BuOZO), 2-octyl (OcOZO), 2-dodecyl (DoOZO), and PhOZO as monomers

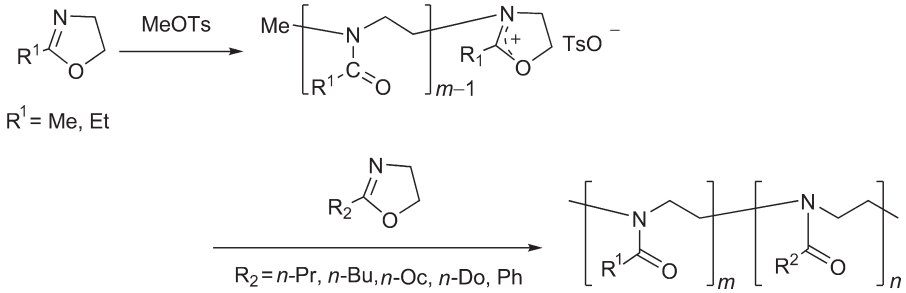


Scheme 15 Synthesis of nonionic amphiphilic block copolymers via living CROP of ROZO monomers giving a hydrophilic segment at 1st stage and a hydrophobic segment at 2nd stage.

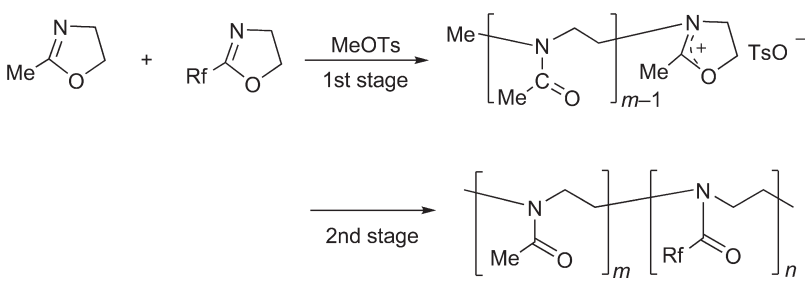
for hydrophobic segments. Typically, at the first stage, a living CROP of MeOZO was induced by MeOTs initiator for a hydrophilic A block, and at the second stage, BuOZO was polymerized from the MeOZO living end for a hydrophobic B block, to produce P[MeOZO-*block*-BuOZO] (one-pot, two-stage sequential method). All the products were soluble in water. The surfactant nature was evaluated by the surface tension value (γ, dyn cm^{-1}), for example, a block copolymer with R^1 = Me (m = 19) and R^2 = Bu (n = 5) exhibits γ = 27.5 in contrast to γ of pure water = 71.3. In addition, by using mono- and bifunctional initiators, surfactants of triblock copolymer (BAB type) were prepared and the copolymer P[$OcOZO_6$-*block*-$MeOZO_6$-*block*-$OcOZO_5$] showed the lowest γ value of 23.7 dyn cm^{-1}. The critical micelle concentration (CMC) of these copolymers was lower than 1.0 wt%. It is important to note that PMeOZO segment is so far the most powerful as a nonionic hydrophilic polymer segment due to the polar amide structure, which is more powerful than poly(ethylene glycol) (PEG) segment. Not only ROZO monomers but six-membered ROZI monomers were used for an A block or B block.

In the usual copolymerization between the two monomers of different reactivity, the polymerization of the less reactive monomer should be conducted first. Then, the second monomer is to be added to the system to complete the two stages. Contrary to this general tendency, the cationic copolymerization between MeOZO and RfOZO produced AB-type block copolymers of well-controlled block lengths; R^2 = Rf (fluoroalkyl group) in **Scheme 16**. The employed initiator MeOTs selectively reacts with the more nucleophilic MeOZO, which is followed by the homopolymerization of MeOZO until almost all MeOZO was consumed. Then, the second propagation proceeds slowly to form RfOZO diblock to produce P[MeOZO-*block*-RfOZO] (**Scheme 16**).[15] The monomer reactivity of MeOZO should be more than a hundred times higher than RfOZO, if estimating from values like 205:1 in **Table 2**. This copolymerization provided a one-pot, two-stage method by the simultaneous feeding of two monomers.

Microwave-assisted CROP was utilized extensively for the synthesis of block copolymers, because of the higher rate of reaction and the living nature of CROP of OZOs. Diblock copolymers were prepared from four monomers, MeOZO, EtOZO, PhOZO, and NonOZO, in acetonitrile at 140 °C, which gave a library of 4 chain-extended homo-PROZOs and 12 diblock co-PROZOs. The CROP reaction to yield a total number of 100 (50 + 50) monomer units was designed and thus-obtained 16 polymers showed a narrow PDI (< 1.30). All polymers were stable up to 300 °C.[32]

Furthermore, microwave-assisted polymerization was extended to prepare amphiphilic triblock terpolymers to prepare a library of desired 30 terpolymers via CROP of the above four monomers. The polymerization was performed in a three-step sequential procedure to complete the monomer consumption ranged from 13.2 to 61.6 min. The terpolymers exhibited narrow PDI (~ 1.3) near the targeted monomer ratio of 33:33:33. The T_g values ranged from 50 to 100 °C depending on the incorporated monomers. Some amphiphilic terpolymers containing two hydrophilic and one hydrophobic blocks formed micelles, whose size ranged between 7 and 18 nm.[33] Similarly, tetrablock ter- and quarter-polymers were prepared from the same four monomers to design the polymers having the monomer units as all 25. Well-defined tetrablock polymers were obtained, having the structures of ABCA, ABCB, ABCD, and ABDC, where A is MeOZO block, B EtOZO block, C PhOZO block, and D NonOZO block. These block polymers showed amphiphilic nature found by the surface energy measurement and formed aqueous micelles whose size varied around 5–40 nm.[34]

Tri- and tetrablock polymers prepared from these four monomers formed micelles, whose morphologies were investigated in binary water–ethanol mixtures.[35] The solvophilic/



Scheme 16 Block copolymer synthesis via one-pot, two-stage method.

solvophobic balance of these block polymers was tuned owing to the solubility dependence of the PPhOZO block on the solvent composition. Solubility of the four polymer blocks for the solvent composition: For EtOH/water (60/40) wt%: PMeOZO (s), PEtOZO (s), PPhOZO (s), and PNonOZO (ns), whereas for EtOH/water (40/60) wt%: PMeOZO (s), PEtOZO (s), PPhOZO (ns), and PNonOZO (ns), where s and ns mean 'soluble' and 'not soluble', respectively. Dynamic light scattering (DLS) and transmission electron microscopy (TEM) measurements revealed that when the solvophobic fraction consists of both the PPhOZO and PNonOZO blocks, spherical and cylindrical micelles as well as vesicles were observed; the size of spherical micelles was of some 10 nm. The block order in the polymers much affected the final micellar morphology.

In the simultaneous copolymerization of PhOZO with MeOZO or with EtOZO under microwave irradiation, a block-like copolymerization took place to give quasi-diblock copolymers.[36] This is because of a big difference in the monomer reactivity ratio previously reported as $r_{MeOZO} = 10$ and $r_{PhOZO} = 0.02$, the situation of which is similar as mentioned in Scheme 16.

CROP of EtOZO and 2-'soy alkyl'-2-oxazoline (SoyOZO) was performed with microwave irradiation by MeOTs initiator, where SoyOZO monomer was derived from soybean fatty acids (Scheme 17).[37,38] Copolymers obtained were of statistical structure, since both monomers possessed close monomer reactivity ratios: $r_{EtOZO} = 1.4$ and $r_{SoyOZO} = 1.7$. The copolymers showed M_n values of $6–13 \times 10^3$ with PDI of 1.2–1.5. UV irradiation gave a cross-linked material via the reaction of the unsaturated soy alkyl group in the copolymer.

In the random and block copolymer formation from EtOZO and NonOZO monomers, structure–property relationships were investigated.[39] Synthesis of the random copolymers were conducted with microwave irradiation in acetonitrile and synthesis of the block copolymers with the conventional heating, both by MeOTs initiator. Under microwave irradiation, both monomers showed close monomer reactivity ratio values: $r_{EtOZO} = 1.07$ and $r_{NonOZO} = 1.05$. All the product copolymers were shown to have well-defined structure. The organization of the monomer units in the copolymers involves a significant effect on the surface energy, thermal transition, and mechanical properties of the copolymer material, showing that the structural control over monomer distributions is an excellent way to control these properties. Microwave-assisted one-step synthesis of EtOZO/2-(*m*-difluorophenyl)-2-oxazoline (F_2PhOZO) and EtOZO/PhOZO copolymers was conducted via CROP with MeOTs initiator in acetonitrile at 140 °C.[40] The CROP reaction produced the well-defined statistical gradient copolymers, which are good surfactants and formed micelles having a diameter of 9–13 nm determined by atomic force microscopy (AFM). Ionic liquids could be used as solvent at 140 °C for microwave-assisted CROP of PhOZO and F_2PhOZO.[41]

When bifunctional initiators are used, a variety of telechelic PROZO polymers are to be prepared via the nucleophilic reaction of the di-oxazolinium living species for introducing target functionality.

Block polymers using blocks other than PROZO chain were prepared. As a typical example, polytetrahydrofuran (PTHF) was introduced to AB-type and BAB-type block copolymer as shown in Scheme 18.[42] For the synthesis of the diblock copolymer, ethyl trifluoromethanesulfonate (EtOTf) was used as initiator, while for the triblock copolymer, anhydride of TfOH was employed, where a living CROP of THF end, an oxonium species, is involved. PTHF is a hydrophobic chain; both copolymers showed very good surfactant properties, when MeOZO or EtOZO was used, as observed by the surface tension value reaching to $\gamma = 30.1–28.2$.

In place of PTHF, PEG was used for triblock copolymers [PMeOZO-*block*-PEG-*block*-PMeOZO] and the deacetylated copolymer exhibited good anti-electrostatic properties. Also, poly(propylene glycol) chain acted as the block segment.[43] A vinyl ether segment was used as a hydrophobic block, whose copolymer was prepared as shown in Scheme 19.[44] The iodine-catalyzed polymerization of vinyl ether proceeds in a living fashon, whose propagating end causes the CROP of ROZO to give an AB-type diblock copolymer. When R^1 group is *n*-Bu, *i*-Oct, or *n*-Cet, the vinyl ether segment is hydrophobic, whereas the ROZO segment is hydrophilic when R^2 is Me or Et. The block copolymers showed good properties as nonionic polymer surfactant (γ value < 30). The copolymer was readily cleavable under weakly acidic conditions due to the labile bond connecting the two blocks. The cleavage mechanism is considered as also shown in Scheme 19. This property can be conveniently utilized depending on the way of the usage as a 'smart' surfactant.

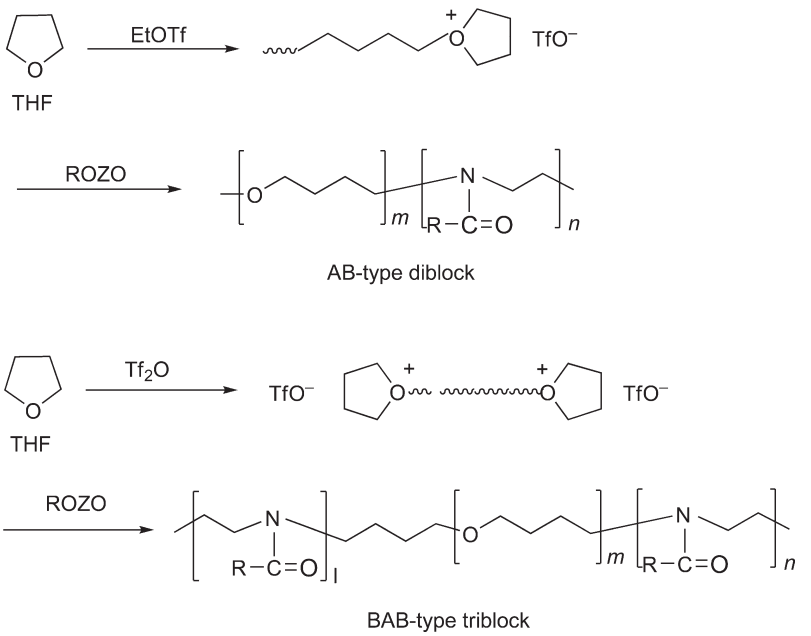
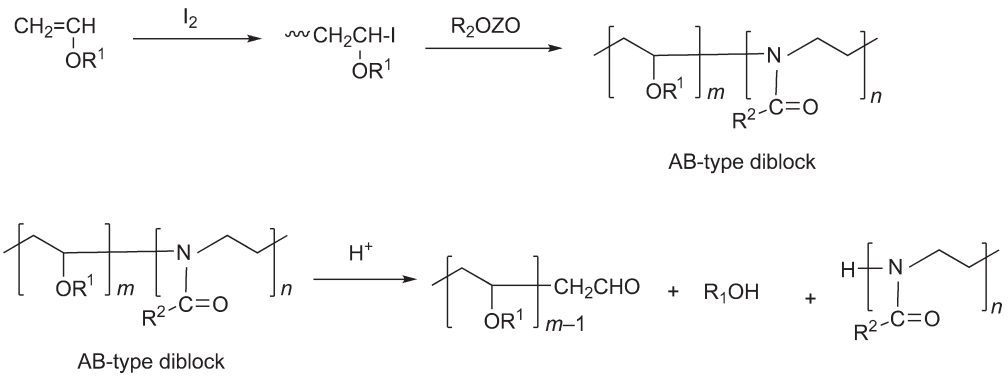


Scheme 18 Synthesis of AB-type and BAB-type block copolymers via CROP of ROZO and tetrahydrofuran (THF).



Scheme 19 A block copolymer from a vinyl ether and ROZO, showing readily cleavable nature.

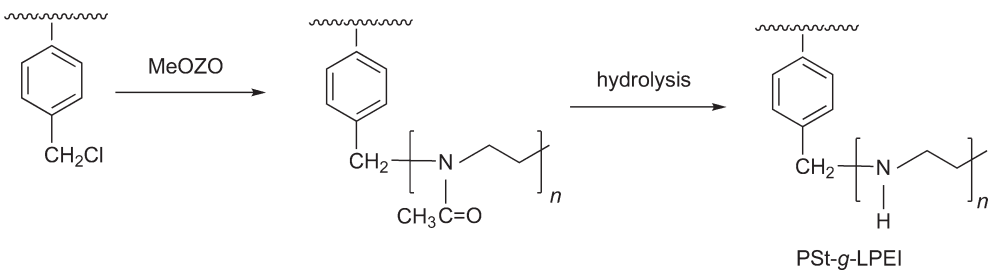
Other examples of polymer chains for the block component are cited such as polystyrene,[45] polyisobutylene for three-armed star-block copolymers,[46] poly(ε-caprolactone),[47] and glycopeptides.[48]

4.15.2.4.2 Graft copolymerization

A variety of graft polymers have been prepared via different methods.

Initiator method: CROP of MeOZO was initiated from chloromethylated polystyrene and the hydrolysis of the PMeOZO produced poly(styrene-*g*-ethylenimine). The graft copolymer (PSt-*g*-LPEI) is an efficient chelating resin for the absorption and recovery of heavy metal ions such as Cu^{+2}, Hg^{+2}, and Cd^{+2} (Scheme 20).[49]

MeOZO and EtOZO were grafted onto cellulose (Cell-OH) and cellulose diacetate, in which CROP of ROZO was initiated



Scheme 20 Synthesis of LPEI-grafted polymer initiated from chloromethylated polystyrene.

from the tosylated group (Scheme 21).[50a] Since the PROZO chains are weakly basic and compatible (miscible) with commodity polymers like poly(vinyl chloride) (PVC) and polystyrene confirmed by measurements using a rheovibron, the graft copolymers (Cell-*g*-PROZO) made cellulose and cellulose diacetate derived from natural polymers well compatible with a commodity polymer.[50b] Therefore, the application of these natural polymers has become widely used.

Terminator method: Another polysaccharide of chitin was used for CROP grafting of ROZO, where the *N*-acetyl group was to be converted to amino group for the next reaction as a deacetylated chitin. Then propagating oxazolinium species was terminated by the reaction with the amino group to produce the graft copolymer (chitin-*g*-PROZO) (Scheme 22).[51] The chitin-based graft copolymer was miscible with poly(vinyl alcohol) (PVA) over a wide range of their composition, whereas chitin and PVA gave a binary blend. The graft copolymer was also miscible with PVC, indicating that PROZO chain functions as the compatiblizer.

Pullulan-*graft*-poly(2-isopropyl-2-OZO) (PiPrOZO) copolymer was obtained by terminating the activated ends of PiPrOZO chain with hydroxy groups of pullulan at room temterature in dimethyl sulfoxide (DMSO). Around one PiPrOZO chain (molecular weight ~3200) was introduced per 100 glucose units.[52]

Macromonomer method: Macromonomers are conveniently used for the graft copolymer synthesis. A macromonomer of PEG chain having an oxazoline polymerizable group was prepared and used for a graft copolymer synthesis (Scheme 23).[53] The macromonomer has a hydrophilic PEG segment, and hence its CROP-type copolymerization with PhOZO proceeded randomly to give an amphiphilic graft copolymer PPhOZO-*g*-PEG, showing good surfactant nature with a γ value of 28.8 dyn cm^{-1}.

Radical copolymerization of an acryl- or methacryl-type PROZO macromonomer (see Scheme 49) with a vinyl monomer of methyl methacrylate (MMA), styrene (St), or acrylamide (AM) produced graft copolymers (Scheme 24).[54] The surface property of the film from the graft copolymer (R = Me) was made hydrophilic due to the character of PMeOZO chain verified by the contact angle measurement. Such behaviors were also observed in the solution of the graft copolymer of PSt-*g*-PMeOZO via ^{1}H NMR measurement.

4.15.2.4.3 Alternating and periodic copoplymerizations

An alternating copolymerization involving a zwitterionic intermediate was widely investigated.[55] When two kinds of monomers, nucleophilic (M_N) and electrophilic (M_E), are combined without catalyst or initiator, they form a zwitterion (genetic zwitterion), which is responsible for both initiation and propagation (Scheme 25). Two molecules of the zwitterion produce a dimeric zwitterion, which further reacts with genetic, dimeric, or polymeric zwitterion of different molecular weight to afford a product alternating copolymer.

Based on this concept, various combinations of M_N and M_E monomers were explored. As M_E monomers, various lactones, (meth)acrylic acid, and acrylates were often employed. Oxazolines were widely used as reactive M_N monomers.[56] An

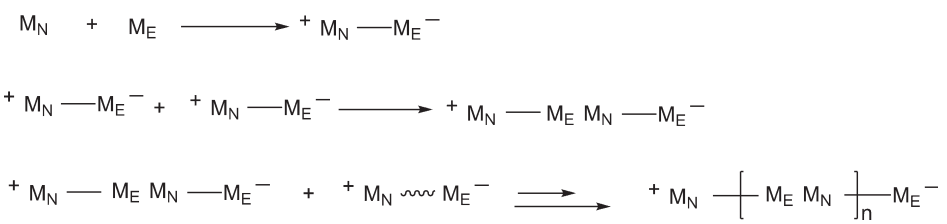

Scheme 25 General scheme of initiation and propagation of alternating copolymerization via zwitterionic intermediates from nucleophilic monomer (M_N) and electrophilic monomer (M_E).

example reaction in the combination of OZO and acrylic acid is shown in Scheme 26, where a proton transfer step of acrylic acid is involved. Hence, the product polymer has the same repeating unit structure of the copolymer from OZO and β-propiolactone.

Ring-opening-closing alternating copolymerization involving a zwitterionic intermediate was found as indicated in Scheme 27, where MeOZO ring was opened, whereas *N*-methyldiacrylamide gave a five-membered ring-closed unit having $M_n = 5600$.[57] The ring closure was at most 65%, the others being of a vinyl-type unit.

Depending on the combination of M_N and M_E monomers, alternating and periodic copolymers were synthesized in various structures such as AB_2, BA_2, $A_{1/2}B$, and ABC types. A periodic A_2B-type copolymer (2:1 monomer composition) having an ABC-type periodic terpolymer structure was produced from OZO and glutaric anhydride (Scheme 28).[58] From OZO, a unit structure of reaction 6 (Scheme 1) is formed.

4.15.3 Ring-Opening Polyaddition

A fundamental reaction mode in this section is generally given in Scheme 29, where a compound having reactive proton (Y-H) adds to ROZO with ring opening (ROPA). The reaction involves a protonated oxazolinium intermediate. As reactive Y-H, RCO_2H-, RSH-, and ArOH-type compounds are normally employed.[2h]

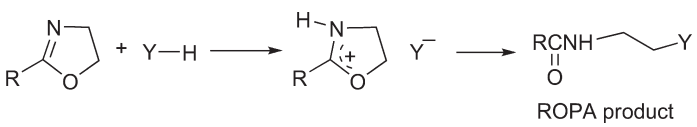


Scheme 29 Reaction mode of ring-opening addition.

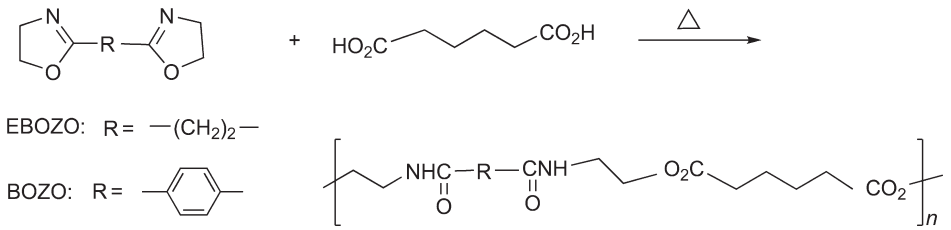
4.15.3.1 ROPA Reaction between A-A-Type Monomer and B-B-Type Monomer

Reaction of 2,2′-ethylene-bis(2-oxazoline) (EBOZO, A-A-type monomer) and adipic acid (B-B-type monomer) produced an amide-ester polymer with melting range 145–155 °C (Scheme 30).[1c]

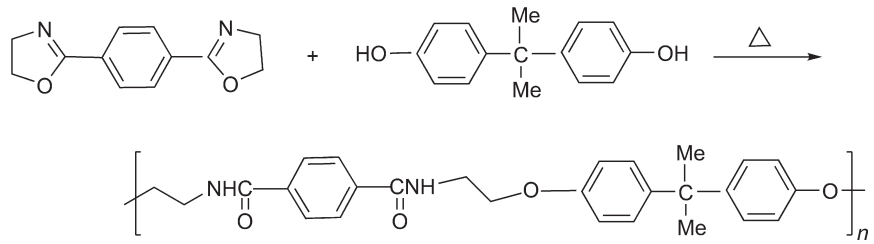
A thermoplastic of an amide-ether type was prepared from an aromatic bis(2-oxazoline) (BOZO) and a bis-phenol at 180 °C. It is an amber, transparent, and brittle solid with molecular weight $M_w \sim 114\,000$ showing melting point 150–160 °C (Scheme 31).[2h]

Also, poly(amide-thioether)s were prepared from a BOZO and a bisthiol (see Scheme 32).[59]

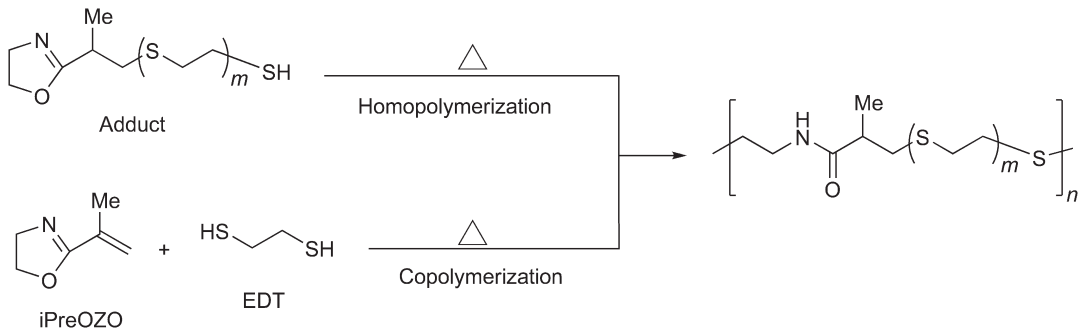
Application of ROPA reaction for chain extender: The highly reactive nature of ROZO toward carboxylic acid group was applied for a chain extender. Poly(ethylene terephthalate) (PET) is an important plastics as it is widely used in daily life. The annual consumption is over 10 million tons worldwide,



Scheme 30 ROPA reaction between A-A-type monomer and B-B-type monomer.



Scheme 31 ROPA reaction between bis(2-oxazoline) and bis-phenol.



Scheme 32 ROPA reactions using thiol containing monomers.

and its recycling is an important subject in view of environmental aspects. The hydrolytic degradation of recycled PET due to moisture as well as its thermal degradation reduces molecular weight, which lowers the mechanical properties of recycled material. The use of a chain extender and solid-state polymerization (SSP) has been a good method to improve the chain length of recycled PET.[60] Recycled PET contains carboxyl end groups. One of the representative examples of carboxyl-reactant chain extenders is BOZO (Scheme 30). For example, the intrinsic viscosity of PET whose [η] increased from 0.66 to >1.0 after the reaction with 1.0 wt% of BOZO at 280 °C after 5 min.[61] Obviously, BOZO is an effective chain extender of high reactivity to increase the PET molecular weight.

Another example is concerned with poly(L-lactic acid) (PLLA). It is already used in packaging, consumer goods, and many other applications. For PLLA, the usage of a BOZO as chain extender is very adequate as T_m of PLLA (~170 °C) is lower than that of PET, in which the chain extender was used for oligo(lactic acid) prepared by the direct polycondensation.[62] To prepare PLLA sample with two carboxyl ends, L-lactic acid (LLA) was condensed with itself in the presence of 2 mol% of succinic anhydride (SA) and 0.05 wt% of tin(II) octoate. Then the chain extension reaction with BOZO was carried out at 190–210 °C.[63] Thus, high-molecular-weight poly(ester-amide) (PEA) was produced from the PLLA prepolymer only at 200 °C for 10 min with BOZO/SA = 1.2/1.0; value of M_w becomes higher from 1×10^4 to 19×10^4. The resulting PEA was thermoplastic and could be processed by injection molding. The mechanical properties of the resulting PEA specimen were substantially better than those of untreated PLLA. The PEA sample had higher tensile strength and modulus than PLLA as well as other commodity polymers such as polystyrene, poly(butylene terephthalate), and nylon-6. The strain of PEA was slightly higher than that of polystyrene and PLLA.

4.15.3.2 ROPA Reaction of AB-Type Monomers

As AB-type monomers, carboxyl group-containing oxazolines are well known and their polymer formation reaction is the same as shown in Scheme 30. From an aromatic carboxylic acid derivative, a commercial resin was developed. Phenol group-containing oxazolines were reacted similarly as given in Scheme 31.[2h]

Poly(amide-thioether)s were prepared from a BOZO and a bisthiol.[59] A 2-(thiomercaptoalkyl)-2-oxazoline adduct (AB-type monomer) was obtained from a reaction of

2-(*i*-propenyl-2-oxazoline, *i*PreOZO) and 1,2-ethanedithiol (EDT), and the adduct was homopolymerized thermally to produce a poly(amide-thioether) having molecular weight range 4100–43 000 (Scheme 32), where the polymerization is considered to proceed involving a zwitterion intermediate.[64] *i*PreOZO and EDT were copolymerized to produce a similar poly(amide-thioether).

4.15.4 ROPA for Polysaccharide Synthesis

For the polysaccharide synthesis, 'enzymatic polymerization' has been developed as a new *in vitro* synthesis method of natural and unnatural polysaccharides having complicated structures.[65] The method utilizes a hydrolysis enzyme to catalyze the bond formation for the polymer construction, a reverse direction of the hydrolysis to cleave the bond. This catalysis is due to the enzymatic characteristics, where enzymes catalyze the reverse reaction involving a common intermediate in both forward and backward reactions. In nature, there are many polysaccharides having *N*-acetyl groups called 'mucopolysaccharides' such as chitin, hyaluronic acid (HA), and chondroitin (Ch).

4.15.4.1 Enzymatic ROPA of Sugar Oxazolines

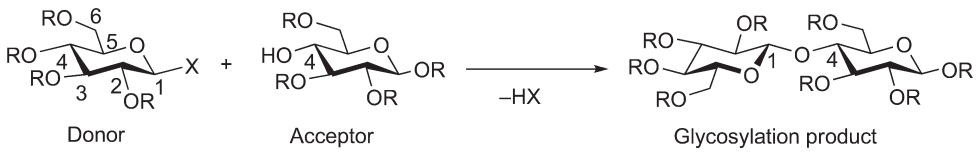
It has been found that various sugar oxazoline derivatives serve as monomers for enzymatic catalysis to produce natural and unnatural mucopolysaccharides, in which the monomers were designed and synthesized on the basis of the transition-state analogue substrate (TSAS) concept (*vide infra*).[65] All the sugar oxazoline monomers are of AB-type structure mentioned in Section 4.15.3.2.

Polysaccharide synthesis requires a repetition of a controlled glycosylation reaction, connecting two sugar units in a regioselective and stereocontrolled manner. The synthesis is achieved only when the repetition of the reaction is achieved multiple times. The glycosylation is a reaction between a glycosyl donor and a glycosyl acceptor; a simple example to form a $\beta(1\rightarrow4)$ glycosylation product via condensation is given in Scheme 33. The anomeric C-1 carbon of the donor is to be activated by introducing X.

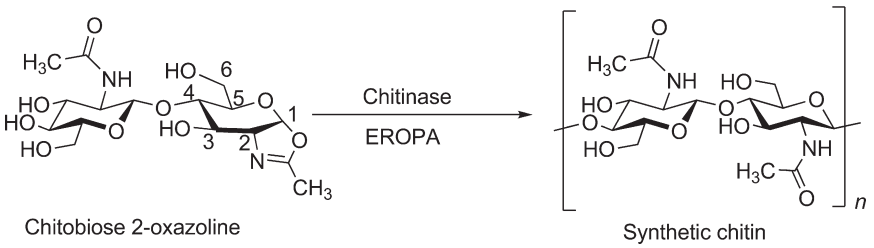
4.15.4.1.1 Synthesis of chitin and chitin derivatives

The first successful *in vitro* synthesis of chitin was achieved in 1995 by the enzymatic ROPA (EROPA) of a chitobiose OZO monomer catalyzed by chitinase enzyme, affording 'synthetic chitin' in high yields with DP value 10–20 (Scheme 34), in which the stereochemistry and regioselectivity are perfectly controlled.[66] A general reaction mode is that of reaction 3 in Scheme 1. In the reaction of Scheme 34, the chitobiose OZO monomer (without protection) acted as a donor as well as an acceptor, where the oxazoline structure activates the anomeric C-1 carbon of the monomer as donor and it attacks regioselctively the 4′-OH of the acceptor. The oxazoline ring opens with isomerization and affords an *N*-acetyl group, leading to the structure of $\beta(1\rightarrow4)$ glycosidic linkage. To understand and explain the reaction to occur, a new concept of a 'transition-state analog substrate' (TSAS) monomer was proposed.[66] The concept implies that the *in vivo* chitinase-catalyzed hydrolysis of chitin involves an oxazoline or oxazolinium ion intermediate (or transition state), which has actually been confirmed.[67] The TSAS concept also suggests the fundamentally important characteristics of enzymatic reactions, in which an enzyme stabilizes the transition state to lower the activation energy, accelerating the reaction in tremendous rate enhancement.[68]

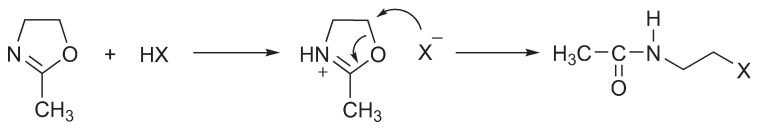
The enzymatic chitin synthesis together with the TSAS concept provided with a new way for the synthesis of mucopolysaccharides having *N*-acetyl group at the 2-position of the sugar unit, which are widely found polysaccharides in nature. Scheme 35 explains that the MeOZO moiety in the monomer



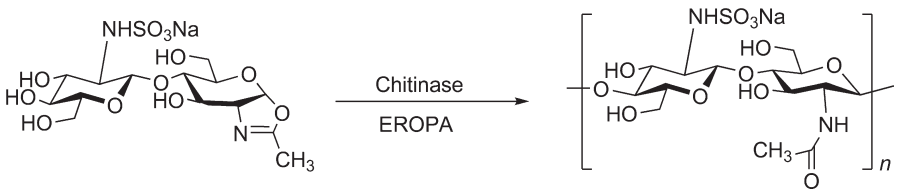
Scheme 33 A glycosylation reaction to form b(1®4) linkage in carbohydrate chemistry.



Scheme 34 Synthetic chitin is produced via enzymatic ROPA (EROPA) reaction.



Scheme 35 MeOZO serves as a latent N-acetyl group.



Scheme 36 Chitinase-catalyzed synthesis of a chitin derivative via EROPA reaction.

is a latent *N*-acetyl group generator with ring-opening isomerization leading to the product chitin, as shown by a simple general reaction of MeOZO with an electrophile HX.

In addition, a monomer having a bulky and ionic *N*-sulfonate group at the 2′-position was also catalyzed by chitinase and gave corresponding chitin derivative of the weight-averaged molecular weight (M_w) 4990 in 62% yield (Scheme 36).[69] These results indicate that chemical structure at C-2′ of chitobiose oxazoline is less influential for chitinase recognition in catalysis.

Monomers substituted with fluorine atom at the 6-position(s), whose covalent radius (0.64 Å) is almost the same with that of oxygen (0.66 Å), showed good polymerizability.[70]

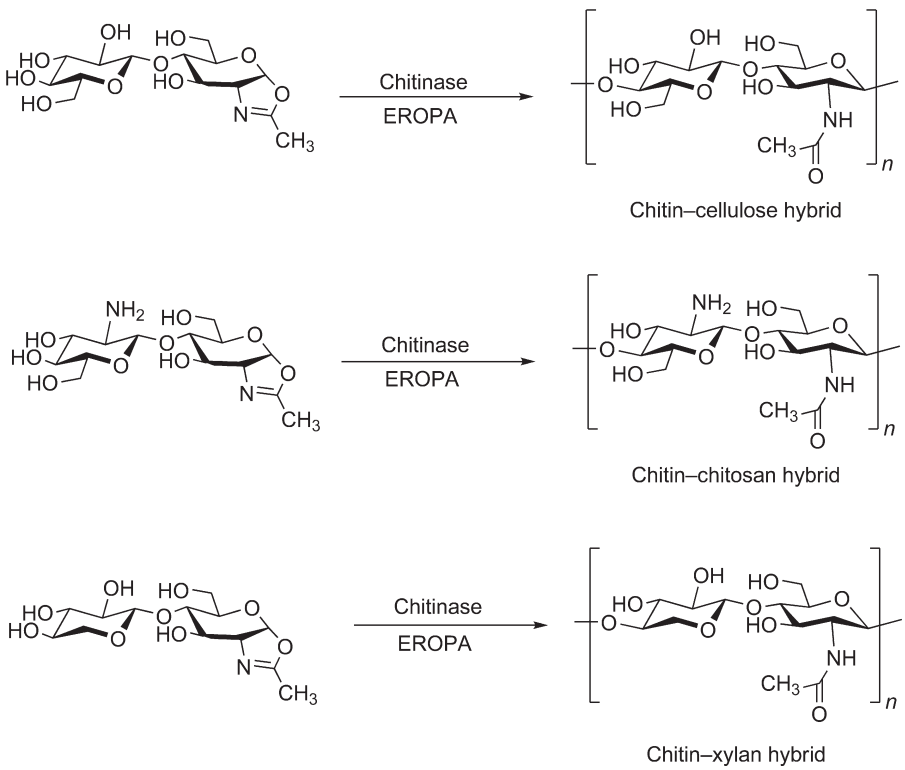
4.15.4.1.2 Synthesis of chitin hybrids

With the appropriate design of monomers, the following three hybrid polymers, chitin–cellulose hybrid with DP value 22 in 79% yields,[71] chitin–chitosan hybrid with M_w 4280 in 75% yields,[72] and a water-soluble chitin–xylan hybrid with M_w 2730 in 80% yields,[73] have successfully been synthesized (Scheme 37). In all EROPA reactions, structural control is perfect, having a $\beta(1\rightarrow4)$ glycosidic linkage.

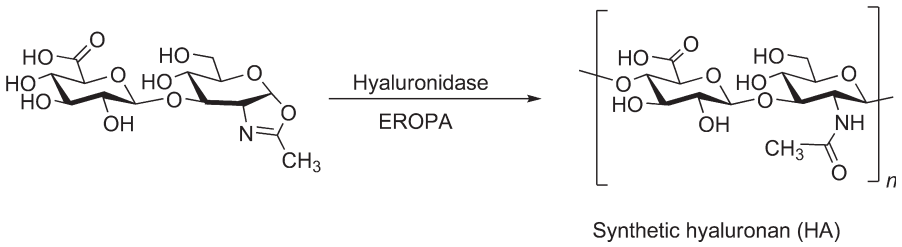
4.15.4.1.3 Synthesis of hyaluronic acid (hyaluronan, HA) and chondroitin (Ch)

HA (hyaluronan) and Ch belong to glycosaminoglycans (GAGs), biomacromolecular heteropolysaccharides, which are normally linked to various proteins to form proteoglycans. Together with collagens, fibronectins, and others, proteoglycans fill the interstitial space between living cells, and they are called extracellular matrices (ECMs). GAGs include HA, chondroitin sulfate (ChS), dermatan sulfate, heparin/heparan sulfate, and keratin sulfate (KS). All GAGs contain hexosamine unit such as *N*-acetyl-D-glucosamine (GlcNAc), *N*-acetyl-D-galactoamine (GalNAc), and their sulfated derivatives. HA is a linear polysaccharide having a repeating unit of β(1 → 3)-GlcNAc-β(1 → 4)-GlcA. Ch is nonsulfated ChS whose repeating unit structure is β(1 → 3)-GalNAc-β(1 → 4)-GlcA.[65i,65j]

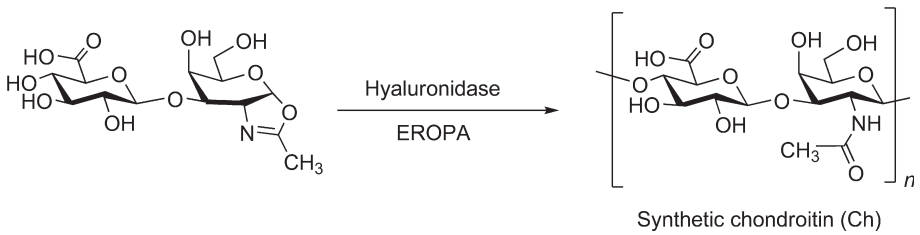
Hyaluronidase (HAase) is known to hydrolyze β(1 → 4)-linked GlcNAc (or GalNAc) and GlcA bond in HA and Ch chains. Based on the TSAS concept, *N*-acetylhyalobiuronate (GlcAβ(1 → 3)GlcNAc) oxazoline derivative and an *N*-acetylchondrosine oxazoline derivative are designed as TSAS monomers for the HAase-catalyzed polymerization. Both monomers were effectively catalyzed by ovine or



Scheme 37 Chitinase-catalyzed three polymerizations to lead to chitin hybrids via EROPA reactions.



Scheme 38 Synthetic hyaluronan (HA) is obtained via hyaluronidase-catalyzed EROPA reaction.



Scheme 39 Synthetic chondroitin (Ch) is produced via hyaluronidase-catalyzed EROPA reaction.

bovine testicular derived HAase, giving rise to the corresponding polysaccharides of 'synthetic HA' (Scheme 38)[74] and 'synthetic Ch' (Scheme 39).[75] The M_w of HA and Ch reached to 25 000 and 6800, respectively. The molecular weight value of Ch corresponds to that of natural Ch. Synthetic HA and Ch provide the first examples having the complicated structure of heteropolysaccharides ever synthesized *in vitro*.

At the catalytic domain of the HAase, there is a conserved DXE(D) motif stabilizing an oxazolinium-ion intermediate (or transition state), and hence the hydrolysis reaction mechanism is considered to be similar to that of chitinases. These observations are in accord with the concept of TSAS monomer, strongly suggesting that two EROPA reactions of Schemes 38 and 39 occur via an oxazolinium transition state.

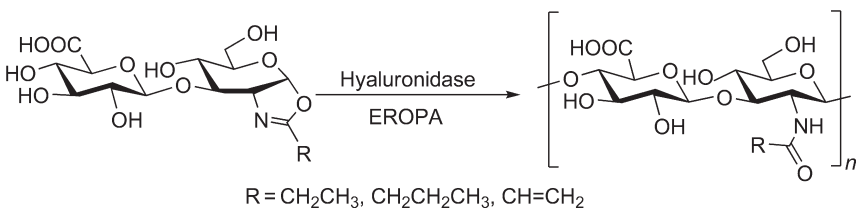
4.15.4.1.4 Synthesis of HA and Ch derivatives

Variously substituted oxazoline monomers, 2-ethyl, 2-*n*-propyl, and 2-vinyl oxazoline monomers for HA, were newly prepared and polymerized with HAase catalysis. The reactions proceeded with total control of regioselectivity and stereochemistry, to afford the corresponding HA and Ch derivatives (unnatural polysaccharides) possessing *N*-propionyl, *N*-butyryl, and *N*-acryloyl group in every hexosamine unit (Scheme 40).[75,76] Similarly, Ch derivatives were also achieved. The resulting *N*-acryloyl HA and Ch are functional polymers having a reactive vinyl group.

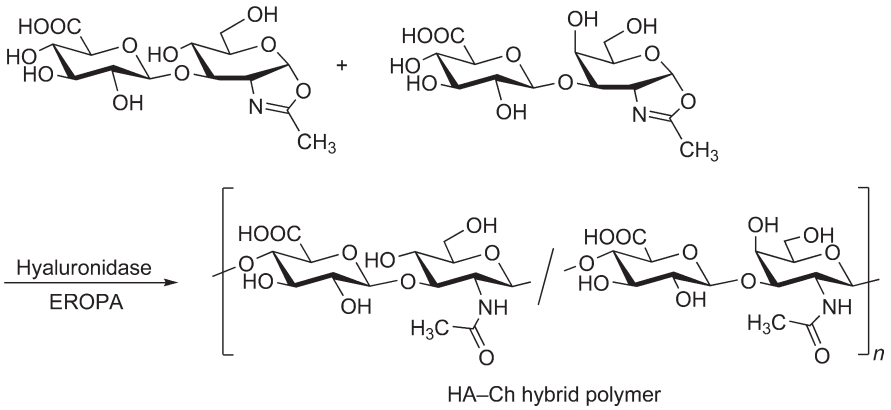
These substituted oxazoline monomers were copolymerized by HAase catalyst to proceed in a regio- and stereoselective manner, producing the corresponding copolymers. Composition of the *N*-acyl group units could be easily controlled by varying the comonomer feed ratio.[77]

HAase-catalyzed copolymerization of an *N*-acetylhyalobiuronate oxazoline monomer and an *N*-acetylchondrosine oxazoline monomer also gave an unnatural intramolecularly hybridized HA–Ch copolymer, which conventional methods can hardly achieve (Scheme 41).[78]

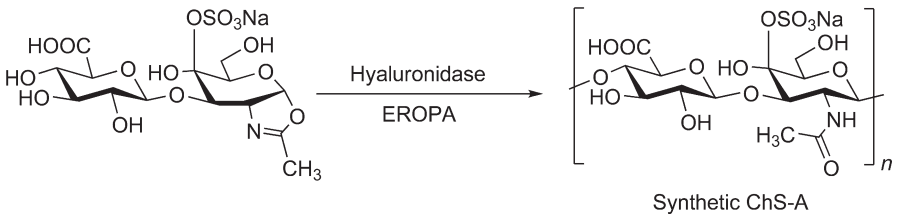
Ch is found in the ECMs and on cell surfaces. Ch is normally sulfated and biological activities of ChS are due to the sulfated pattern. Depending on the major sulfation pattern, natural ChS is classified into the following five types: ChS-A, ChS-C, ChS-D, ChS-E, and ChS-K. None of them is composed of a single repeating unit; all are of mixed type. For example, in a whale cartilage, the so-called ChS-A contains ~20% of ChS-C as a minor component besides the major ~80% of ChS-A. Preparation of ChS to have a well-defined sulfation pattern is, therefore, important for the fundamental investigation of the correlation between the polysaccharide structure and the bioactivities. *N*-Acetylchondrosine oxazoline monomer having a 4-sulfate group at GlcNAc unit was successfully polymerized by HAase, giving rise to ChS in high yields having the sulfate group only at C-4 position on all GlcNAc residues (Scheme 42).[79] The product is a 'pure' ChS-A with M_w values ranging from 5600 to 36 500. Biological activity examination of the synthetic pure ChS-A will be a future study of interest.



Scheme 40 Hyaluronidase-catalyzed synthesis of HA derivatives.



Scheme 41 Hyaluronidase-catalyzed synthesis of HA-Ch hybrid.



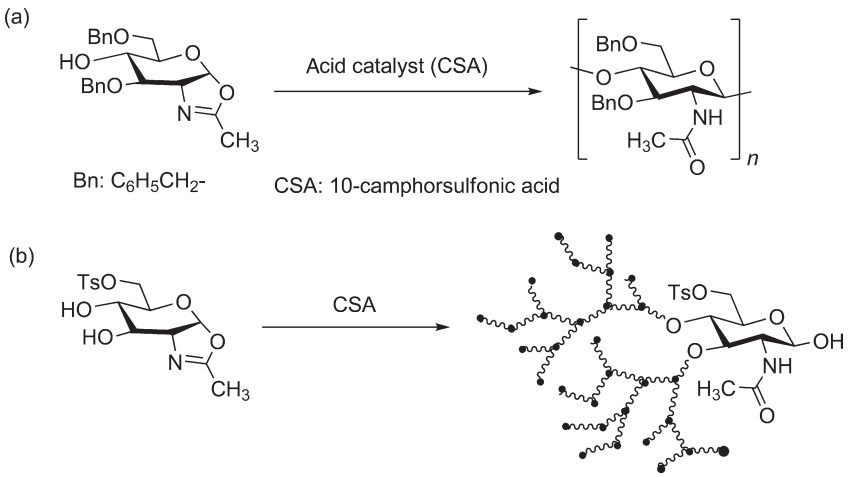
Scheme 42 Synthesis of chondroitin sulfate via hyaluronidase-catalyzed EROPA reaction.

4.15.4.2 Cationic ROPA of Sugar Oxazolines

Polysaccharide synthesis using sugar oxazoline monomers was carried out via cationic ROPA (CROPA) reaction; CROPA of 3,6-di-*O*-benzylated chitin-oxazoline monomer (AB-type monomer) was induced by 10-camphorsulfonic acid (CSA) catalyst to produce di-*O*-benzylated chitin (**Scheme 43(a)**).[80] The CROPA was carried out at a reflux temperature in 1,2-dichloroethane and proceeded involving stereoregular glycosylation, giving rise to a dibenzylchitin product having $\beta(1\rightarrow4)$-grucopyranan structure with M_n up to 4900 in around 50% yields. The debenzylation of the products via the catalytic hydrogenation was incomplete. It is important that the OH groups not to be reacted must be protected! The acid-catalyzed ROPA was extended to the synthesis of the dibenzylchitin having $\beta(1\rightarrow6)$-grucopyranan structure.[81] The product is of unnatural-type structure, whose yield was at most 32% and M_n reached 13 100. The debenzylation of the products took place perfectly to produce the corresponding free aminopolysaccharide of unnatural type.

The principle of the reaction was applied for the preparation of a hyperbranched polymer from an A-B_2-type monomer. In the latter, 3- and 4-positions have free OH groups (**Scheme 43(b)**).[82] The product polymer possessed M_n up to 6600 (PDI < 2), whose detosylation gave a free hyperbranched aminopolysaccharide.

The reaction mode of these CROPA is similar to that of EROPA; both employ sugar oxazoline monomers for the



Scheme 43 Acid-catalyzed ROPA reactions to give a chitin derivative (a) and a hyperbranched chitin type polymer (b).

synthesis of various mucopolysaccharides. The exception is the monomer structure, where CROPA needs protection of OH groups at necessary positions, but in the EROPA the reaction takes place regioselectively at the unprotected OH groups.

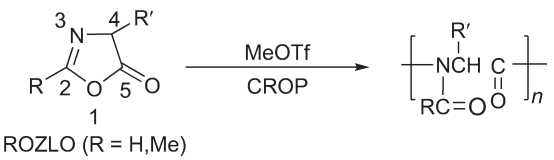
4.15.5 Ring-Opening Polymerizations of Other Oxazoline Derivative Monomers

In addition to ROZO monomers, the monomers to be mentioned are listed in Scheme 3. They are 5-oxazolones (4,5-dihydro-1,3-oxazol-5-one, ROZLO), six-membered analogs (5,6-dihydro-4*H*-1,3-oxazines, ROZI), and seven-membered ones (4,5,6,7-tetrahydro-4*H*-1,3-oxazepine, ROXP) as well as *exo*-cyclic imino ether derivatives of ROZO, ITHFs which are not mentioned here.

4.15.5.1 Polymerization of 5-Oxazolone

Introduction of a carbonyl group at the 5-position of OZO ring leads to 2-oxazolin-5-one or an 'azlactone' termed by Erlenmeyer (ROZLO). The first paper on CROP reaction of ROZLO was reported in 1986, describing the production of a poly(*N*-formyl-α-peptide) at 60 °C in diglyme in high yields (R = H, R′ = Me, Scheme 44).[83] The peptide is a white powdery material with molecular weight of 5100. The monomer (R = R′ = H) gave the corresponding poly(*N*-formyl-α-peptide) having molecular weight 2400. When the monomer was prepared from L-alanine, optically active poly(*N*-formyl-L-alanine) (R = H, R′ = Me) was derived; the specific rotation value $[\alpha]_D^{22}$ –3.60.

2-Alkoxy derivatives (ROOZLO) were polymerized by MeOTf via CROP mode since its polymerization yields polypeptide derivatives.[84,85] The CROP of (*S*)-4-isopropyl-2-ethoxy-5-oxazolone (R = EtO, R′ = *i*-Pr) (Scheme 44) yields poly(*N*-ethoxycarbonyl-L-valine), which was converted to poly(L-valine) by basic hydrolysis.[84] Contrary to poly(L-valine), poly(*N*-ethoxycarbonyl-L-valine) is soluble in many organic solvents probably due to the lack of amide hydrogen bonding, which is expected to expand the availability of polypeptide derivatives.[85]



Scheme 44 CROP of an OZO derivative, 5-oxazolone, to produce a poly(α-peptide).

ROZLO (R = H, R′ = H, Me) monomers behaved as electrophilic monomer (M_E) in the combination of M_N monomers according to Scheme 25.[86] As M_N monomer, acrylamide and 2-hydroxyethyl acrylate were employed to produce alternating copolymers, involving zwitterionic intermediate. In these reactions, a proton transfer step was involved.

A corresponding six-membered 'azlactone' (1,3-oxazine-6-one) was polymerized via CROP-mode reaction to produce a poly(*N*-acyl-β-peptide), whose molecular weight reached 5400.[87]

4.15.5.2 Polymerization of 1,3-Oxazine

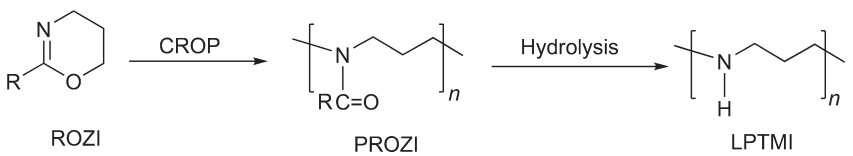
2-Unsubstituted 1,3-oxazines (R = H, ROZI) were first prepared and polymerized via CROP mode in 1973, whose alkaline hydrolysis gave linear poly(trimethylenimine) (LPTMI) for the first time (Scheme 45).[88] The molecular weight M_n was up to 4840.

Kinetic studies on the ROZI monomer reactivity were examined in detail.[89] All CROP reactions of OZI, MeOZI, and PhOZI monomers with MeOTs initiator proceeded involving oxazinium propagating species in a similar way to Scheme 5 of the ROZO case. For comparison of the monomer polymerizability, rough values are given in $k_p \times 10^4$ values (with MeOTs at 100 °C in acetonitile* or in nitrobenzene#) in $l\,mol^{-1}\,s^{-1}$: OZO (13000*), MeOZO (120*), PhOZO (13*), OZI (110#), MeOZI (19#), and PhOZI (2.5#). With MeI initiator, OZI and MeOZI had oxazinium propagating species, whereas PhOZI showed covalent alkyl iodide propagating species.

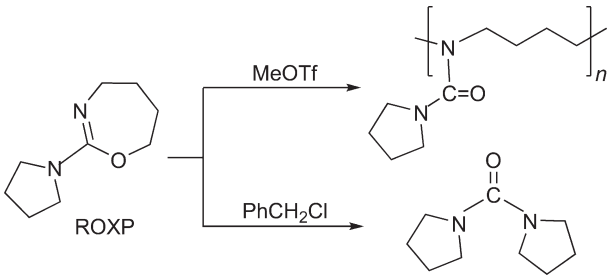
Polymerization of ROZI monomers behaved in almost all cases similarly to ROZO monomers in many respects, except for the product polymer structures with a trimethylenimine chain of PROZI instead of an EI chain of PROZO.[2] Many similar behaviors in both monomers of ROZI and ROZO include a living character of CROP, various copolymer syntheses, DIP, and an M_N monomer in zwitterionic alternating copolymerizations. It may be important to mention, however, that ROZI is a little more basic than ROZO from the initiation reaction studies; for example, pK_a value for iPrOZI and iPrOZO are 7.1 and 5.4 in water at 25 °C, respectively.

4.15.5.3 Polymerization of 1,3-Oxazepine

Only one paper appeared on the CROP reaction of 1,3-oxazepine (ROXP).[90] With expected DIP of ROXP, however, it was polymerized to afford the product polyamide according to normal CROP mode; DIP did not occur with MeOTf initiator. With benzyl chloride initiator, only isomerization of the monomer took place to produce a urea without giving a polymer (Scheme 46).



Scheme 45 CROP reaction of 1,3-oxazine (ROZI) to lead to linear poly(trimethylenimine).



Scheme 46 CROP reaction of 1,3-oxazepine (POXP) gives different products depending on the initiator.

4.15.6 Sythesis of Functional Polymers via CROP Process and Their Applications

The fundamental chemistry of oxazoline polymerization has been extensively accomplished over the past four decades. The main trend of oxazoline polymerization, therefore, is currently and will be in the future toward application studies by utilization of the unique properties of the PROZO polymers.

4.15.6.1 Synthesis of End-Functionalized Polymers

End-functionalized polymers include macromonomers, telechelics, and polymers having functional groups pending to the main chain, for example, employed for click chemistry. End-functional groups can be introduced at the initiating step ('initiator method'), at the terminating step ('terminator method'), or during the polymerization like the copolymerization.

4.15.6.1.1 Synthesis of macromonomer and telechelics

Macromonomers and telechelics are important starting materials for the synthesis of functional polymers. The former was extensively used for graft copolymer synthesis as seen in Section 4.15.2.4.2. They are normally produced via a couple of methods.

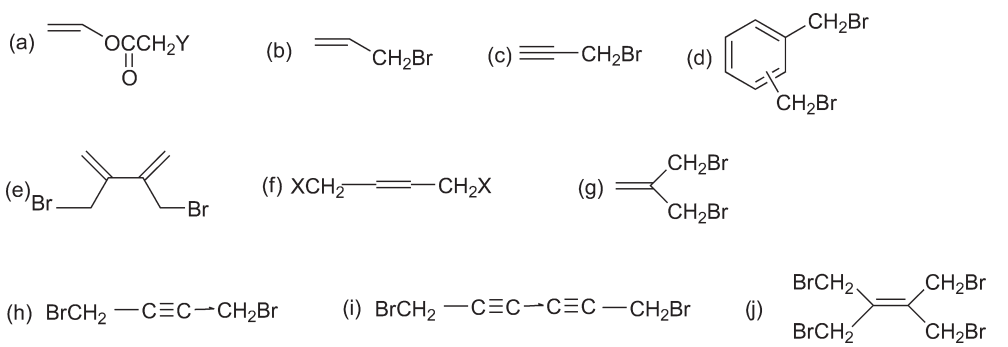
Initiator method: An oxazoline-CROP polymerizable macromonomer was first prepared from 2-(hydroxyphenyl)-oxazolines leading to a ROZO macromonomer having a PEG chain as given in **Scheme 24**.[53a] Styryl-type macromonomers were synthesized by using iodomethylstyrene as initiator (**Scheme 47**).[53b]

Numerous types of macromonomers were prepared using various halides as shown in **Scheme 48**.[91] These halides include not only monohalides (a–c) for, for example, a vinyl ester macromonomer, but also dihalides (d–i) and a tetrafunctional halide (j). Allyl-type halides, acetylene-containing halides, and benzyl-type halides are activated and exhibited a higher reactivity than a simple alkyl halide. These halides gave a number of macromonomers and telechelics from ROZO monomers with molecular weights up to several thousand. Compound (j) produced a star-shaped polymer. Polymers derived from these initiators contain reactive olefin, acetylene, diene, and diacetylene groups and can be used not only for macromonomers and telechelics but also further for cross-linking, modification, and so on.

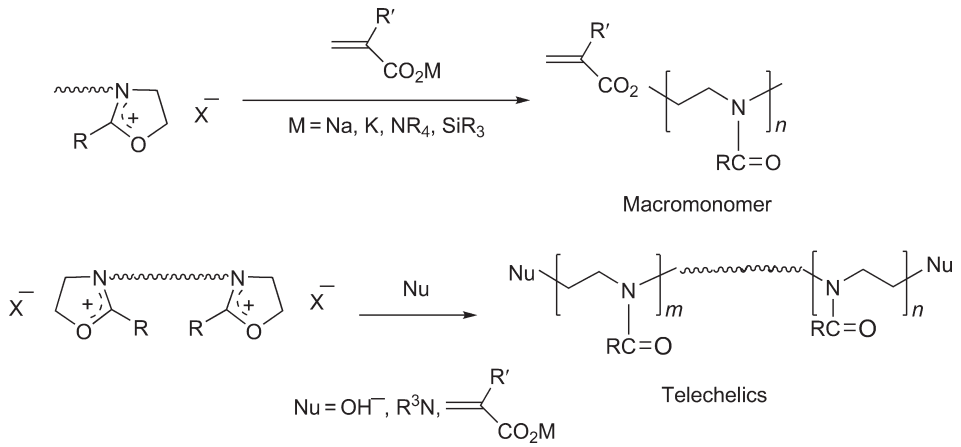
As a typical example of surfactant synthesis via initiator method, 2-(perfluorooctyl)ethyl trifluoromethanesulfonate (RfOTf for R′X in **Schemes 5** and **6**) was used as initiator for CROP of ROZO, then the product polymer was a very efficient surfactant, showing the lowest γ value of 23.9 dyn cm^{-1} (R = Et, DP = 5.7) due to the specific fluoroalkyl group hydrophilicity.[92]

Pluritriflate initiators, derived from mono-, di-, tri-, and tetrafunctional alcohols, were used for CROP of MeOZO for preparing hydrophilic star polymers. It was shown that the propagation of the each arm proceeded in a similar rate in the reaction of these initiators (k_p value = ~ 5×10^{-3} l mol^{-1} s^{-1} at 85 °C).[93]

Scheme 47 Synthesis of styryl-type macromonomer via CROP of MeOZO using initiator method.



Scheme 48 Various reactive halide initiators for synthesizing macromonomers, telechelics, and a tetra-arm PROZO via initiator method.



Scheme 49 Synthesis of macromonomers and telechelics via terminator method.

Terminator method: A (meth)acryl-type macromonomer or telechelics can be obtained by the reaction of the POZO living end terminated with a (meth)acrylate salt (Scheme 49).[94] Thus, various functional groups are introduced at one or both terminals.

When a higher fatty acid as a hydrophobic group was introduced at one or both end(s) ($X = RCO_2$ or $Nu = RCO_2^-$) of PMeOZO or PEtOZO of a hydrophilic segment, the products showed excellent surfactant properties.[95] This method seems to be the simplest and economical way for the PROZO surfactants. In addition, a dihalide initiated living POZO and a diamine reacted to afford PROZO ionen polymers.[96]

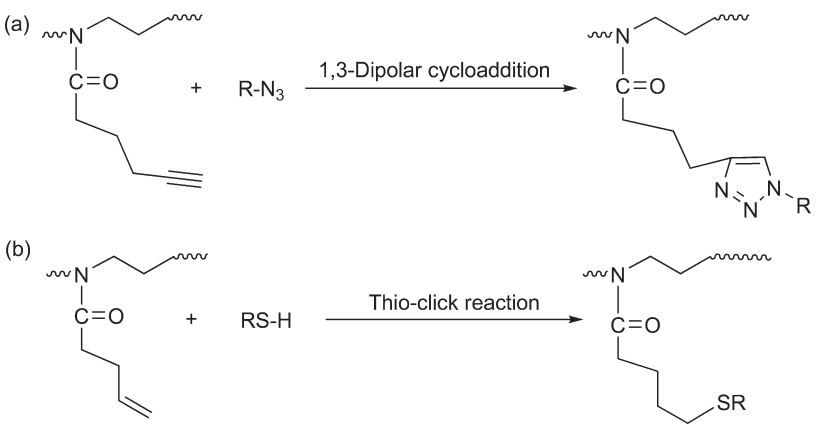
4.15.6.1.2 Polymer modification via click chemistry

Combination of click chemistry and polymer chemistry leads to new materials. A functional group for click chemistry can be introduced via the CROP of the functional group-containing monomers. A pendant alkyne group-containing PROZO was prepared by CROP of 2-(4-pentynyl)-OZO (PynOZO) monomer, both via its homopolymerization and copolymerization with MeOZO or EtOZO. The copolymer (unit composition; PynOZO: MeOZO = 5:45) was reacted with an azide compound ($R\text{-}N_3$) in aqueous solution via copper-catalyzed Huisgen 1,3-dipolar cycloaddition (click chemistry) to form the 1,2,3-triazole ring (Scheme 50(**a**)).[97]

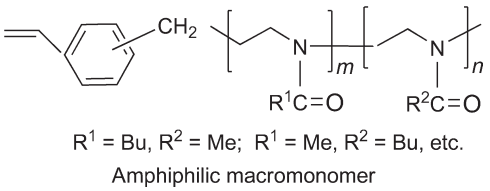
It was suggested that this type of polymer modification reaction may lead to attached peptidic cell recognition sites for targeted drug delivery system. Another example of click chemistry is a 'thio-click' modification of 3-butenyl (But) group of PButOZO unit with a mercaptan (RS-H) under UV light (Scheme 50(**b**)).[98] Further, to prepare a clickable PROZO, propargyl or 3-butynyl *p*-toluenesulfonate was employed for initiating CROP of MeOZO, EtOZO, NonOZO, and PhOZO monomers under microwave irradiation at 140 °C in acetonitrile. The product PROZOs contain the alkyne end group and the click chemistry reaction of the group with an azide via a copper-catalyzed Huisgen 1,3-cycloaddition to form a 1,2,3-triazole. Reactions of these alkyne end-functionalized PROZOs and various azides will produce new materials for block and graft copolymers.[99]

4.15.6.2 Synthesis of Amphiphilic Copolymers

Amphiphilic copolymers are mentioned above for block and graft copolymers in Section 4.15.2.4. Hence, some specific cases are included mainly for applications here.



Scheme 50 PROZO polymer modifications via click reactions using an azide (a) and a thiol (b).



Scheme 51 Styryl-type amphiphilic macromonomers.

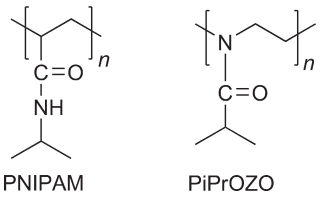
A styryl-type macromonomer having a water-soluble ROZO segment (Scheme 47) or having an amphiphilic ROZO block copolymer (Scheme 51) was extensively used as surfactant for the emulsion or dispersion polymerization.[100] Polymerization of St or MMA in the presence the macromonomer as stabilizer (less than ~3 wt% for the total monomer) in water took place with a radical initiator to give stable monodisperse polymer particles with a micron-size diameter. The macromonomer acted as both comonomer and stabilizer; actually the copolymerization occurred. Therefore, the system is micelle forming but soap-free. Hydrophilic PMeOZO segments are preferential on the particle surface.

A vinyl ester-type amphiphilic macromonomer was also employed for emulsion copolymerization of vinyl acetate with the macromonomer to yield polymer particles.[101]

Polymer catalyst ligands utilized an amphiphilic block copolymer, which is bound to the metal catalyst site and forms micelles in aqueous solution reaction. An example is a Ru-containing Hoveyda–Grubbs catalyst (Scheme 52(**a**)).[102] The copolymer uses PMeOZO for hydrophilic segments and PNonOZO for hydrophobic segments. Ru-catalyst (a) was used for the ring-closing metathesis reaction of diethyl diallylmalonate to produce diethyl 3-cyclopentene-1,1′-dicarboxylate plus ethylene (Scheme 52(**b**)), in which the reaction proceeded in micelles effectively, showing a turnover number reaching to 390 in water. A Rh-catalyst with a polymer ligand containing amino group was employed as micellar catalyst for the 1-octene reaction of hydroformylation and hydroxyaminomethylation.[103]

4.15.6.3 Synthesis of Stimuli-Responsible Polymers

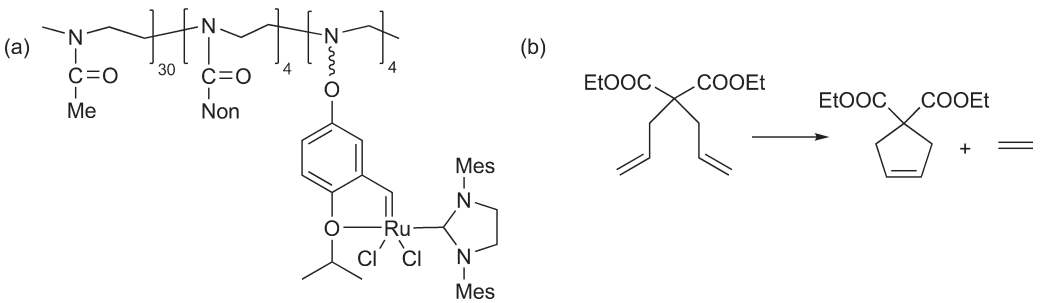
Stimuli-responsible polymers are well known, as exemplified by poly(*N*-isopropylacrylamide) (PNIPAM) of vinyl-type polymer, which is a smart thermosensitive polymer (Scheme 53).[104]



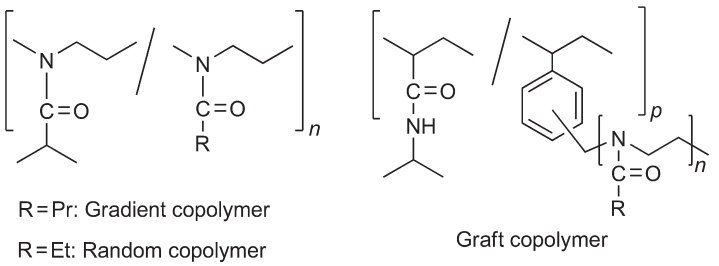
Scheme 53 Two typical thermosensitive polymers, PNIPAM and PiPrOZO.

By using an oxazoline chain, PiPrOZO was first found to be excellent thermosensitive polymer, as well as a smart material (Scheme 53).[105] PiPrOZO ($M_n = 16\,700$, $M_w/M_n = 1.13$) showed a clouding point (CP) of 36.0 °C in water with 0.5 wt% of the polymer, in which the polymer was soluble below CP. It is to be noted that the CP value is near human body temperature. The CP value decreased with increasing the polymer concentration. The value was also affected by an additive; by adding 0.1 and 0.5 mol l^{-1} of NaCl, the value was decreased to 35.6 and 31.5 °C, respectively, whereas by adding 0.01 and 0.05 mol l^{-1} of sodium dodecyl sulfate (SDS), the value was increased to 76.7 °C and >100 °C, respectively. It was explained that in the former, NaCl breaks the hydrogen bonding between the polymer and the water, and in the latter, a nonionic polymer PiPrOZO is complexed with an ionic surfactant of SDS. As an application, the thermosensitive hydrogel was prepared by radical copolymerization of a PiPrOZO macromonomer[106] with ethylene glycol dimethacrylate in an aqueous methanol solution.[105] Further, the hydrogel of PiPrOZO was prepared, whose swelling transition is around human body temperature. This is a good situation for the application of thermosensitively functional biomaterials. Applying the above results to biomedical materials, end-functionalized PiPrOZOs were synthesized, giving the polymers with structures of Me-PiPrOZO-OH, Me-PiPrOZO-NH_2, and acetal-PiPrOZO-OH. A polymer showing the CP near 37 °C was derived.[2i]

Via cationic living copolymerization, iPrOZO as hydrophobic monomer and EtOZO as hydrophilic monomer produced a copolymer P[iPrOZO-*co*-EtOZO]. Monomer reactivity ratios were determined as $r_{iPrOZO} = 0.79$ and $r_{EtOZO} = 1.78$, respectively. These values allowed the development of gradient copolymers (M_n 8000–10 000) with varying compositions and narrow PDI (≤1.02). Lower critical solution temperature (LCST, corresponding to CP) of the copolymers could be precisely tuned over a broad range of 38.7–67.3 °C by varying



Scheme 52 PROZO-Ru catalyst (a) for a ring-closing metathesis reaction (b).



Scheme 54 Thermosensitivity-tuned gradient, random, and graft copolymers containing PROZO chains.

the molar ratio of iPrOZO to EtOZO, showing a linear increase in LCST with an increasing molar percent of EtOZO (Scheme 54).[107]

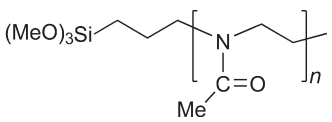
Thermosensitivity of the ROZO polymers was accurately tuned by using three monomers, PrOZO, iPrOZO, and EtOZO, by designing the reaction to combine PrOZO with either iPrOZO or EtOZO.[108] Cationic copolymerization of PrOZO and iPrOZO ($r_{PrOZO} = 3.15$ and $r_{iPrOZO} = 0.57$, respectively) gave gradient copolymers P[PrOZO-*grad*-iPrOZO], whereas that of PrOZO and EtOZO ($r_{PrOZO} = 1.28$ and $r_{EtOZO} = 1.04$, respectively) produced random copolymers P[PrOZO-*ran*-EtOZO]. The LCST of both the gradient and random copolymers could be tuned over a wide range of temperatures by varying the molar ratio of the two monomers. Most of the random copolymers of M_n around 10 000–14 000 ($M_w/M_n < 1.1$) showed a rapid and modulated response to the temperature change from 23.8 to 75.1 °C. This is good for an ideal system for tuning the LCST around the physiological conditions. In addition, PPrOZO was found to show a sharp LCST behavior near room temperature.

For the investigation of thermosensitive behaviors, gradient and graft copolymers consisting of PNIPAM chain and PiPrOZO as well as PROZO (R = Me, Et) chains were prepared (Scheme 54).[109] The turbidity temperature was tuned by the hydrophilic ROZO chain content from 28 to 42 °C; with increasing the content of ROZO chain, the CT value became higher. Thermosensitive polymers of P[iPrOZO-*block*-3-butenylOZO] with thiol groups were synthesized. A glucose moiety was introduced to the olefinic side chain via 'click' addition of a glucose thiol. Then, the CP of these copolymers was changed from 10 to 85 °C as a function of composition and hydrophilicity of the side chain.[110]

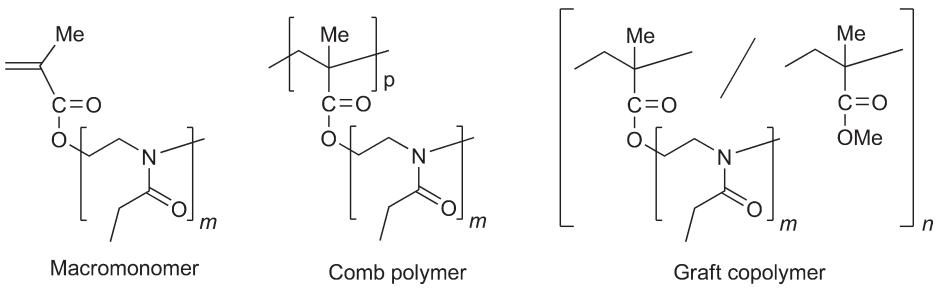
Macromonomer method was used for the synthesis of comb and graft polymers and their LCST behavior was examined, where a hydrophilic oligoEtOZO was utilized as side chains and a hydrophobic methacrylate as backbone (Scheme 55).[111] First, CROP of EtOZO was carried out under microwave irradiation using MeOTs initiator and the living end was terminated with ammonium methacrylate to form macromonomers (M_n 900–3300, $M_w/M_n < 1.1$). Second, homopolymerization of the macronomomer via the reversible addition–fragmentation chain transfer (RAFT) method gave comb polymers (M_n 7000–24 000, $M_w/M_n \leq 1.31$). Copolymerization of the macromonomer with MMA was performed similarly, to produce graft copolymers (MMA, 40–80 mol%, M_n 12000–26 000, $M_w/M_n < 1.3$). The LCST of the graft polymers measured in aqueous solutions was tuned from 35 to 80 °C depending on the MMA content. The LCST value of the comb polymer was significantly decreased when compared to that of linear PEtOZO, which was correlated with microdomain formation due to the crowded comb structure. The solution properties and LCST behaviors of random and block copolymers from EtOZO and NonOZO were also investigated.[112]

4.15.6.4 Archtecture of New Polymeric Systems

An organic–inorganic hybrid was obtained by using a hydrophilic PMeOZO silane coupling agent (Scheme 56).[113] A mixture of the coupling agent and silica gel showed the PMeOZO chain concentrated on the silica gel surface after heating in acetonitrile. The modified gel became more hydrophilic than the untreated gel. The acid-catalyzed hydrolysis of the agent in the presence of tetraethoxysilane (the so-called sol-gel method) afforded a homogeneous and transparent silica gel. The homogeneity of the composite gel is due to the



Scheme 56 An organic-inorganic hybrid using PMeOZO chain.



Scheme 55 Macromonomer, comb polymer, and graft copolymer, all containing EtOZO chain for the examination of LCST behaviors.

chemical bonding of the PMeOZO ends and the interaction between the amide group in PMeOZO and the silica through hydrogen bonding, thus giving an organic–inorganic polymer hybrid.

By utilizing an excellent hygroscopic nature of PMeOZO chain, nonionic hydrogels were prepared. Solvent philicity can be tuned by the combination of monomers. CROP mode copolymerization of MeOZO with 2,2′-tetramethylenebis (2-oxazoline) (TBOZO, R = -$(CH_2)_4$- in **Scheme 30**) produced a hydrogel, showing swelling property in water and an aqueous solution. The water uptake was up to 45 multiples of the dry gel. From EtOZO and TBOZO, a characteristic amphiphilic gel (amphigel) was obtained, swelling both in water and in organic solvents. A lipogel (organogel) derived from hydrophobic ROZO (R = Pr, Bu, or Oct) and TBOZO is swollen in less polar organic solvents such as toluene and 1,2-dichloroethane. A ROZO monomer with a photo-cross-linkable group of coumarin was CROP type copolymerized with MeOZO, giving rise to a hydrogel, uptaking water up to 20 times the weight of the dried gel. The cross-linking could be controlled by irradiation of Hg lamp with different wavelength, that is, cross-linking with hν > 300 nm, whereas cleavage of the gel with hν 253 nm.[114]

A new comb-burst dendrimer was synthesized via termination reaction of the living PEtOZO polymerization ends with LPEI, followed by the acid hydrolysis to remove the propionyl group. These reactions were repeated to give dendritic polyethylenimine (PEI).[115]

Self-assembling synthetic polymers are currently an important, widely conducted topic of research; they form a unique architecture in bulk and in solution to give a new material. The following are some examples of self-assembling systems from PROZO chains.

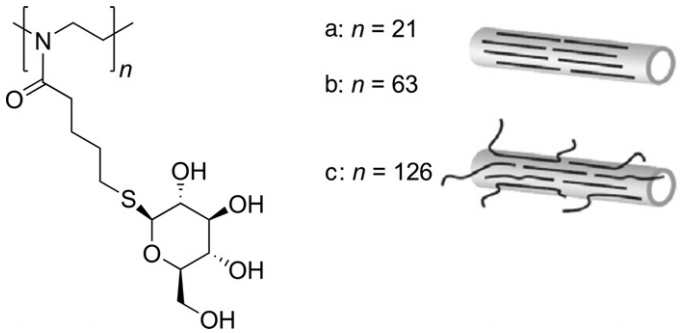
Glycosylated PROZO chains self-assembled into nanotubes in water through intermolecular hydrogen bonding interactions (**Scheme 57**).[116] The driving force for the nanotube formation is considered to be due to the unique polymer structure of the tertiary polyamide backbone (hydrogen-accepting) and glucose side chains (hydrogen-donating), first forming and bending a two-dimensional (2D) hydrogen-bonded layer of interdigitated polymer chains and then closing to form a tube. Rough values of outer and inner radii (r_o and r_i) and wall thickness ($r_o - r_i$) from three polymers are as follows (given in nanometers): a (2.0, 0.8, and 1.2); b (3.0, 2.0, and 1.0); and c (4.5, 1.0, and 3.5).

Langmuir monolayers were prepared at the air–water interface from amphiphilic polymers derived from hydrophilic PMeOZO and hydrophobic stearyl ether groups. A large lowering of the stretching frequencies was detected within the plateau region by IR analysis, probably due to a condensed packing.[117] An ultrathin film grew on the basal plane of graphite via polymerization-induced epitaxy by using PhOZO as monomer. STM observation confirmed the crystalline layer formation.[118] Living CROP of EtOZO was induced from triflate group (TfO) attached to a self-assembled monolayer on planer gold substrates. The resulting polymer was capped with a dialkylamine to show a uniform layer.[119]

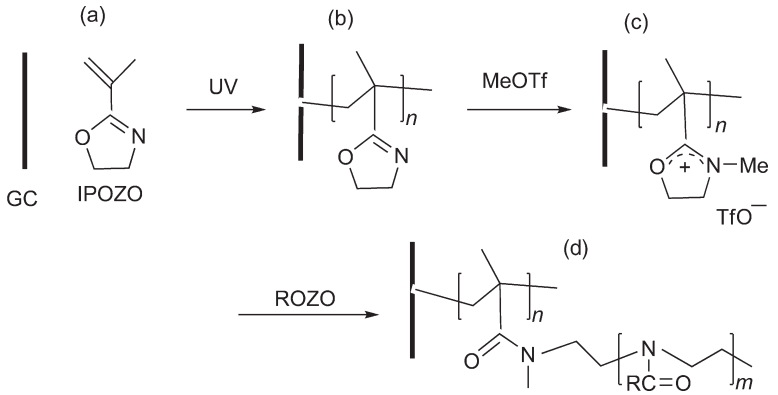
The architecture of molecular brushes was developed. They are linear macromolecules having graft polymer side chains with high graft density. The side-chain crowding causes a strong stretching of backbone, resulting in a cylindrical molecular brush structure (**Scheme 58**, neglecting glassy carbon (GC)). First, radical or anionic vinyl polymerization of 2-isopropenyl-2-oxazoline (IPOZO) (a) was carried out to form a backbone polymer with $n = 88$ via radical process and 220 via anionic process (b). Then pendant OZO groups were methylated by MeOTf to form oxazolinium ions that served as macroinitiators (c), and CROP of ROZO monomer was initiated, to give rise to cylindrical molecular brushes P[IPOZO-*graft*-ROZO] (oxazoline units, $m = 18–23$) (d). The substituents R used were Me, Et, and *i*Pr. The LCST was determined by turbidity measurements of a 1.0 wt% aqueous solution, being 63 °C for the brush ($n = 88$, EtOZO, $m = 23$), 30 °C for the brush ($n = 88$, iPrOZO, $m = 18$), and 27 °C for the brush ($n = 220$, iPrOZO, $m = 18$), respectively.[120]

The molecular brush synthesis was extended to synthesize brushes of bottle brushes of PROZO on polished GC substrates (**Scheme 58**).[121] First, UV-induced vinyl polymerization of IPOZO monomer at room temperature was directly initiated from the GC surface (a) and gave PIPOZO-grafted brush layers with thickness up to 160 nm (b). The pendant oxazoline ring of the PIPOZO was used, followed by the oxazolinium-ion formation (c) to perform a second CROP of ROZO monomers to result in bottle-brush brushes (d). It was possible to functionalize the bottle-brush brushes' side-chain end groups with a steric-demanding molecule.

Alkoxy-substituted benzoyl-PEIs having $C_8–C_{13}$ alkyl groups formed self-assembly of hexagonal, columnar, 2D phase.[122] Molecular structures of self-assembling from poly (2-(3,4-bis(*n*-alkoxy)phenyl)-2-oxazoline)s were systematically investigated with regard to the DP and alkoxy chain



Scheme 57 A nanotube is formed via self-assembling of glycosylated PROZO chains.



Scheme 58 Architecture of molecular brushes via vinyl polymerization of IPOZO monomer and subsequent CROP processes.

length.[123] The polymers with alkoxy chain length C_8–C_{13} formed columnar hexagonal lattices, whereas polymers with C_{14} and C_{15} alkoxy chains underwent a transition from a three-dimensional (3D) cubic phase for a low DP to a 2D hexagonal columnar phase.

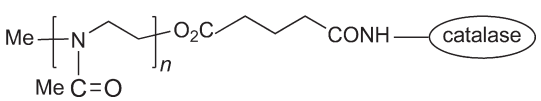
PEtOZO and PiPrOZO bearing a C_{18} alkyl group at the end(s) are effective surfactants, with M_n 7000–13 000. These telechelics self-assembled into micelle aggregates, below the clouding temperature. Further heating brought about the formation of clusters of the micelles, whereas PROZO chains were flexible. When the temperature exceeded 2 °C above the clouding temperature, rigid objects were formed and their size remained constant. These behaviors of PROZO surfactants are quite different, compared with those of PNIPAM or PEG chains. This is considered to be due to different chain conformation of the amide main chain of PROZO involving hydration/dehydration of the chain through hydrogen bonding.[124]

4.15.6.5 Sythesis of Bio-Related Polymers

Applications of PROZO chains in the biomedical and pharmacological areas have been much increasing in recent years.[2k,2l,2m,125] This is mainly because CROP of ROZOs is easily able to achieve the living polymerization to lead to facile design of various polymer structures, PROZOs are of no or low toxicity, and the hydrophilic/hydrophobic nature of the polymers can be tuned readily. Furthermore, PROZO polymers produced from CROP are viewed as 'pseudopeptides' as mentioned in Section 4.15.1. The following are only few examples among many studies for such applications of PROZOs.

PMeOZO-coupled bovine liver catalase was prepared and enabled the enzyme to be used in organic solvents (Scheme 59).[126] The modified enzyme showed catalytic activity in water as well as in benzene and chloroform.

An aggregate of a block copolymer (Scheme 16, R^1 = Me, R^2 = Bu, m = 9, n = 36) and horseradish peroxidase (HRP) were obtained by mixing them in buffer solution as a new



Scheme 59 Bovine liver catalase linked to PMeOZO chain to be used in organic solvents.

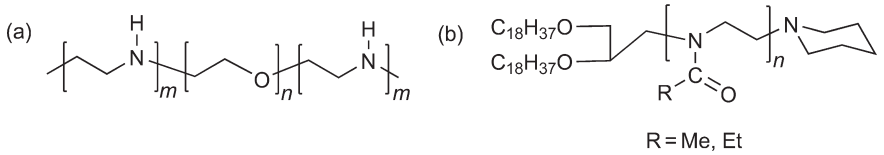
biocatalyst. With the formation of the aggregates, the catalytic activity was significantly enhanced.[127] Adducts from PROZO and human protein C retained catalytic avidity for the monoclonal antibody.[128]

Biocompatibility studies of PROZOs using a radio-labeled polymer found that when PMeOZO and PEtOZO were administrated in mice, they were excreted without accumulation from the bloodstream. These results suggest that the polymers possess the 'stealth' nature, meaning the suppression of all interactions with the body, being free from the immune system.[129] This is beneficial for application as drug carriers and other biomedical purposes.

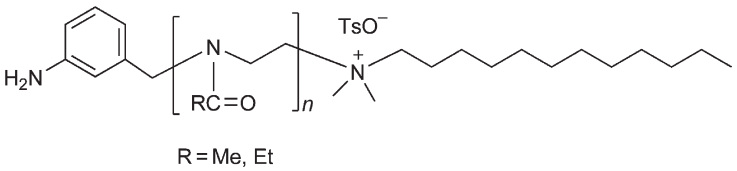
For the application as drug carriers, micelles were prepared from PEtOZO-*block*-poly(ε-caprolactone), which were loaded with an anticancer drug with a poor solubility in water. The micelles were of low cytotoxicity. The loaded micelles were effective *in vitro* inhibition of the proliferation of a human carcinoma cells.[130] Similarly, a triblock copolymer, [PLA-*b*-PEtOZO-*b*-PLA], was employed for micelle roading, and also a diblock copolymer, [PEtOZO-*b*-PEI], for nonviral gene carriers.[131]

LPEI was used for DNA complexation. Novel two triblock copolymers, LPEI-*b*-PEG-*b*-LPEI (M_w 2100-3400-2100 and 4000-3400-4000) (Scheme 60(a)), were shown to condense plasmid DNA effectively to give polymer/DNA complexes (polyplexes) of small sizes (< 100 nm) and moderate ζ-potentials (~ +10 mV) at polymer/plasmid weight ratios ≥ 1.5/1. These polyplexes efficiently transfected COS-7 cells and primary bovine endothelial cells *in vitro* and are a novel class of nonviral gene delivery systems.[132] Lipopolymers were prepared as a potential candidate for constructing tailored model cell membranes. A lipid triflate was used as initiator for CROP of hydrophilic monomers, MeOZO and EtOZO, to produce an amphiphilic polymer as the model (Scheme 60(b)).[133]

Ammonium group-containing PEtOZO and PMeOZO chains showed efficient antimicrobial properties (Scheme 61).[134] Antimicrobial potential of the polymers was evaluated by determining the minimal inhibitory concentration (MIC) of the polymer against the ubiquitous Gram-positive bacterium. MIC is defined as the minimal required concentration to inhibit the growth of 99% of the bacterial cells in a suspension. For example, MIC value of the MeOZO polymer chain (R = Me, n = 53 in Scheme 15) was 1.0 mg ml^{-1}, which is 9 times more effective than the corresponding PEG polymer chain. Also, effect of



Scheme 60 DNA forms a complex with LPEI triblock copolymers (a) and an amphiphilic polymer model consisted from a hydrophilic PROZO chain and a lipid component (b).



Scheme 61 Ammonium-containing PROZO chain showing antimicrobial properties.

end-group structures on the antimicrobial activity was investigated.[135]

A glycoprotein plays important roles in areas such as bioadhesion, cell–cell interactions, and recognition phenomena. A glycoprotein analog was prepared by combining a linear polysaccharide block and a PROZO block ('psuedopeptide'), for which HA (hyaluronan) and PEtOZO were employed, respectively. A lower molecular-weight HA ($M_w = 2700$) was reacted with an amino group-containing PEtOZO to produce HA-*block*-PEtOZO ($M_w = 10\,200$).[136] Preliminary experiments showed that the anionic copolymer formed colloidally stable particles ($R_h \sim 130$ nm) with a cationic drug diminazene.

Biographical Sketch

Shiro Kobayashi studied organic chemistry and polymer chemistry at Kyoto University. After the PhD course, he was a postdoctoral fellow at stayed at Case Western Reserve University for 2 years and investigated cationic reaction mechanisms. He joined Kyoto University and restarted polymer synthesis studies. He was a Humboldt fellow at Mainz University in 1976. Then he was appointed as a full professor of Tohoku University in 1986. He moved to Kyoto University in 1997 and officially retired in 2005 to become a professor emeritus. Since then, he has been a distinguished professor at Kyoto Institute of Technology. His research interests include polymer synthesis, enzymatic polymerizations, organic reactions, and materials chemistry. He has been studying the polymerization of oxazolines for many years. He received the Award of the Chemical Society of Japan for Young Chemists (1976), the Award of the Society of Polymer Science Japan (1987), the Humboldt Research Award (1999), the Chemical Society of Japan Award (2001), the John Stauffer Distinguished Lecture Award (2002), the Medal with Purple Ribbon (2007), and others. He has been a foreign member of the Northrhine Westfalian Academy of Science since 1999. He currently serves as a member of (executive) advisory board and editorial (advisory) board for 14 international journals.

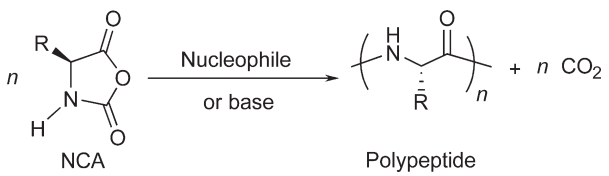
4.16 Ring-Opening Polymerization of Amino Acid *N*-Carboxyanhydrides

TJ Deming, University of California–Los Angeles, Los Angeles, CA, USA

4.16.1 Introduction

Peptide polymers have many advantages over conventional synthetic polymers since they are able to hierarchically assemble into stable ordered conformations.[1] Depending on the amino acid side-chain substituents, polypeptides are able to adopt a multitude of conformationally stable regular secondary structures (e.g., helices, sheets, turns), tertiary structures (e.g., the β-strand-helix-β-strand unit found in β-barrels), and quaternary assemblies (e.g., collagen microfibrils).[1] There is considerable interest in developing synthetic routes for preparation of polypeptide materials to make products for applications in biotechnology (artificial tissues, implants), biomineralization (resilient, lightweight, ordered inorganic composites), and analysis (biosensors, medical diagnostics).[2] To be successful in these applications, it is important that the polypeptides possess precisely defined compositions, sequences, and structures.

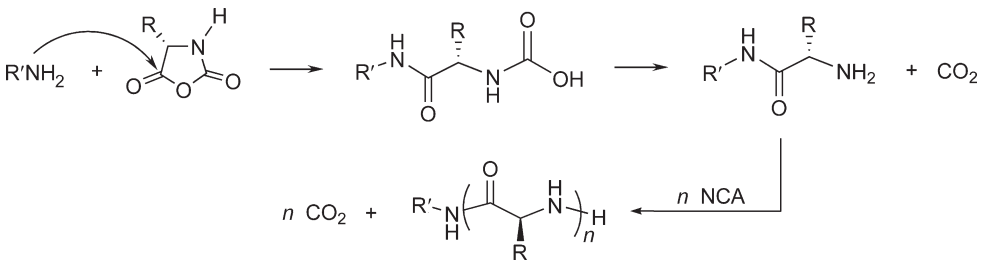
Synthetic peptide-based polymers are not new materials: homopolymers of polypeptides have been available for many decades, yet have only seen limited use in materials applications.[3] However, new methods in chemical synthesis have made possible the preparation of increasingly complex polypeptide sequences of controlled molecular weight that display properties far superior to ill-defined homopolypeptides.[4] Examination of the different methods for polypeptide synthesis reveals the limitations of these techniques for preparation of well-defined copolymers. Conventional solid-phase peptide synthesis is neither useful nor practical for direct preparation of large polypeptides (> 100 residues) due to unavoidable deletions and truncations that result from incomplete deprotection and coupling steps. The most economical and expedient process for synthesis of long polypeptide chains is the polymerization of α-amino acid *N*-carboxyanhydrides (NCAs) (eqn [1]).[5] This method involves the simplest reagents and high-molecular-weight polymers can be prepared in good yield and large scale with no detectable racemization at the chiral centers. The considerable variety of NCAs that have been synthesized (> 200) allows exceptional diversity in the types of polypeptides that can be prepared.[5]



[1]

Since the late 1940s, NCA polymerizations have been the most common technique used for large-scale preparation of high-molecular-weight polypeptides.[6] However, these materials have primarily been homopolymers, random copolymers, or graft copolymers that lack the sequence specificity and monodispersity of natural proteins. Only in recent decades has the level of control in NCA polymerizations been able to rival that found in other synthetic polymerizations (e.g., vinyl addition polymerizations) where sophisticated polymer architectures have been prepared (e.g., stereospecific polymers and block copolymers).[7] Early attempts to prepare block copolypeptides and hybrid block copolymers using NCAs resulted in polymers whose compositions did not match monomer feed compositions and that contained significant homopolymer contaminants.[8] Block copolymers could only be obtained in pure form by extensive fractionation steps, which significantly lowered the yield and efficiency of this method.

Historical limitations of NCA polymerizations have been the presence of side reactions (chain termination and chain transfer) that restrict control over molecular weight, give broad molecular weight distributions, and prohibit formation of well-defined block copolymers.[9] Recent progress in elimination of these side reactions has been a major breakthrough for the polypeptide materials field. This chapter will cover background and recent developments in methods for the ring-opening polymerization (ROP) of NCAs. It will also cover applications of these methods for preparation of block, star, brush, and branched copolypeptides, side-chain functional polypeptides, and poly-β-peptides. Finally, methods for removal of protecting groups and purification of polypeptides will be reviewed. Polypeptide containing hybrid copolymers, where considerable work and progress has been made in recent years,[10] are not covered in this chapter.



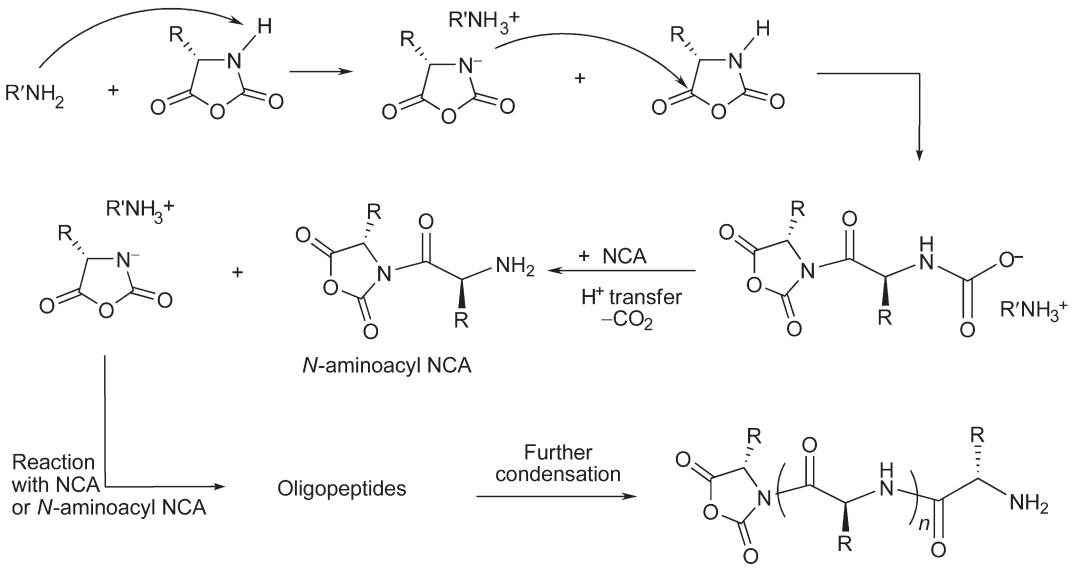
[2]

4.16.2 Polypeptide Synthesis using NCAs

4.16.2.1 Conventional Methods

NCA polymerizations have been initiated using many different nucleophiles and bases, the most common being primary amines and alkoxide anions.[5] Primary amines, being more nucleophilic than basic, are good general initiators for polymerization of NCA monomers. Tertiary amines, alkoxides, and other initiators that are more basic than nucleophilic have found use since they are in some cases able to prepare polymers of very high-molecular-weight where primary amine initiators cannot. Optimal polymerization conditions have often been determined empirically for each NCA, and thus there have been no universal initiators or conditions by which to prepare high polymers from any monomer. This is in part due to the different properties of individual NCAs and their polymers (e.g., solubility) but is also strongly related to the side reactions that occur during polymerization.

The most likely pathways of NCA polymerization are the so-called 'amine' and the 'activated monomer' (AM) mechanisms.[5] The amine mechanism is a nucleophilic ring-opening chain growth process where the polymer could grow linearly with monomer conversion if side reactions were absent (eqn [2]). On the other hand, the AM mechanism is initiated by deprotonation of an NCA, which then becomes the nucleophile that initiates chain growth (eqn [3]). It is important to note that a polymerization can switch back and forth between the amine and AM mechanisms many times: a propagation step for one mechanism is a side reaction for the other, and vice versa. It is because of these side reactions that block copolypeptides and hybrid block copolymers prepared from NCAs using amine initiators have structures different than predicted by monomer feed compositions and most likely have considerable homopolymer contamination. These side reactions also prevent control of chain-end functionality desirable for many applications.



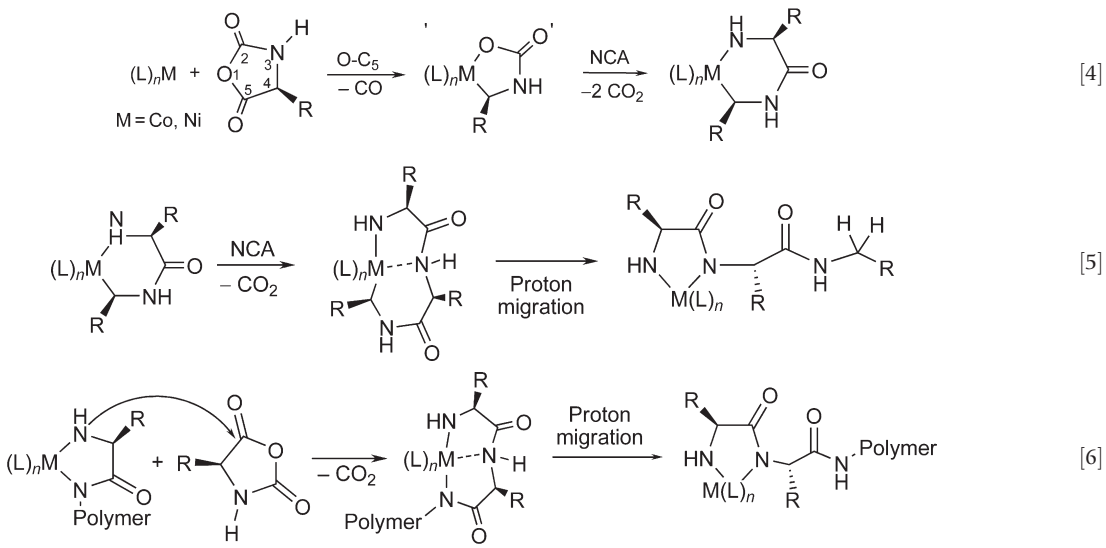
[3]

One inherent problem in conventional NCA polymerizations is that there is no control over the reactivity of the growing polymer chain end during the course of the polymerization. Once an initiator reacts with an NCA monomer, it is no longer involved in the polymerization and the resulting primary amine, carbamate, or NCA anion end group is free to undergo a variety of undesired side reactions. Another problem is one of purity. Although most NCAs are crystalline compounds, they typically contain minute traces of acid, acid chlorides, or isocyanates that can quench propagating chains. The presence of other adventitious impurities, such as water, can cause problems by acting as chain-transfer agents or even as catalysts for side reactions. Overall, the abundance of potential side reactions present in reaction media makes it difficult to achieve a living polymerization system where only chain propagation occurs.

4.16.2.2 Transition Metal Initiators

A successful strategy to eliminate side reactions in NCA polymerizations has been the use of transition metal complexes as active species to control addition of NCA monomers to polymer chain ends. The use of transition metals to control reactivity has been proven in organic and polymer synthesis as a means to increase reaction selectivity, efficiency, and rate.[11] Using this approach, a significant advance in controlled NCA polymerization was realized in 1997. Highly effective zero-valent nickel and cobalt initiators (i.e., bpyNi(COD) and $(PMe_3)_4Co$)[12,13] were developed by Deming that allow the living polymerization of NCAs into high-molecular-weight polypeptides by an unprecedented activation of the NCAs to generate covalent propagating species. The metal ions can be conveniently removed from the polymers by simple precipitation or dialysis of the samples after polymerization.

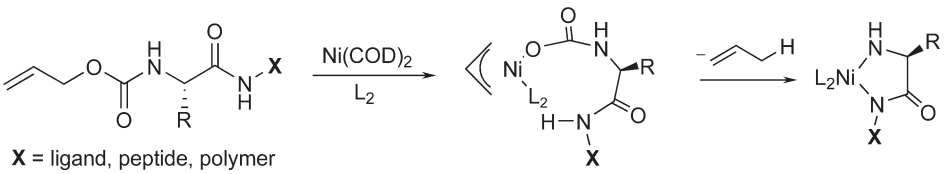
Mechanistic studies on the initiation process showed that both these metals react identically with NCA monomers to form metallacyclic complexes by oxidative addition across the anhydride bonds of NCAs.[12,13] These oxidative-addition reactions were followed by addition of a second NCA monomer to yield complexes identified as six-membered amido-alkyl metallacycles (eqn [4]). These intermediates were found to further contract to five-membered amido-amidate metallacycles upon reaction with additional NCA monomers. This ring contraction is thought to occur by migration of an amide proton to the metal-bound carbon, which liberates the chain end from the metal (eqn [5]).[14] The resulting amido-amidate complexes were thus proposed as the active polymerization intermediates. Propagation through the amido-amidate metallacycle was envisioned to occur by initial attack of the nucleophilic amido group on the electrophilic C_5 carbonyl of an NCA monomer (eqn [6]). This reaction would result in a large metallacycle that can contract by elimination of CO_2. Proton transfer from the free amide to the tethered amidate group further contracts the ring to regenerate the amido-amidate propagating species, while in turn liberating the end of the polymer chain.



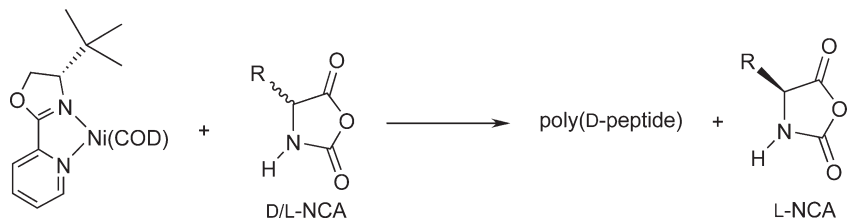
In this manner, the metal is able to migrate along the growing polymer chain, while being held by a robust chelate at the active end. The formation of these chelating metallacyclic intermediates appears to be a general requirement for obtaining living NCA polymerizations using transition metal initiators. These cobalt and nickel complexes are able to produce polypeptides with narrow chain length distributions ($M_w/M_n < 1.20$) and controlled molecular weights ($500 < M_n < 500\,000$).[15] This polymerization system is very general, and gives controlled polymerization of a wide range of NCA monomers as pure enantiomers (D or L configuration) or as racemic mixtures. These polymerizations can be

conducted in a variety of solvents (e.g., tetrahydrofuran (THF), dimethylformamide (DMF), ethyl acetate (EtOAc), dioxane, and acetonitrile (MeCN)) and over a broad range of temperatures (i.e., 10–100 °C) with no loss of polymerization control. By addition of different NCA monomers, the preparation of block copolypeptides of defined sequence and composition is feasible.[4,16]

One potential limitation of using zero-valent metal complexes as initiators is that the active propagating species are generated *in situ*, where the C-terminal end of the polypeptide is derived from the first NCA monomer. Consequently, this method does not allow attachment of functionality (e.g., polymer or small molecule) to the carboxyl chain end. For this reason, Deming and co-workers pursued alternative methods for direct synthesis of the amido-amidate metallacycle propagating species and developed allyloxycarbonylaminoamides as universal precursors to amido-amidate nickelacycles. These simple amino acid derivatives undergo tandem oxidative additions to nickel(0) to give active NCA polymerization initiators (eqn [7]).[17] These complexes were found to initiate polymerization of NCAs yielding polypeptides with defined molecular weights, narrow molecular weight distributions, and with quantitative incorporation of the initiating ligand as a C-terminal end group. This chemistry provides a facile means to incorporate diverse molecules such as polymers, peptides, oligosaccharides, or other ligands onto the chain ends of polypeptides by a robust amide linkage, and was further elaborated by Witte and Menzel[18] to grow polypeptides off polystyrene particles.



[7]



[8]

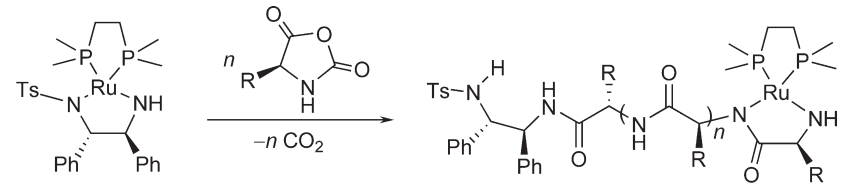
By knowing the active intermediates in these polymerizations, Cheng and Deming[19] were also able to use chiral donor ligands to prepare optically active nickel initiators for the enantioasymmetric polymerization of NCAs. Since polypeptides are chiral polymers, the ability to control stereochemistry during polymerization is a feature worth pursuing. This is especially true since the self-assembly and properties of polypeptides are critically dependent on the stereochemistry of the amino acid components. Due to constraints imposed by the initial oxidative-addition reactions and the stability of zero-valent cobalt and nickel complexes, only a limited pool of chiral ligands could be used. For example, common chiral aryl-substituted bisphoshines were completely ineffective in promoting oxidative additions of NCAs with nickel(0). Using optically active 2-pyridinyl oxazoline ligands that were mixed with bis(1,5-cyclooctadiene)nickel in THF, it was found that the resulting chiral nickel complexes were able to selectively polymerize one enantiomer of an NCA over the other.[19] The highest selectivity was observed with the nickel complex of (*S*)-4-*tert*-butyl-2-pyridinyl oxazoline, which gave a ratio of enantiomer polymerization rate constants (k_D/k_L) of 5.2(0.1) (eqn [8]). This initiator also gave a 17% enantiomeric excess of the D-antipode in the copolymer formed at 16% conversion in the polymerization of racemic NCA. It was found that subtle modification of this ligand by incorporation of additional substituents had a substantial impact on initiator selectivities. These results were a first step toward the ability to readily synthesize optically pure polypeptides from inexpensive racemic monomer pools. The main limitation of this system, however, is the fluxional coordination geometry around nickel(II), which hinders the development of a rigid, chiral environment at the metal center.

Subsequently, Deming identified new initiating systems based on amido-sulfonamide metallacycles prepared by deprotonation of the corresponding amine complexes. Seidel and Deming[20] studied a ruthenium(II) amido-sulfonamide complex, which although not an amido-amidate metallacycle, was recognized to possess all the required features for controlled NCA polymerization (eqn [9]). This complex contains a nucleophilic alkyl amido group, stabilized by a rigid chelate, and a proton-accepting sulfonamide group on the other end of the metallacycle that allows the chain end to migrate off the metal. This ruthenium complex and the corresponding isoelectronic Cp*iridium(III) (Cp* = C_5Me_5) complex were found to initiate living polymerizations of NCAs,[20] which shows that effective initiators can also be prepared with second and third

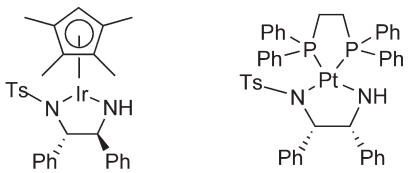
row metals.[21] Furthermore, these initiators were found to give much higher enantiomeric selectivities, as well as polymerization activities, in polymerizations of racemic NCAs compared to the nickel systems studied earlier. This work was elaborated by Peng *et al.*[22] who prepared similar amido-sulfonamide metallacycles using platinum(II), and found that these complexes give controlled polymerization of ε-carbobenzyloxy-L-lysine NCA, Z-Lys NCA (eqn [9]).

4.16.2.3 Controlled Polymerization using Amine Initiators

In the past 7 years, a number of new approaches have been reported to give controlled NCA polymerizations. These approaches share a common theme in that they are all improvements on the use of conventional primary amine polymerization initiators. This approach is attractive since primary amines are readily available and since the initiator does not need to be removed from the reaction after polymerization. In



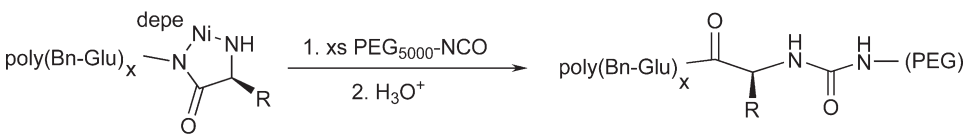
[9]



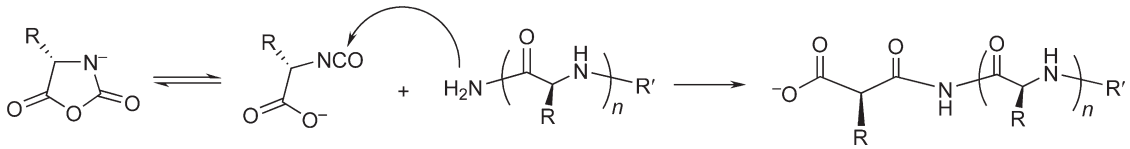
Further extending this work, Deming also developed a means to end-cap living polypeptide chains with electrophilic reagents. When a macromolecular electrophile is used, the resulting product is a polypeptide hybrid block copolymer. It is well known in NCA polymerizations that electrophiles, such as isocyanates, act as chain-terminating agents by reaction with the propagating amine chain ends.[5] Brzezinska *et al.*[23] reported that the reactive living nickelacycle polypeptide chain ends could be quantitatively capped by reaction with excess isocyanate, isothiocyanate, or acid chloride. Using this chemistry, they prepared isocyanate end-capped poly(ethylene glycol) (PEG), and reacted this, in excess, with living poly(γ-benzyl-L-glutamate) (poly (Bn-Glu)) to obtain poly(Bn-Glu)-*b*-PEG diblock copolymers (eqn [10]). Overall, it can be seen that the use of transition metal-initiated NCA polymerization allows formation of well-defined copolymer architectures that rival those prepared using any polymerization system.

fact, if the polymerization proceeds without any chain-breaking reactions, the amine initiator becomes the C-terminal polypeptide end group. In this manner, there is potential to form chain-end-functionalized polypeptides or even hybrid block copolymers if the amine is a macroinitiator. The challenge in this approach is to overcome the numerous side reactions of these systems without the luxury of a large number of experimental parameters to adjust.

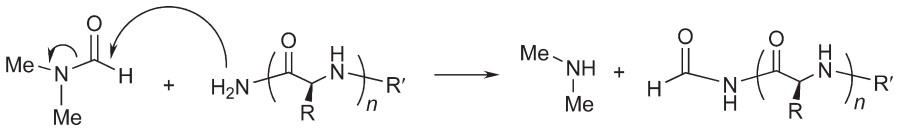
In 2004, Aliferis *et al.*[24] reported the primary amine-initiated polymerization of NCAs under high-vacuum conditions. The strategy here was to determine if a reduced level of impurities in the reaction mixture would lead to fewer polymerization side reactions. Unlike the vinyl monomers usually polymerized under high-vacuum conditions, NCAs cannot be purified by distillation. Consequently, it is unclear if NCAs can be obtained in higher purity by high-vacuum recrystallization than by recrystallization under a rigorous inert atmosphere. However, the high-vacuum method does allow for better purification of polymerization



[10]



[11]



[12]

solvents and the *n*-hexylamine initiator. It was found that polymerizations of Bn-Glu NCA and Z-Lys NCA under high vacuum in DMF solvent displayed all the characteristics of a living polymerization system.[24] Polypeptides could be prepared with control over chain length, chain length distributions were narrow, and block copolypeptides were prepared.

The authors concluded that the side reactions normally observed in amine-initiated NCA polymerizations are simply a consequence of impurities. Since the main side reactions in NCA polymerizations do not involve reaction with adventitious impurities such as water, but instead reactions with monomer, solvent, or polymer (i.e., termination by reaction of the amine end with an ester side chain, attack of DMF by the amine end, or chain transfer to monomer),[5] it appears removal of water suppresses these side reactions. A possible explanation for the polymerization control observed under high vacuum is that impurities (e.g., water) act to catalyze side reactions of growing chains with monomer, polymer, or solvent. In this scenario, it is reasonable to speculate that polar species such as water can bind to monomers or the propagating chain end and thus influence their reactivity. Recently, in polymerizations of *O*-benzyl-L-tyrosine NCA (Bn-Tyr NCA) in DMF, it was determined that although most side reactions are insignificant in the high-vacuum polymerization, some termination of chains by reaction with DMF solvent does occur.[25]

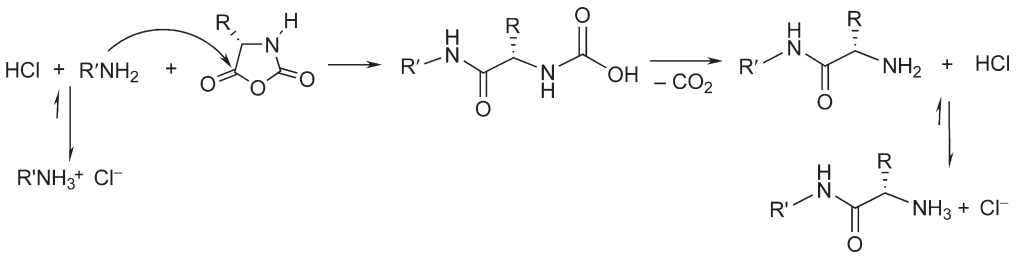
Further insights into amine-initiated NCA polymerizations were also reported in 2004 by Vayaboury *et al.*[26] This group studied the polymerization of ε-trifluoroacetyl-L-lysine NCA (TFA-Lys NCA) in DMF using *n*-hexylamine initiator at different temperatures. Contrary to the high-vacuum work, the solvent and initiator were purified using conventional methods and the polymerizations were conducted under a nitrogen atmosphere on a Schlenk line. After complete consumption of NCA monomer, the crude polymerization mixtures were analyzed by gel permeation chromatography (GPC) and nonaqueous capillary electrophoresis (NACE). A unique feature of this work was the use of NACE to separate and quantify the amount of polymers with different chain ends, which corresponded to living chains (amine end groups) and 'dead' chains (carboxylate and formyl end groups from reaction with NCA anions and DMF solvent, respectively, eqns [11] and [12]). Not surprisingly, at 20 °C, the polymer products consisted of 78% dead chains, and only 22% living chains, which illustrates the abundance of side reactions in these polymerizations under normal conditions.

An intriguing result was found for polymerizations conducted at 0 °C, where 99% of the chains had living amine chain ends, and only 1% were found to be dead chains. To verify that these were truly living polymerizations, additional NCA monomer was added to these chains at 0 °C, resulting in increased molecular weight and no increase of the amount of dead chains. While TFA-Lys NCA was the only monomer studied, this work showed that most common NCA polymerization side reactions can also be eliminated by lowering temperature. The effect of temperature is not unusual, as similar trends can be found in cationic and anionic vinyl polymerizations.[27] At elevated temperature, the side reactions have activation barriers similar to chain propagation. When the temperature is lowered, the activation barrier for chain propagation becomes lower than that of the side reactions and chain propagation dominates kinetically. A key limitation of this method is that these polymerizations are very slow at 0 °C, often requiring numerous days to obtain polypeptide chains of modest length. A remarkable feature of this system is that increased impurity levels, as compared to the high-vacuum method, did not result in side reactions at low temperature. This result further substantiates the idea that the growing chains do not react with the adventitious impurities, but that impurities mainly affect these polymerizations by altering the rates of discrete reaction steps.

4.16.2.4 Amine Hydrochloride-Initiated Polymerizations

An innovative approach to controlling amine-initiated NCA polymerizations was reported in 2003 by Dimitrov and Schlaad.[28] Their strategy was to avoid formation of NCA anions, which cause significant chain termination after rearranging to isocyanocarboxylates,[5] through use of primary amine hydrochloride salts as initiators. The reactivity of amine hydrochlorides with NCAs was first explored by the group of Knobler, who found that they can react with NCAs to give single NCA addition products.[29] Use of the hydrochloride salt takes advantage of its diminished reactivity as a nucleophile compared to the parent amine, which effectively halts the reaction after a single NCA insertion by formation of an inert amine hydrochloride in the product. The reactivity of the hydrochloride presumably arises from formation of a small amount of free

amine by reversible dissociation of HCl (eqn [13]). This equilibrium, which lies heavily toward the dormant amine hydrochloride species, allows for only a very short lifetime of reactive amine species. Consequently, as soon as a free amine reacts with an NCA, the resulting amine end group on the product is immediately protonated and is prevented from further reaction. The acidic conditions also assist elimination of CO_2 from the reactive intermediate, and more importantly, suppress formation of unwanted NCA anions.



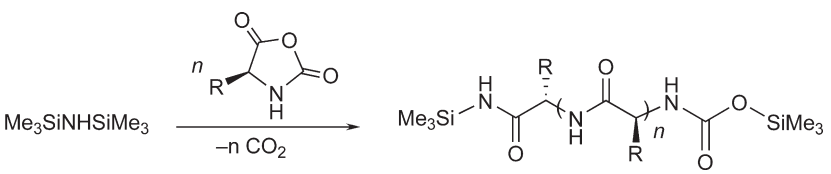
[13]

To obtain controlled polymerization, and not just single NCA addition reactions, Schlaad's group increased the reaction temperature (40 to 80 °C), which was known from Knobler's work to increase the equilibrium concentration of free amine, as well as increase the exchange rate between amine and amine hydrochloride.[29] Using primary amine hydrochloride end-capped polystyrene macroinitiators to polymerize Z-Lys NCA in DMF, Schlaad's group obtained polypeptide hybrid copolymers in 70–80% yield after 3 days at elevated temperature. Although these polymerizations are slow compared to amine-initiated polymerizations, the resulting polypeptide segments were well defined with very narrow chain length distributions ($M_w/M_n < 1.03$). These distributions were much narrower than those obtained using the free amine macroinitiator, which argues for diminished side reactions in the polypeptide synthesis. The molecular weights of the resulting polypeptide segments were found to be *c.* 20–30% higher than would be expected from the monomer to initiator ratios. This result was attributed to termination of some fraction of initiator species by traces of impurities in the NCA monomers, although the presence of unreacted polystyrene chains was not reported. Recently, this methodology was extended to the preparation of new hybrid copolymers of poly(Bn-Glu) from poly(2-isopropyl-2-oxazoline)[30] and PEG-amine hydrochloride[31] macroinitiators.

The use of amine hydrochloride salts as initiators for controlled NCA polymerizations shows tremendous promise. The concept of fast, reversible deactivation of a reactive species to obtain controlled polymerization is a proven concept in polymer chemistry, and this system can be compared to the persistent radical effect employed in all controlled radical polymerization strategies.[32] Like those systems, success of this method requires a carefully controlled matching of the polymer chain propagation rate constant, the amine/amine hydrochloride equilibrium constant, and the forward and reverse exchange rate constants between amine and amine hydrochloride salt. This means it is likely that reaction conditions (e.g., temperature, halide counterion, and solvent) will need to be optimized to obtain controlled polymerization for each different NCA monomer, as is the case for most vinyl monomers in controlled radical polymerizations. Within these constraints, it is possible that controlled NCA polymerizations utilizing simple amine hydrochloride initiators can be obtained.

4.16.2.5 *N*-Trimethylsilyl Amine Initiators

A very promising approach to obtain controlled NCA polymerization using silylated amines was reported in 2007 by Cheng. Hexamethyldisilazane (HMDS) was used to initiate polymerizations of either Z-Lys NCA or Bn-Glu NCA in DMF at ambient temperature and was found to give well-defined polypeptides of controlled chain length and low polydispersity in high yield.[33] Addition of a second batch of monomer to completed chains afforded block copolymers. Chain growth in this system does not appear to show any of the common side reactions found in amine-initiated NCA polymerization, which is attributed to the unique properties of the *N*-trimethylsilyl (N-TMS) groups. The HMDS is proposed to transfer a TMS group to the NCA followed by addition of the silylamine to the resulting intermediate (eqn [14]). This process yields a ring-opened monomer with a TMS-carbamate active end group on the growing chain, similar to processes that occur in group transfer polymerization of vinyl monomers.[34] The TMS-carbamate mediates NCA addition in a way that suppresses side reactions. This system has an advantage in that it proceeds at much higher rates (*c.* 12–24 h at ambient temperature) compared to low-temperature or amine hydrochloride-initiated polymerizations, yet still is slower than transition metal-initiated systems (*c.* 30–60 min at ambient temperature).



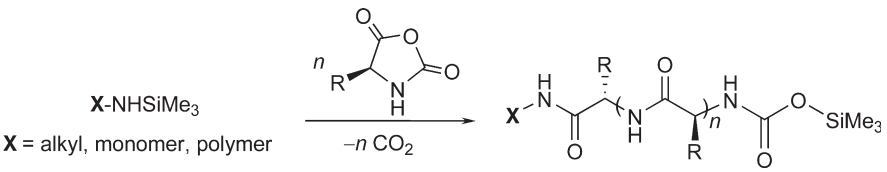
[14]

Cheng elaborated this method by showing that a variety of N-TMS amines can be used as initiators in place of HMDS to give controlled polymerizations by a similar process. These initiators also provide defined C-terminal end groups on the polypeptides from the N-TMS amine initiator (eqn [15]).[35] This chain-end functionalization was found to work well for both Z-Lys NCA and Bn-Glu NCA as well as for block copolymers of these monomers. The TMS-carbamate active chain ends are highly moisture sensitive, yet this is not much of an issue since NCAs themselves are moisture sensitive and must be polymerized in an anhydrous environment. This methodology was used to prepare polypeptide-poly(norbornene diimide) brush copolymers by both 'grafting-from' and 'grafting-through' approaches (eqn [16]).[36] In the grafting-from approach, poly(norbornenes) bearing N-TMS amine functionalities were used as macroinitiators to grow polypeptide brush segments. In the grafting-through approach, N-TMS amine-functionalized norbornene monomers were used to prepare end-functionalized polypeptide segments that were then linked by ring-opening metathesis polymerization (ROMP) of the norbornene end groups.

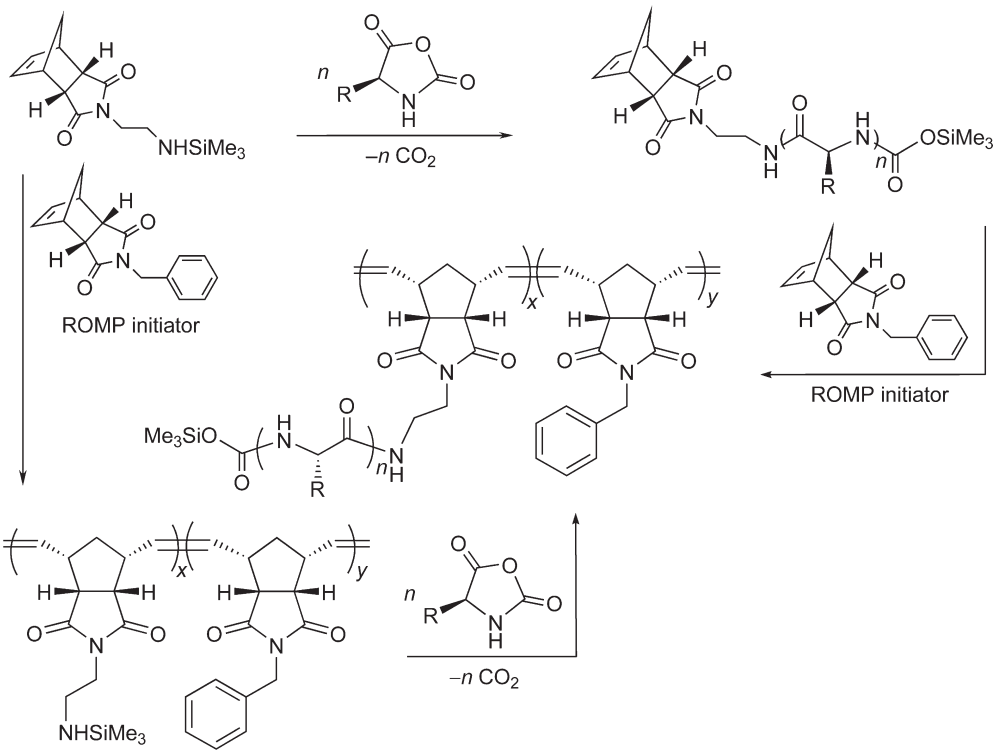
4.16.3 Copolypeptide Synthesis via ROP

4.16.3.1 Block Copolypeptides

For assembly of novel three-dimensional (3D) structures, block copolypeptides are required that have structural domains (i.e., amino acid sequences) whose size and composition can be precisely adjusted. Such materials have proven elusive using conventional techniques. Strong base-initiated NCA polymerizations are very fast. These polymerizations are poorly understood and well-defined block copolymers cannot be prepared. Primary amine-initiated NCA polymerizations are also not free of side reactions. Even after fractionation of the crude preparations, the resulting polypeptides are relatively ill-defined, which may complicate unequivocal evaluation of their properties and potential applications. Nevertheless, there are many reports on the preparation of block copolypeptides using conventional primary amine initiators.[37] Examples include many hydrophilic–hydrophobic and hydrophilic–hydrophobic–hydrophilic di- and triblock copolypeptides (where hydrophilic residues were glutamate and lysine, and hydrophobic residues were leucine,[38,39] valine,[40] isoleucine,[41] phenylalanine,[42] and alanine[43]) prepared to study



[15]



[16]

conformations of the hydrophobic domain in aqueous solution. More recently, Gibson and Cameron[44] reported the synthesis of novel (α-helix)-*b*-(β-sheet) block copolypeptides using amine initiation. These polymers were reported to have polydispersities ranging from 1.47 to 1.60.

The majority of amine-initiated block copolypeptides were often subjected to only limited characterization (e.g., amino acid compositional analysis) and, as such, their structures, and the presence of homopolymer contaminants, were not conclusively determined. Some copolymers, which had been subjected to chromatography, showed polymodal molecular weight distributions containing substantial high- and low-molecular-weight fractions.[42] The compositions of these copolymers were found to be different from the initial monomer feed compositions and varied widely for different molecular weight fractions. It appears that most, if not all, block copolypeptides prepared using amine initiators have structures different than predicted by monomer feed compositions and likely have considerable homopolymer contamination due to the side reactions described above.

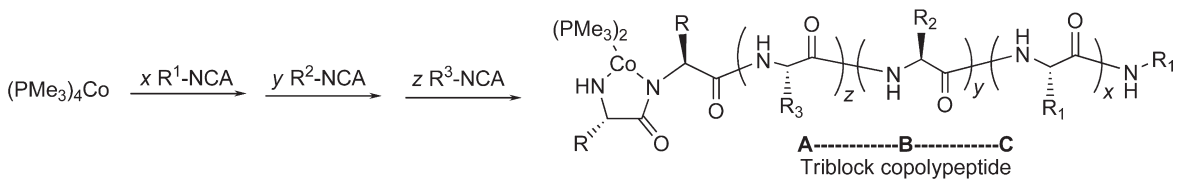
Polypeptide block copolymers prepared by transition metal-mediated NCA polymerization are well defined, with the sequence and composition of block segments controlled by order and quantity of monomer added to initiating species, respectively. These block copolypeptides can be prepared with the same level of control found in anionic and controlled radical polymerizations of vinyl monomers, which greatly expands the potential of polypeptide materials. The N-TMS amine initiators and amine initiators under high vacuum have recently also been used to prepare well-defined diblock copolypeptides.[24,34] The unique chemistry of NCAs allows these monomers to be polymerized in any order, which is a challenge in most vinyl copolymerizations, and the robust chain ends allow the preparation of copolypeptides with many block domains (e.g., > 2). The robust nature of transition metal initiation was shown by the linear, stepwise synthesis of tri- and pentablock copolypeptides (eqn [17]).[45] The self-assembly of block copolypeptides has also been investigated, for example, to direct the biomimetic synthesis of ordered silica structures,[46] to form polymeric vesicular membranes,[47,48] to stabilize oil droplets in emulsions,[49] or to prepare self-assembled polypeptide hydrogels.[50] Furthermore, poly(L-lysine)-*b*-poly(L-cysteine) block copolypeptides have been used to generate hollow, organic/inorganic hybrid microspheres composed of a thin inner layer of gold nanoparticles surrounded by a thick layer of silica nanoparticles.[51] In emulsion formation, the use of a racemic hydrophobic segment in poly(L-lysine)-*b*-poly(D/L-leucine) was found to greatly stabilize the oil–water interface allowing the formation of stable water-in-oil-in-water double nanoemulsions.[49]

4.16.3.2 Star Copolypeptides

Star copolymers can be prepared by two main synthetic routes: the 'arm-first' and 'core-first' methodologies. In the first case, living, or end-reactive, polymer chains are coupled to a multifunctional core. In the second case, a multifunctional core molecule is used to initiate the polymerization of the arms. Most of the star polypeptides reported so far have been obtained following the core-first strategy and were prepared using conventional primary amine-initiated NCA polymerization. In this way, Daly *et al.*[52,53] successfully prepared a series of 3-, 4-, 6-, and 9-arm poly(γ-stearyl-L-glutamate) star polypeptides. Inoue *et al.*[54,55] have used hexakis(4-aminophenoxy) cyclotriphosphazene as initiator for the synthesis of 6-arm poly(β-benzyl-L-aspartate), poly(Bn-Asp), and poly(Bn-Glu) stars. These authors used the ability of 5-(4-(dimethylamino) phenyl)-2,4-pentadienal (DMAPP) to selectively react with aromatic primary amines under the formation of the corresponding Schiff bases to quantify the efficiency of the initiation step. For the poly(Bn-Asp) stars, complete consumption of all aromatic primary amine-initiating groups, that is, the formation of well-defined 6-arm star polymers, was observed at sufficiently high monomer/initiator ratios (≥ 100) and high conversions.[54] In a subsequent paper, Inoue *et al.* reported the synthesis of oligo(ethylene glycol)-modified 6-arm poly (L-glutamate) star polymers. These polymers were prepared by transesterification of the benzyl ester groups of 6-arm poly (Bn-Glu) stars with di- or triethylene glycol monomethyl ether in the presence of *para*-toluenesulfonic acid.[56] Depending on the reaction time and temperature, degrees of substitution of 52–63% could be achieved.

Klok and coworkers[57,58] have prepared several water-soluble, fluorescent and near-infrared absorbing 4-arm star polypeptides based on L-lysine and L-glutamic acid. The synthesis of these star polymers started with the ROP of Bn-Glu NCA or Z-Lys NCA using perylene-, terrylene-, or quaterrylene-based multifunctional primary amine initiators. Subsequent removal of the side-chain protective groups afforded the corresponding water-soluble star polypeptides. The experimentally determined peptide arm lengths were in good agreement with those expected based on the monomer/initiator ratio. Furthermore, for the lower-molecular-weight star polymers, ^{1}H NMR spectra indicated complete consumption of all initiator groups, which provided additional evidence for the structural integrity of the star polypeptides.

A first example of the use of controlled NCA polymerization for the preparation of star polypeptides was reported by Aliferis *et al.*[59] Using high-vacuum techniques, these authors first prepared several linear poly(Bn-Glu), poly(Z-Lys), poly(Bn-Glu)-*b*-poly(Z-Lys), and poly(Z-Lys)-*b*-poly(Bn-Glu) precursors, which



[17]

were subsequently coupled to a trifunctional core, triphenylmethane-4,4′,4″-triisocyanate (Scheme 1). An excess of the linear precursor and reaction times of up to 4 weeks were needed to drive the coupling reaction to completion. Although the excess of the linear precursor could be removed by an additional precipitation step and well-defined star polypeptide could be obtained, this example illustrates the main drawbacks of the arm-first method as compared to the core-first method that has been most widely used for the synthesis of star polypeptides.

To address this issue, Hadjichristidis developed the synthesis of 3- and 4-arm star copolypeptides by high-vacuum polymerization using the core-first method. They prepared 3-arm stars containing poly(Z-Lys) and poly(Bn-Glu) block copolymers that were simultaneously grown off of a 2(aminomethyl)-2-methyl-1,3-propanediamine initiator core (Scheme 2).[60] This method produced well-defined star copolymers with narrow molecular weight distributions. Attempts to prepare 4-arm star copolymers using initiators containing four primary amine groups as well as two tertiary amine groups gave only ill-defined star polymers with bimodal molecular weight distributions.[60] The high polydispersity in these samples was likely due to initiation from both the primary and tertiary amine groups, which have different polymerization characteristics.

4.16.3.3 Brush and Branched Copolypeptides

Most early reports on brush and branched polypeptides utilized conventional NCA polymerization techniques. The first graft polypeptides were published in 1956 by Sela *et al.*[61] Using poly(L-lysine) or poly(D/L-ornithine) as a multifunctional initiator for the ROP of a number of different NCAs, these authors prepared a variety of graft polypeptides, which they termed multichain poly(amino acids) (eqn [18]). Since the NCA polymerizations were carried out in aqueous dioxane,

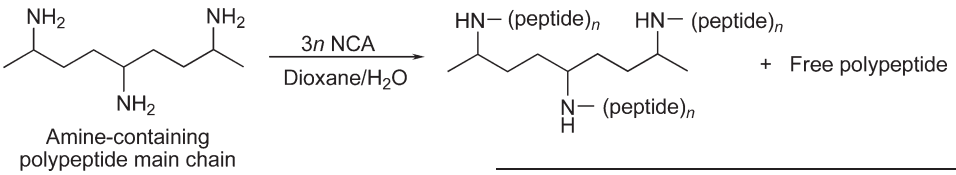
the synthesis of the graft polypeptides was accompanied by the formation of short linear polypeptides. These by-products, however, could be removed by dialysis. For the graft polymerization, multifunctional poly(L-lysine) or poly(D/L-ornithine) initiators with degrees of polymerization between 20 and 200 were used. The number of amino acid residues per graft was determined by chromatographic analysis of the hydrolyzed product or by end-group titrations. Depending on the length of the poly(L-lysine) or poly(D/L-ornithine) initiator, the number of amino acids per graft varied from 3 to 25. In a subsequent paper, Sela *et al.*[62] used this procedure to prepare a family of multichain copolymers with grafts containing L-tyrosine, L-glutamic acid, and L-alanine residues. The interest in these polymers was due to their potential application as synthetic polypeptide antigens. In this case, in addition to poly(L-lysine) homopolymer, copolymers of D/L-alanine and L-lysine were also used as multifunctional initiators for the NCA graft copolymerization. Furthermore, the grafts of the multichain copolymers were not only simple homopolypeptides, but, in most cases, block-type sequences.



[18]

Since in the examples discussed above, the polymerizations were carried out in the presence of water, the formation of linear polypeptide by-products was inevitable. To overcome this problem, attempts have been made to synthesize multichain polypeptides in anhydrous, polar aprotic solvents such as DMF and dimethyl sulfoxide (DMSO). Sakamoto and co-workers[63–65] prepared different multichain polypeptides using random copolymers of L-lysine and γ-methyl-L-glutamate as initiators for the graft copolymerization of Z-Lys NCA, Bn-Glu NCA, and Bn-Asp NCA. These random copolymers had degrees of polymerizations ranging from 82 to 118 and contained 12–36 lysine residues. The NCA graft copolymerizations were carried out in DMF containing 3 or 9% (v/v) DMSO. However, under these conditions, linear homopolypeptide by-products were also generated, which had to be removed by reprecipitation in diethyl ether (poly(Z-Lys)), methanol (poly(Bn-Glu)), or acetone (poly(Bn-Asp)). The number-average degree of polymerization of the polypeptide grafts was estimated by osmometric molecular weight determination and amino acid analysis and ranged from 20 to 60 amino acids, depending on the initiator and the relative amounts of monomer and initiator that were used.

The findings by Sakamoto are in agreement with earlier observations by Yaron and Berger,[66] who also identified linear homopolypeptide by-products when NCA graft copolymerizations were carried out in dry dioxane or DMF. Tewksbury and Stahmann,[67] in contrast, reported that the synthesis of multichain poly(amino acids) using poly(L-lysine) initiator and D/L-phenylalanine NCA, L-leucine NCA, or Bn-Glu NCA in anhydrous DMSO was not accompanied by the formation of linear by-products. These contradictory observations are characteristic for primary amine-initiated NCA polymerizations, where the success of the polymerization, that is, the homogeneity of the reaction product, can vary significantly depending on the specific monomers and polymerization conditions that are used.

More complex, higher branched polypeptide architectures can be obtained when functional groups in the side chains of the polypeptide grafts are used to initiate a subsequent NCA ROP step. Repetition of this graft-on-graft strategy leads to highly branched, so-called dendrigraft, polypeptides.[68] This is illustrated in **Scheme 3**, which shows the synthesis of dendrigraft polylysine by a repetitive sequence of ROP and deprotection steps using two orthogonally protected L-lysine NCA derivatives. Following this strategy, dendrigraft polylysines containing up to ~160 amino acids, corresponding to a number-average molecular weight of ~40 kDa, could be prepared in just four ring-opening copolymerization–deprotection cycles.[68]

Another approach to prepare polylysine dendrigrafts was reported by Tsogas *et al.*[69] Here, TFA-Lys NCA was oligomerized in aqueous buffer, followed by removal of the TFA groups at pH 11 to give an oligolysine macroinitiator. This process was then repeated by adding more TFA-Lys NCA to the macroinitiator to give a second-generation branched polymer. This cycle was then repeated to give third-generation dendrigraft polylysine (**Scheme 4**). Simultaneous NCA polymerization and side-chain deprotection have also been used to prepare hyperbranched copolypeptides. Vlasov *et al.*[70] reported the ROP of Z-Lys NCA in the presence of H_2/activated Pd, which removes the side-chain protecting groups during polymerization, allowing simultaneous branching and chain growth (**Scheme 5**). Here, the side-chain amine groups that are revealed after hydrogenation serve as polymerization initiation sites. Hyperbranched copolypeptides of lysine containing alanine and glutamic acid were also prepared using this process. Although neither of these processes are controlled polymerizations, branched copolymers with properties substantially different from the linear chains could be prepared.

In addition to the graft-on-graft strategies discussed above, highly branched polypeptides can also be prepared by an iterative sequence of NCA ROP and end-functionalization reactions as illustrated in **Scheme 6**.[71] Each NCA ROP step is followed by an end-functionalization reaction with an appropriate N^{α},N^{ε}-diprotected lysine derivative. Deprotection of the lysine amine groups doubles the number of end groups that can be used to initiate a subsequent NCA ROP step and leads to branching of the polymer architecture. The strategy outlined in **Scheme 6** has been used to prepare highly branched polylysines with number-average molecular weights of up to 33 kDa in only a small number of reaction steps. Birchall and North[72] have used a related approach to prepare highly branched block copolypeptides. In this case, however, relatively hydrophobic

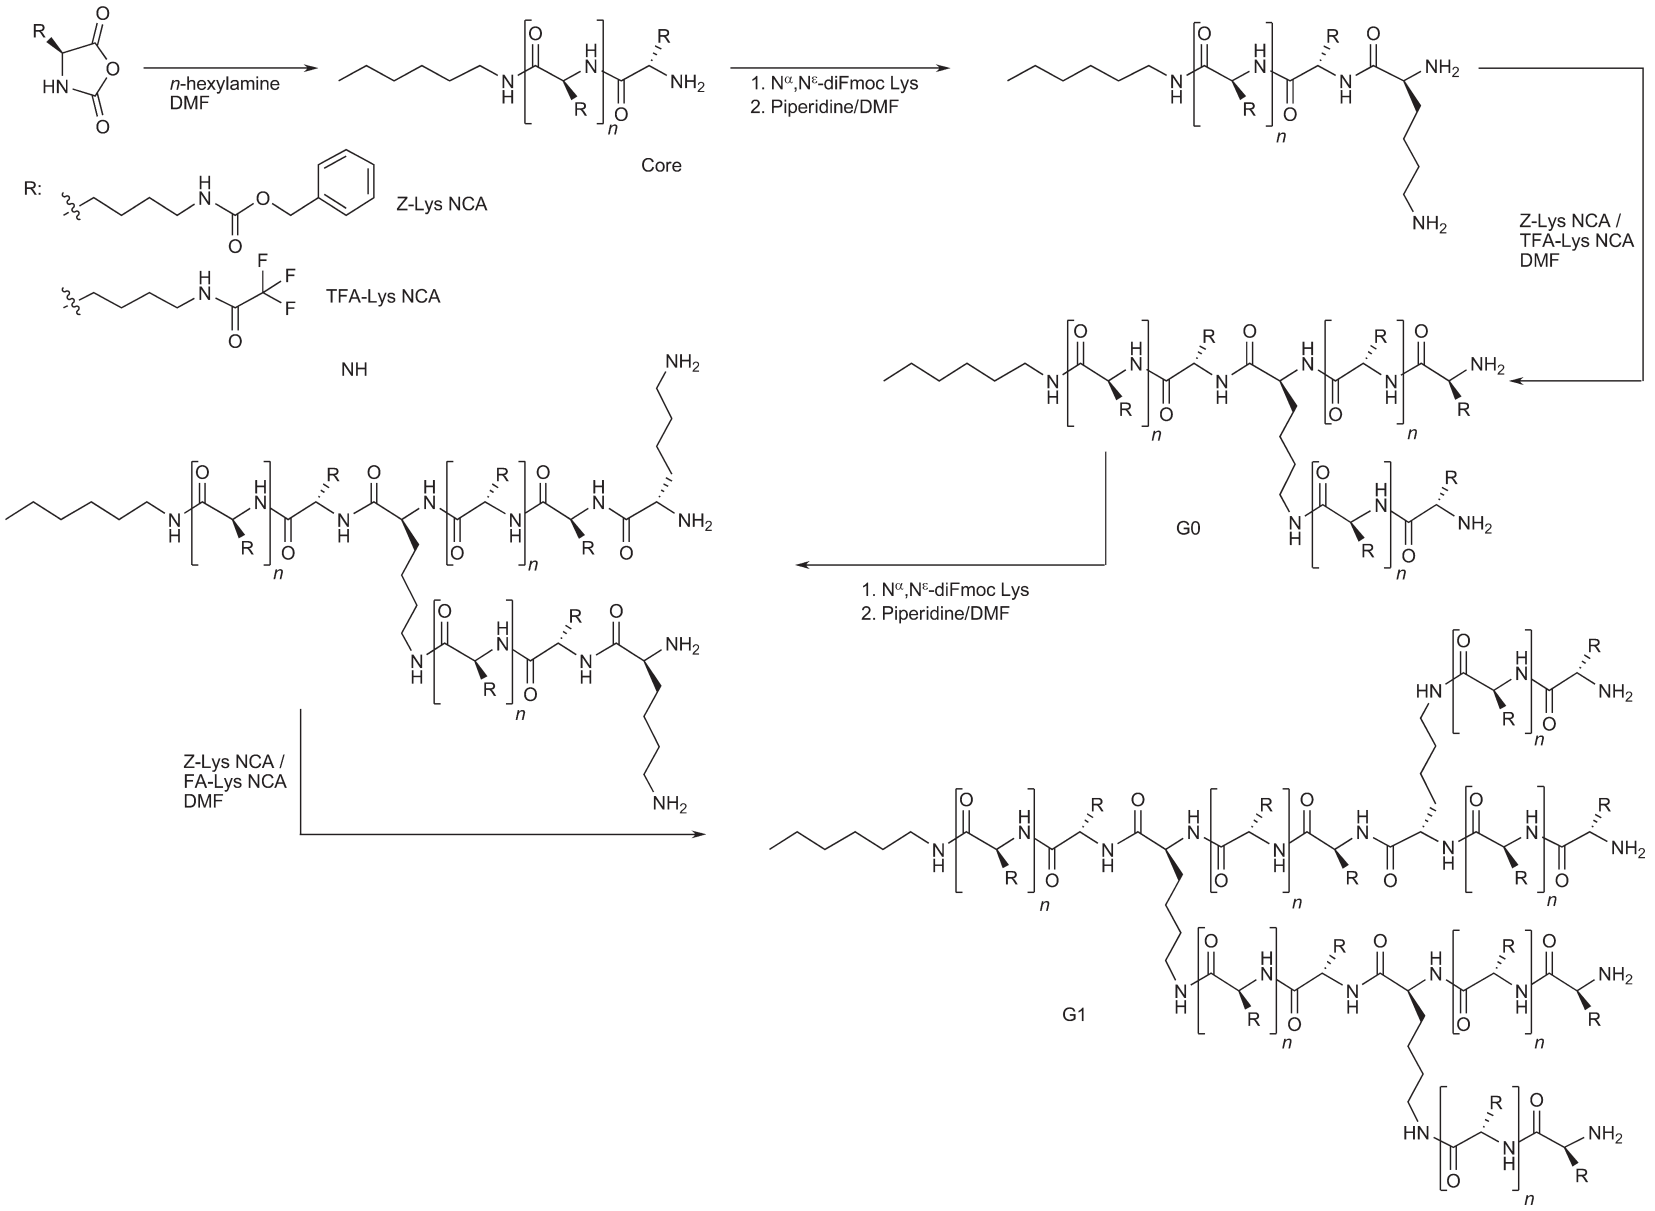
water-insoluble amino acids such as alanine, leucine, and phenylalanine were used, which made it necessary to keep the polymer chains relatively short (~5 to 10 amino acid repeat units) in order to avoid solubility problems.

4.16.4 Side-Chain Functionalized Polypeptides

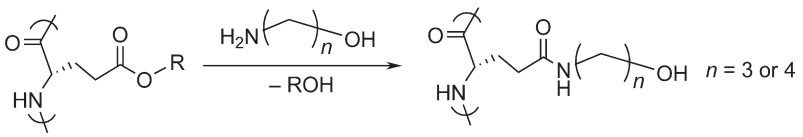
There have been many examples where polypeptides were chemically modified to improve their properties for biomedical applications. Typically, this strategy involves the hydrophobic modification of poly(lysine) or poly(glutamate/aspartate) side chains by covalent attachment of lipophilic groups.[73] These modifications are akin to polymer grafting reactions and thus result in random placement of these hydrophobic substituents (typically long alkyl chains) along the polypeptide chains. These modifications were performed in order to increase the polypeptide's ability to bind hydrophobic drugs, aggregate in aqueous solution, and/or penetrate the lipid bilayers of cell walls. The random placement of the hydrophobes along the



Scheme 6 Preparation of chain-end branched polylysine in a stepwise process.

chain meant that they cannot act as distinct domains in supramolecular assembly, as in a block copolymer, thus limiting their ability to organize.

Other types of chemical polypeptide modification include the addition of nonionic, polar groups to increase solubility and blood circulation lifetime, addition of mesogenic groups, addition of linker groups to allow efficient functionalization of preformed polypeptides by 'click' reactions, and the addition of sugars. Increasing bioavailability and biofunctionality are major goals for development of useful synthetic polypeptide materials.



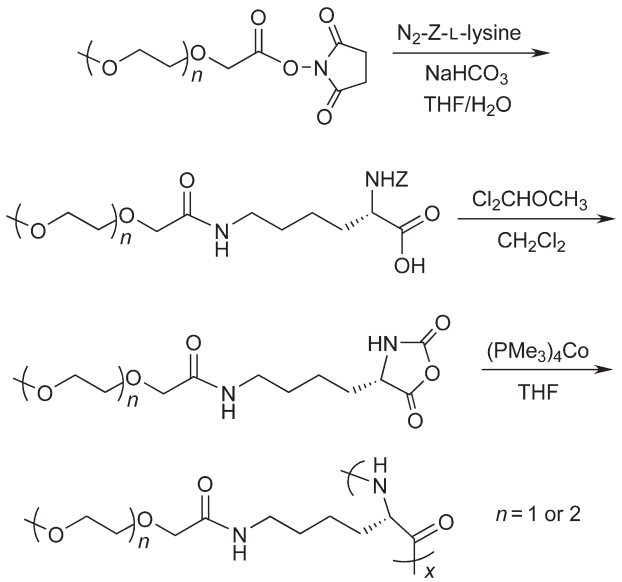
[19]

4.16.4.1 Nonionic Water-Soluble Polypeptides

The amino acid functionalities that provide water solubility (e.g., the amino group of lysine, or the carboxylates of glutamate and aspartate) are also detrimental for biomedical applications in that their polymers behave as polyelectrolytes. As such, they bind strongly to oppositely charged biomolecules (i.e., proteins, polynucleic acids, polysaccharides, and lipids) resulting in aggregation and either rapid removal from the bloodstream or rapid digestion within cells.[74] To circumvent this issue, nonionic, water solubilizing polypeptide residues have long been sought for biomedical uses.[75,76] Following the discovery that optically pure poly(serine) is not water soluble at chain lengths greater than 20 residues,[77] there have been many attempts to prepare nonionic polypeptides that would have good water solubility. The simplest of these approaches is the grafting of PEG chains ($1000 < M_n < 5000$) onto side-chain functionalities, which results in highly heterogeneous materials that retain considerable charge.[78] A more sophisticated solution was the development of hydroxyalkylglutamine polymers, prepared by the reaction of poly (alkyl-L-glutamate) esters with α,ω-amino alcohols (eqn [19]). These polypeptides, poly(hydroxypropyl-L-glutamine) and poly (hydroxybutyl-L-glutamine), in particular, were found to be nonionic and soluble in water over a wide pH range.[79] The major detriments of these materials, however, were that they are recognized as foreign and rapidly degraded *in vivo*, they are difficult to prepare without significantly degrading the polypeptide chains, and they lack ordered secondary structures in solution.[79] The last property is important since a main reason for using polypeptide scaffolds in biomedical applications is to take advantage of their ordered chain conformations to mimic protein structures.

Deming and, more recently, Klok have taken a different approach toward the development of nonionic, water-soluble polypeptides. They incorporated the solubilizing and protective properties of PEG into polypeptides by conjugation of short ethylene glycol (EG) repeats onto amino acid monomers as opposed to the well-documented approach of grafting PEG to the ends or side chains of polypeptides. This strategy avoided both the need for expensive amino- or carboxylato-functionalized PEG molecules necessary for coupling, as well as difficulties associated with derivatization of polymers. In particular, the presence of short EG repeats on every residue resulted in a high density of EG around polymer chains. In effect, the polypeptides are surrounded by an EG sheath that mimics the physical properties of PEG,[80] which did not destabilize the secondary structure of the polypeptide core. The molecular weights of these 'PEG-mimic' polymers could also be easily adjusted by controlling the degree of polymerization of the amino acid.

EG-functionalized monomers and polymers of lysine were first prepared by Deming as shown in **Scheme 7**.[81] Lysine was chosen as the amino acid component for the ease of coupling



Scheme 7 Preparation of poly(EG_n-Lys).

of the side-chain amine with inexpensive EG-containing carboxylates and for its propensity to form stable α-helical conformations. The formation of EG-L-lysine NCAs allowed facile polymerization into high-molecular-weight polymers by transition metal catalysis. Both poly(N_ε-2-[2-(2-methoxyethoxy)ethoxy]acetyl-L-lysine), poly(EG_2-Lys), and poly(N_ε-2-(2-methoxyethoxy)acetyl-L-lysine) were found to be water soluble, although the greater solubility of poly(EG_2-Lys), which is completely miscible with water in all proportions, led to studies being focused on this polypeptide.
